RAY, in Geometry, the same as RADIUS.

RAY, in Optics, a beam or line of light, propagated from a radiant point, through any medium.

If the parts of a Ray of light lie all in a straight line between the radiant point and the eye, the Ray is said to be *direct*: the laws and properties of which make the subject of Optics.—If any of them be turned out of their direction, or bent in their passage, the Ray is said to be *refracted*.—If it strike on the surface of any body, and be thrown off again, it is said to be *reflected*.—In each case, the Ray, as it falls either directly on the eye, or on the point of reflection, or of refraction, is said to be *incident*.

Again, if several Rays be propagated from the radiant object equidistantly from one another, they are called *parallel* Rays. If they come inclining towards each other, they are called *converging* Rays. And if they go continually receding from each other, they are called *diverging* Rays.

It is from the different circumstances of Rays, that the several kinds of bodies are distinguished in Optics. A body, for example, that diffuses its own light, or emits Rays of its own, is called a *radiating* or *lucid* or *luminous* body. If it only reflect Rays which it receives from another, it is called an *illuminated* body. If it only transmit Rays, it is called a *transparent* or *translucent* body. If it intercept the Rays, or refuse them passage, it is called an *opaque* body.

It is by means of Rays reflected from the several points of illuminated objects to the eye, that they become visible, and that vision is performed; whence such Rays are called *visual* Rays.

The Rays of light are not homogeneous, or similar, but differ in all the properties we know of; viz, refrangibility, reflexibility, and colour. It is probably from the different refrangibility that the other differences have their rise; at least it appears that those Rays which agree or differ in this, do so in all the rest. It is not however to be understood that the property or effect called colour, exists in the Rays of light themselves; but from the different sensations the differently disposed Rays excite in us, we call them *red Rays*, *yellow Rays*, &c. Each beam of light however, as it comes from the sun, seems to be compounded of all the sorts of Rays mixed together; and it is only by splitting or separating the parts of it, that these different sorts become observable; and this is done by transmitting the beam

beam through a glass prism, which refracting it in the passage, and the parts that excite the different colours having different degrees of refrangibility, they are thus separated from one another, and exhibited each apart, and appearing of the different colours.

Beside refrangibility, and the other properties of the Rays of light already ascertained by observation and experiment, Sir I. Newton suspects they may have many more; particularly a power of being inflected or bent by the action of distant bodies; and those Rays which differ in refrangibility, he conceives likewise to differ in flexibility.

These Rays he suspects may be very small bodies emitted from shining substances. Such bodies may have all the conditions of light: and there is that action and reaction between transparent bodies and light, which very much resembles the attractive force between other bodies. Nothing more is required for the production of all the various colours, and all the degrees of refrangibility, but that the Rays of light be bodies of different sizes; the least of which may make violet the weakest and darkest of the colours, and be the most easily diverted by refracting surfaces from its rectilinear course; and the rest, as they are larger and larger, may make the stronger and more lucid colours, blue, green, yellow, and red. See COLOUR, LIGHT, REFRACTION, REFLECTION, INFLECTION, CONVERGING, DIVERGING, &c, &c.

Reflected RAYS, those Rays of light which are reflected, or thrown back again, from the surfaces of bodies upon which they strike. It is found that, in all the Rays of light, the angle of reflection is equal to the angle of incidence.

Refracted RAYS, are those Rays of light, which are bent or broken, in passing out of one medium into another.

Pencil of RAYS, a number of Rays issued from a point of an object, and diverging in the form of a cone.

Principal RAY, in Perspective, is the perpendicular distance between the eye and the vertical plane or table, as some call it.

RAY *of Curvature*. See *Radius of* CURVATURE.

REAUMUR (RENE-ANTOINE-FERCHAULT, Sieur de), a respectable French philosopher, was born at Rochelle in 1683. After the usual course of school education, he was sent to Poitiers to study philosophy, and, in 1699, to Bourges to study the law, the profession for which he was intended. But philosophy and mathematics having very early been his favourite pursuits, he quitted the law, and repaired to Paris in 1703, to pursue those sciences to the best advantage; and here his character procured him a seat in the Academy in the year 1708; which he held till the time of his death, which happened the 18th of November 1757, at 74 years of age.

Reaumur soon justified the choice that was made of him by the Academy. He made innumerable observations, and wrote a great multitude of pieces upon the various branches of natural philosophy. His History of Insects, in 6 vols. quarto, at Paris, is his principal work. Another edition was printed in Holland, in 12 vols. 12mo. He made also great and useful discoveries concerning iron; shewing how to change common wrought iron into steel, how to soften cast iron, and to make works in cast iron as fine as in wrought iron. His labours and discoveries concerning iron were rewarded by the duke of Orleans, regent of the kingdom, by a pension of 12 thousand livres, equal to about 500l. Sterling; which however he would not accept but on condition of its being put under the name of the Academy, who might enjoy it after his death. It was owing to Reaumur's endeavours that there were established in France manufactures of tin-plates, of porcelain in imitation of china-ware, &c. They owe to him also a new thermometer, which bears his name, and is pretty generally used on the continent, while that of Fahrenheit is used in England, and some few other places. Reaumur's thermometer is a spirit one, having the freezing point at 0, and the boiling point at 80.

Reaumur is esteemed as an exact and clear writer; and there is an elegance in his style and manner, which is not commonly found among those who have made only the sciences their study. He is represented also as a man of a most amiable disposition, and with qualities to make him beloved as well as admired. He left a great variety of papers and natural curiosities, which he bequeathed to the Academy of Sciences.

The works published by him, are the following.

1. The Art of changing Forged Iron into Steel; of Softening Cast Iron; and of making works of Cast Iron, as fine as of Wrought Iron. Paris, 1722, 1 vol. in 4to.

2. Natural History of Insects, 6 vols. in 4to.

His memoirs printed in the volumes of the Academy of Sciences, are very numerous, amounting to upwards of a hundred, and on various subjects, from the year 1708 to 1763, several papers in almost every volume.

RECEIVER, *of an Air Pump*, is part of its apparatus; being a glass vessel placed on the top of the plate, out of which the air is to be exhausted.

RECEPTION, in Astrology, is a dignity befalling two planets when they exchange houses: for example, when the sun arrives in Cancer, the house of the moon; and the moon, in her turn, arrives in the sun's house.—The same term is also used when two planets exchange exaltation.

RECESSION *of the Equinoxes*. See PRECESSION *of the Equinoxes*.

RECIPROCAL, in Arithmetic, &c, is the quotient arising by dividing 1 by any number or quantity. So, the Reciprocal of 2 is $\frac{1}{2}$; of 3 is $\frac{1}{3}$, and of a is $\frac{1}{a}$, &c. Hence, the Reciprocal of a vulgar fraction is found, by barely making the numerator and the denominator mutually change places: so the Reciprocal of $\frac{1}{2}$ is $\frac{2}{1}$ or 2; of $\frac{2}{3}$, is $\frac{3}{2}$; of $\frac{a}{b}$, is $\frac{b}{a}$, &c. Hence also, any quantity being multiplied by its Reciprocal, the product is always equal to unity or 1: so $\frac{1}{2} \times \frac{2}{1} = \frac{2}{2} = 1$, and $\frac{2}{3} \times \frac{3}{2} = \frac{6}{6} = 1$, and $\frac{a}{b} \times \frac{b}{a} = \frac{ab}{ab} = 1$.

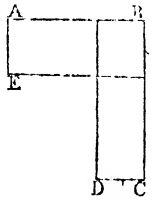
Of the preceding Table, the uſe is evidently to ſhorten arithmetical calculations, and will appear eminently great to thoſe mathematicians and others who are frequently concerned in ſuch kinds of computations. The ſtructure of the Table is evident; the firſt column contains the natural ſeries of numbers from 1 to 1000, the 2d the Reciprocals. Theſe Reciprocals (which are no other than the decimal values of the quotients reſulting from the diviſion of unity or 1 by each of the ſeveral numbers from 1 to 1000) are not only uſeful in ſhewing by inſpection the quotient when the dividend is unity, but are alſo applied with much advantage in turning many diviſions into multiplications, which are much eaſier performed, and are done by multiplying the Reciprocal of the diviſor (as found in the Table) by the dividend, for the quotient; they will alſo apply to good purpoſe in ſumming the terms of many converging ſeries.

The Reciprocals are carried on to 7 places of decimals (for the column of Reciprocals muſt be accounted all decimal figures, although they have not the decimal point placed before them, which is omitted to ſave room), each being ſet down to the neareſt figure in the laſt place, that is, when the next figure beyond the laſt ſet down in the Table came out a 5 or more, the laſt figure

figure was increaſed by 1, otherwiſe not; excepting in the repetends which occurred among the Reciprocals, where the real laſt figure is always ſet down; the Reciprocals, which in the Table conſiſt of leſs than ſeven figures, are thoſe which terminate, and are complete within that number; ſuch as ·5 the Reciprocal of 2, ·25 the Reciprocal of 4, &c.

RECIPROCAL *Figures*, in Geometry, are ſuch as have the antecedents and conſequents of the ſame ratio in both figures. So, in the two rectangles BE and BD, if AB : DC :: BC : AE, then thoſe rectangles are reciprocal figures; and are alſo equal.



RECIPROCAL *Proportion*, is when, in four quantities, the two latter terms have the Reciprocal ratio of the two former, or are proportional to the Reciprocals of them. Thus, 24, 15, 5, 8 form a Reciprocal proportion, becauſe

$$\frac{1}{24} : \frac{1}{15} :: 5 : 8, \text{ or } 15 : 24 :: 5 : 8.$$

RECIPROCAL *Ratio*, of any quantity, is the ratio of the Reciprocal of the quantity.

RECIPROCALLY. One quantity is Reciprocally as another, when the one is greater in proportion as the other is leſs; or when the one is proportional to the Reciprocal of the other. So a is Reciprocally as b, when a is always proportional to $\frac{1}{b}$. Like as in the mechanic powers, to perform any effect, the leſs the power is, the greater muſt be the time of performing it; or, as it is ſaid, what is gained in power, is loſt in time. So that, if p denote any power or agent, and t the time of its performing any given ſervice; then p is as $\frac{1}{t}$, and t is as $\frac{1}{p}$; that is, p and t are Reciprocally proportionals to each other.

RECKONING, in Navigation, is the eſtimating the quantity of a ſhip's way; or of the courſe and diſtance run. Or, more generally, a ſhip's Reckoning is that account, by which it may at any time be known where the ſhip is, and conſequently on what courſe or courſes ſhe muſt ſteer to gain her intended port. The Reckoning is uſually performed by keeping an account of the courſes ſteered, and the diſtance run, with any accidental circumſtances that occur. The courſes ſteered are obſerved by the compaſs; and the diſtances run are eſtimated from the rate of running, and the time run upon each courſe. The rate of running is meaſured by the log, from time to time; which however is liable to great irregularities. Anciently Vitruvius, for meaſuring the rate of ſailing, adviſed an axis to be paſſed through the ſides of the ſhip, with two large heads protending out of the ſhip, including wheels touching the water, by the revolution of which the ſpace paſſed over in a given time is meaſured. And the ſame has been ſince recommended by Snellius.

RECKONING, *Dead.* See DEAD *Reckoning*.

RECLINATION *of a Plane*, in Dialling, is the angular quantity which a dial-plane leans backwards, from an exactly upright or vertical plane, or from the zenith.

RECLINER, or RECLINING *Dial*, is a dial whoſe plane reclines from the perpendicular, that is, leans backwards, or from you, when you ſtand before it.

RECLINER, *Declining*, or *Declining* RECLINING *Dial*, is one which neither ſtands perpendicularly, nor oppoſite to one of the cardinal points.

RECOIL, or REBOUND, the reſilition, or flying backward, of a body, eſpecially a fire-arm. This is the motion by which, upon exploſion, it ſtarts or flies backwards; and the cauſe of it is the reſiſtance of the ball and the impelling force of the powder, which acts equally on the gun and on the ball. It has been commonly ſaid by authors, that the momentum of the ball is equal to that of the gun with its carriage together; but this is a miſtake; for the latter momentum is nearly equal to that of the ball and half the weight of the powder together, moving with the velocity of the ball. So that, if the gun, and the ball with half the powder, were of equal weight, the piece would recoil with the ſame velocity as the ball is diſcharged. But the heavier any body is, the leſs will its velocity be, to have the ſame momentum, or force; and therefore ſo many times as the cannon and carriage is heavier than the ball and half the powder, juſt as many times will the velocity of the ball be greater than that of the gun; and in the ſame ratio nearly is the length of the barrel before the charge, to the quantity the gun Recoils in the time the ball is paſſing along the bore of the gun. So, if a 24 pounder of 10 feet long be 6400lb weight, and charged with 6lb of powder; then, when the ball quits the piece, the gun will have Recoiled $\frac{28}{6400} \times 10 = \frac{7}{160}$ of a foot, or nearly half an inch.

RECORDE (ROBERT), a learned phyſician and mathematician, was born of a good family in Wales, and flouriſhed in the reigns of Henry the 8th, Edward the 6th, and Mary. There is no account of the exact time of his birth, though it muſt have been early in the 16th century, as he was entered of the univerſity of Oxford about the year 1525, where he was elected fellow of Allſouls college in 1531. Making phyſic his profeſſion, he went to Cambridge, where he was honoured with the degree of doctor in that faculty, in 1545, and highly eſteemed by all that knew him for his great knowledge in ſeveral arts and ſciences. He afterwards returned to Oxford, where, as he had done before he went to Cambridge, he publicly taught arithmetic, and other branches of the mathematics, with great applauſe. It ſeems he afterwards repaired to London, and it has been ſaid he was phyſician to Edward the 6th and Mary, to which princes he dedicates ſome of his books; and yet he ended his days in the King's bench priſon, Southwark, where he was confined for debt, in the year 1558, at a very immature age.

Recorde publiſhed ſeveral mathematical books, which are moſtly in dialogue, between the maſter and ſcholar. They are as follow:

1. *The Pathway to Knowledge*, containing the firſt Principles of Geometrie, as they may moſte aptly be applied unto practiſe, bothe for uſe of Inſtrumentes Geometricall and Aſtronomicall, and alſo for Projection of Plattes much neceſſary for all ſortes of men. Lond. 4to, 1551.

2. *The Ground of Arts*, teaching the perfect worke and practice of Arithmeticke, both in whole numbers and

and fractions, after a more easie and exact forme then in former time hath beene set forth, 8vo, 1552.—This work went through many editions, and was corrected and augmented by several other persons; as first by the famous Dr. John Dee; then by John Mellis, a schoolmaster, 1590; next by Robert Norton; then by Robert Hartwell, practitioner in mathematics, in London; and lastly by R. C. and printed in 8vo, 1623.

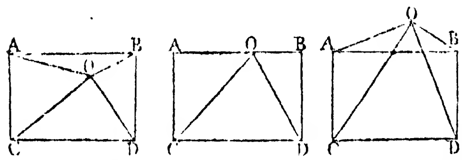
3. *The Castle of Knowledge*, containing the Explication of the Sphere bothe Celestiall and Materiall, and divers other things incident thereto. With sundry pleasaunt proofes and certaine newe demonstrations not written before in any vulgare woorkes. Lond. folio, 1556.

4. *The Whetstone of Witte*, which is the seconde part of Arithmetike: containing the Extraction of Rootes: the Cossike Practise, with the rules of Equation: and the woorkes of Surde Nombers. Lond. 4to, 1557.—For an analysis of this work on Algebra, with an account of what is new in it, see pa. 79 of vol. 1, under the article ALGEBRA.

Wood says he wrote also several pieces on physic, anatomy, politics, and divinity; but I know not whether they were ever published. And Sherburne says that he published *Cosmographie Isagogen*; also that he wrote a book, *De Arte faciendi Horologium*; and another, *De Usu Globorum, & de Statu Temporum*; which I have never seen.

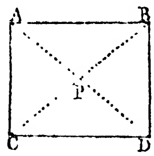
RECTANGLE, in Geometry, is a right-angled parallelogram, or a right-angled quadrilateral figure.

If from any point O, lines be drawn to all the four



angles of a Rectangle; then the sum of the squares of the lines drawn to the opposite corners will be equal, in whatever part of the plane the point O is situated; viz, $OA^2 + OD^2 = OB^2 + OC^2$. For other properties of the Rectangle, see PARALLELOGRAM; for the Rectangle being a species of the parallelogram, whatever properties belong to the latter, must equally hold in the former.

For the Area of a RECTANGLE. Multiply the length by the breadth or height.—*Otherwise*; Multiply the product of the two diagonals by half the sine of their angle at the intersection.



That is, $AB \times AC$, or $AD \times BC \times \frac{1}{2}$ sin. $\angle P$ = area. A Rectangle, as of two lines AB and AC, is thus denoted, $AB \times AC$, or $AB . AC$; or else thus expressed, the Rectangle of, or under, AB and AC.

RECTANGLE, in Arithmetic, is the same with product or factum. So the Rectangle of 3 and 4, is 3×4 or 12; and of a and b is $a \times b$ or ab.

RECTANGLED, RIGHT-ANGLED, or RECTANGULAR, is applied to figures and solids that have at least one right angle, if not more. So a Right-angled triangle, has one right angle: a Right-angled parallelogram is a rectangle, and has four right angles. Such also are squares, cubes, parallelopipedons.

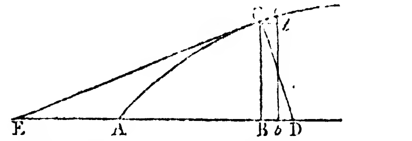
Solids are also said to be Rectangular with respect to their situation, viz, when their axis is perpendicular to their base; as right cones, pyramids, cylinders, &c.

The Ancients used the phrase *Rectangular section of a cone*, to denote a parabola; that conic section, before Apollonius, being only considered in a cone having its vertex a right angle. And hence it was, that Archimedes entitled his book of the quadrature of the parabola, by the name of *Rectanguli Coni Sectio*.

RECTIFICATION, in Geometry, is the finding of a right line equal to a curve. The Rectification of curves is a branch of the higher geometry, a branch in which the use of the inverse method of Fluxions is especially useful. This is a problem to which all mathematicians, both ancient and modern, have paid the greatest attention, and particularly as to the Rectification of the circle, or finding the length of the circumference, or a right line equal to it; but hitherto without the perfect effect: upon this also depends the quadrature of the circle, since it is demonstrated that the area of a circle is equal to a right-angled triangle, of which one of the sides about the right angle is the radius, and the other equal to the circumference: but it is much to be feared that neither the one nor the other will ever be accomplished. Innumerable approximations however have been made, from Archimedes, down to the mathematicians of the present day. See CIRCLE and CIRCUMFERENCE.

The first person who gave the Rectification of any curve, was Mr. Neal, son of Sir Paul Neal, as we find at the end of Dr. Wallis's treatise on the Cissoid; where he says, that Mr. Neal's Rectification of the curve of the semicubical parabola, was published in July or August, 1657. Two years after, viz in 1659, Van Heuraet, in Holland, also gave the Rectification of the same curve; as may be seen in Schooten's Commentary on Des Cartes's Geometry.

The most comprehensive method of Rectification of curves, is by the inverse method of fluxions, which is thus: Let ACc be any curve line, AB an abscis, and



BC a perpendicular ordinate; also bc another ordinate indefinitely near to BC; and Cd drawn parallel to the abscis AB. Put the abscis $AB = x$, the ordinate $BC = y$, and the curve $AC = z$: then is $Cd = Bb = \dot{x}$ the fluxion of the abscis AB, and $cd = \dot{y}$ the fluxion of the ordinate BC, also $Cc = \dot{z}$ the fluxion of the curve AB. Hence because Ccd may be considered as a plane right-angled triangle, $Cc^2 = Cd^2 + cd^2$, or $\dot{z}^2 = \dot{x}^2 + \dot{y}^2$; and therefore $\dot{z} = \sqrt{\dot{x}^2 + \dot{y}^2}$; which is the fluxion of the length of any curve; and consequently, out of this equation expelling either $\dot{x}$ or $\dot{y}$, by means of the particular equation expressing the nature of the curve in question, the fluents of the resulting equation, being then taken, will give the length of the curve, in finite terms when it is rectifiable,

rectifiable, otherwise in an infinite series, or in a logarithmic or exponential &c expression, or by means of some other curve, &c.

Ex. 1. *To rectify the common parabola.*—In this case, the equation of the curve is $2ax = y^2$, where a is half the parameter. The fluxion of this equation is $2a\dot{x} = 2y\dot{y}$, and hence $\dot{x}^2 = \frac{y^2\dot{y}^2}{a^2}$; this being substituted in the general equation $\dot{z} = \sqrt{\dot{x}^2 + \dot{y}^2}$, it becomes $\dot{z} = \frac{\dot{y}\sqrt{aa + yy}}{a}$, the correct fluent of which gives

$$z = \frac{y\sqrt{aa + yy}}{2a} + \tfrac{1}{2}a \times \text{hyp. log. of } \frac{y + \sqrt{aa + yy}}{a},$$

which is the length of the curve AC, when it is a parabola.

And the same might be expressed by an infinite series, by expanding the quantity $\sqrt{aa + yy}$. See my Mensuration, pa. 361, 2d edit.

Ex. 2. *To rectify the Circle.*—The equation of the circle may be expressed either in terms of the sine, or versed sine, or tangent, or secant, &c, and the radius. Let therefore the radius of the circle be DA or DC $= r$, the versed sine AB $= x$, the right sine BC $= y$, the tangent CE $= t$, and the secant DE $= s$; then, by the nature of the circle, we have these equations,

$$y^2 = 2rx - x^2 = \frac{r^2t^2}{r^2 + t^2} = \frac{s^2 - r^2}{s^2}r^2; \text{ and by}$$

means of the fluxions of these equations, with the general equation $\dot{z}^2 = \dot{x}^2 + \dot{y}^2$, are obtained the following fluxional forms for the fluxion of the curve, the fluent of any one of which will be the curve itself, viz,

$$\dot{z} = \frac{r\dot{x}}{\sqrt{2rx - xx}} = \frac{r\dot{y}}{\sqrt{rr - yy}} = \frac{r^2\dot{t}}{r^2 + t^2} = \frac{r^2\dot{s}}{\sqrt{s^2 - r^2}}.$$

Hence the value of the curve, from the fluent of each of these, gives the four following forms, in series, viz, the curve, putting $d = 2r$ the diameter, is z

$$= \left(1 + \frac{x}{2.3d} + \frac{3x^2}{2.4.5d^2} + \frac{3.5x^3}{2.4.6.7d^3} \text{ \&c}\right)\sqrt{dx},$$

$$= \left(1 + \frac{y^2}{2.3r^2} + \frac{3y^4}{2.4.5r^4} + \frac{3.5y^6}{2.4.6.7r^6} \text{ \&c}\right)y,$$

$$= \left(1 - \frac{t^2}{3r^2} + \frac{t^4}{5r^4} - \frac{t^6}{7r^6} + \frac{t^8}{9r^8} \text{ \&c}\right)t,$$

$$= \left(\frac{s - r}{s} + \frac{s^3 - r^3}{2.3s^3} + \frac{3(s^5 - r^5)}{2.4.5s^5} \text{ \&c}\right)r.$$

See my Mensur. 2d edit. pa. 118 &c, also most treatises on Fluxions.

It is evident that the simplest of these series is the third, or that which is expressed in terms of the tangent. It will therefore be the properest form to calculate an example by in numbers. And for this purpose it will be convenient to assume some arc whose tangent, or at least its square, is known to be some small finite number. Now the arc of 45° it is known has its tangent equal to the radius; and therefore, taking the radius $r = 1$, and consequently the tangent of 45° or $t = 1$ also, in this case the arc of 45° to the radius 1, or the quadrant to the diameter 1, will be $= 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9}$ &c. But as this series converges very slowly, some smaller arch must be taken, that the series may converge faster; such as the arc of 30°, whose tangent is $= \sqrt{\frac{1}{3}} = .5773502$, or its square $t^2 = \frac{1}{3}$; and hence, after the first term, the succeeding terms will be found by dividing always by 3, and these quotients divided by the absolute numbers 3, 5, 7, 9, &c; and lastly adding every other term together into two sums, the one the sum of the positive terms, and the other the sum of the negative ones, then lastly the one sum taken from the other leaves the length of the arc of 30°, which is the 12th part of the whole circumference when the radius is 1, or the 6th part when the diameter is 1, and consequently 6 times that arc will be the length of the whole circumference to the diameter 1; therefore multiply the 1st term $\sqrt{\frac{1}{3}}$ by 6, and the product is $\sqrt{\frac{36}{3}}$ or $\sqrt{12} = 3.4641016$; hence the operation will be conveniently made as follows:

		+ Terms.	− Terms.
1)	3·4641016	(3·4641016	
3)	1·1547005	(	0·3849002

		+ 3·5462332	−0·4046406
		− 0·4046406	
		3·1415926 the circumference.	

Various other series for the Rectification of the circle may be seen in different parts of my Mensuration, as at pa. 121, 122, 137, 138, 422, &c. See also my paper on this subject in the Philos. Trans. vol. 66, pa. 476.

RECTIFIER, in Navigation, is an instrument used for determining the variation of the compass, in order to rectify the ship's course. It consists of two circles, either laid upon, or let into one another, and so fastened together in their centres that they represent two compasses, the one fixed, and the other moveable. Each is divided into 32 points of the compass, and 360°, and numbered both ways, from the north and the south, ending at the east and west in 90°. The fixed compass represents the horizon, in which the north, and all the other points, are liable to variation. In the centre of the

the moveable compafs is faftened a filk thread, long enough to reach the outfide of the fixed compafs: but when the inftrument is made of wood, an index is ufed inttead of the thread.

RECTIFYING *of Curves*. See RECTIFICATION.

RECTIFYING *of the Globe or Sphere*, is a previous adjuftment of it, to prepare it for the folution of problems. This ufually confifts in placing it in the fame pofition as the true fphere of the world has at fome certain time propofed; which is done firft by elevating the pole above the horizon as much as the latitude of the place is, then bringing the fun's place for the given day, found in the ecliptic, to the graduated fide of the brafs or general meridian, next move the hour-index to the upper hour of 12, fo fhall the globe be Rectified for noon of that day; and if the globe be turned about till the hour-index point at any propofed hour, then is the globe in the real pofition of the earth at that time, if the whole globe be fet in the north and fouth pofition by means of the compafs.

RECTILINEAL, RECTILINEAR, or *Right-lined*, is the quality or nature of figures that are bounded by right lines, or formed by right lines.

RECURRING *Series*, is a feries conftituted in fuch a manner, that having taken at pleafure any number of its terms, each following term fhall be related to the fame number of preceding terms according to a conftant law of relation. See *Recurring* SERIES.

RED, in Phyfics, or Optics, one of the fimple or primary colours of natural bodies, or rather of the rays of light.—The Red rays are the leaft refrangible of all the rays of light. And hence, as Newton fuppofes the different degrees of refrangibility to arife from the different magnitudes of the luminous particles of which the rays confift; therefore the Red rays, or Red light, is concluded to be that which confifts of the largeft particles. See COLOUR and LIGHT.

Authors diftinguifh three general kinds of Red: one bordering on the blue, as colombine, or dove-colour, purple, and crimfon; another bordering on yellow, as flame-colour and orange; and between thefe extremes is a medium, which is that which is properly called Red.

REDANS, or REDANT, or REDENS, in Fortification, is a kind of work indented like the teeth of a faw, with falient and re-entering angles; to the end that one part may flank or defend another. It is called alfo *faw work*, and *indented work*.

Redans are often ufed in fortifying of walls, where it is not neceffary to be at the expence of building baftions; as when they ftand on the fide of a river, or a marfh, or the fea, &c. But the fault of fuch fortification is, that the befiegers from one battery may ruin both the fides of the tenaille or front of a place, and make an affault without fear of being enfiladed, fince the defences are ruined.

The parapet of the corridor alfo is frequently Redented, or carried on by the way of Redans.

REDINTEGRATION, is the taking or finding the integral or fluent again, from the fluxion. See FLUXION and FLUENT.

REDOUBT, or REDOUTE, in Fortification, a fmall fort, without any defence but in front, ufed in trenches, lines of circumvallation, contravallation, and approach; as alfo for the lodging of corps de garde, and to defend paffages.

A Detached REDOUBT, is a kind of work refembling a ravelin, with flanks, placed beyond the glacis.—It is made to occupy fome fpot of ground which might be advantageous to the befiegers; and alfo to oblige the enemy to open his trenches farther off than he would otherwife do.

REDUCING *Scale*, or SURVEYING *Scale*, is a broad, thin flip of box, or ivory, having feveral lines and fcales of equal parts upon it; ufed by furveyors for turning chains and links into roods and acres, by infpection. They ufe it alfo to reduce maps and draughts from one dimenfion to another.

REDUCTION, in general, is the bringing or changing fome thing to a different form, ftate, or denomination.

REDUCTION, in *Arithmetic*, is commonly underftood of the changing of money, weights, or meafures, to other denominations, of the fame value; and it is of two kinds, *Reduction Defcending*, which is the changing a number to its equivalent value in a lower denomination; as pounds into fhillings or pence: and *Reduction Afcending*, which is the changing numbers to higher denominations; as pence to fhillings or pounds.

RULE. *To perform Reduction*; confider how many of the lefs denomination make one of the greater, as how many pence make a fhilling, or how many fhillings make a pound; and multiply by that number when the Reduction is defcending, but divide by it when it is afcending. So to reduce 23l. into pence; and converfely thofe pence into pounds; multiply or divide by 12 and 20, as here below.

$$\begin{array}{r} 23\ l. \\ 20 \\ \hline 460\ sh. \\ 12 \\ \hline 5520\ d. \end{array} \qquad \begin{array}{r} 12\ )\ 5520\ d. \\ 20\ )\ 460\ sh. \\ 23\ l. \end{array}$$

REDUCTION *of Fractions*. See FRACTION, and DECIMAL.

REDUCTION *of Equations*, in Algebra. See EQUATION.

REDUCTION *of Curves*. See CURVE.

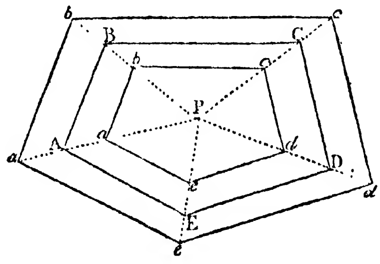
REDUCTION *of a Figure, Defign, or Draught*, is the making a copy of it, either larger or fmaller than the original, but ftill preferving the form and proportion.

Figures and plans are reduced, and copied, in various ways; as by the Pentagraph, and Proportional compaffes. See PENTAGRAPH, and *Proportional* COMPASSES. The beft of the other methods of reducing are as below.

To reduce a Simple Rectilinear Figure by Lines.

Pitch upon a point P any where about the given figure ABCDE, either within it, or without it, or in one fide or angle; but near the middle is beft. From that point P draw lines through all the angles; upon one of

of which take Pa to PA in the propofed proportion of the fcales, or linear dimenfions; then draw ab parallel to AB, bc to BC, &c; fo fhall $abcde$ be the reduced figure fought, either greater or fmaller than the original.

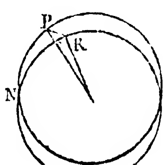


To Reduce a Figure by a Scale.—Meafure all the fides, and diagonals, of the figure, as ABCDE, by a fcale; and lay down the fame meafures refpectively, from another fcale, in the proportion required.

To Reduce a Map, Defign, or Figure, by Squares.—Divide the original into a number of little fquares; and divide a frefh paper, of the dimenfions required, into the fame number of other fquares, either greater or fmaller as required. This done, in every fquare of the fecond figure, draw what is found in the correfponding fquare of the firft or original figure.

The crofs lines forming thefe fquares, may be drawn with a pencil, and thefe rubbed out again after the work is finifhed. But a more ready and convenient way, efpecially when fuch Reductions are often wanted, would be to keep always at hand frames of fquares ready made, of feveral fizes; for by only juft laying them down upon the papers, the correfponding parts may be readily copied. Thefe frames may be made of four ftiff or inflexible bars, ftrung acrofs with horfe hairs, or fine catgut.

Reduction *to the Ecliptic*, in Aftronomy, is the difference between the argument of latitude, as NP, and an arc of the ecliptic NR, intercepted between the place of a planet, and the node.—To find this Reduction, or difference; in the right-angled fpherical triangle NPR, are given the angle of inclination, and the argument of latitude NP; to find NR; then the difference between NP and NR is the Reduction fought.



REDUNDANT *Hyperbola*, is a curve of the higher kind, fo called becaufe it exceeds the conical hyperbola in the number of legs; being a triple hyperbola, with 6 hyperbolic legs. See Newton's Enum. Lin. tertii Ordinis, nomina formarum, &c.

RE-ENTERING *Angle*, in Fortification, is an angle whofe point is turned inwards, or towards the place.

REFLECTED *Ray*, or *Vifion*, is that which is made by the reflection of light, or by light firft received upon the furface of fome body, and thence reflected again. See Ray, Vision, and Reflection.

REFLECTING, or Reflexive, *Dial*, is a kind of dial which fhews the hour by means of a thin piece of looking-glafs plate, duly placed to throw the fun's rays to the top of a cieling, on which the hour-lines are drawn.

REFLECTION, or Reflexion, in Mechanics, is the return, or regreffive motion of a moveable body, occafioned by the refiftance of another body, which hinders it from purfuing its former courfe of direction.

Reflection is conceived, by the lateft and beft authors, as a motion peculiar to elaftic bodies, by which, after ftriking on others which they cannot remove, they recede, or turn back, or afide, by their elaftic power.

On this principle it is afferted, that there may be, and is, a period of reft between the incidence and the reflection; fince the reflected motion is not a continuation of the other, but a new motion, arifing from a new caufe or principle, viz, the power of elafticity.

It is one of the great laws of Reflection, that the angle of incidence is equal to the angle of Reflection; i. e. that the angle which the direction of motion of a ftriking body makes with the furface of the body ftruck, is equal to the angle made between the fame furface and the direction of motion after the ftroke. See Incidence and Percussion.

Reflection *of the Rays of Light*, like that of other bodies, is their motion after being reflected from the furfaces of bodies.

The Reflection of the rays of light from the furfaces of bodies, is the means by which thofe bodies become vifible. And the difpofition of bodies to reflect this or that kind of rays moft copioufly, is the caufe of their being of this or that colour. Alfo, the Reflection of light, from the furfaces of mirrors, makes the fubject of catoptrics.

The Reflection of light, Newton has fhewn, is not effected by the rays ftriking on the very parts of the bodies; but by fome power of the body equally diffufed throughout its whole furface, by which it acts upon the ray, attracting or repelling it without any real immediate contact. This power he alfo fhews is the fame by which, in other circumftances, the rays are refracted; and by which they are at firft emitted from the lucid body.

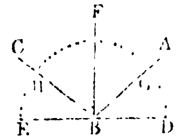
Dr. Prieftley fays, it is not more probable, that the rays of light are tranfmitted from the fun, with an uniform difpofition to be reflected or refracted, according to the circumftances of the bodies on which they impinge; and that the tranfmiffion of fome of the rays, apparently under the fame circumftances, with others that are reflected, is owing to the minute vibrations of the fmall parts of the furfaces of the mediums through which the rays pafs; vibrations that are independent of action and reaction between the bodies and the particles of light at the time of their impinging, though probably excited by the action of preceding rays. Hift. of Light and Colours, pa. 309.

Newton concludes his account of the Reflection of light with obferving, that if light be reflected not by impinging on the folid parts of bodies, but by fome other principle, it is probable that as many of its rays

rays as impinge on the ſolid parts of bodies are not reflected, but ſtifled and loſt in the bodies. Otherwiſe, he ſays, we muſt ſuppoſe two kinds of Reflection; for ſhould all the rays be reflected which impinge on the internal parts of clear water or cryſtal, thoſe ſubſtances would rather have a cloudy colour, than a clear tranſparency. To make bodies look black, it is neceſſary that many rays be ſtopped, retained and loſt in them; and it does not ſeem probable that any rays can be ſtopped and ſtifled in them, which do not impinge on their parts: and hence, he ſays, we may underſtand, that bodies are much more rare and porous than is commonly believed. However, M. Bouguer diſputes the fact of light being ſtifled or loſt by impinging on the ſolid parts of bodies.

Reflection, in Catoptrics, is the return of a ray of light from the poliſhed ſurface of a ſpeculum or mirror, as driven thence by ſome power reſiding in it.

The ray thus returned is called a *reflex* or *reflected ray*, or a *ray of Reflection*; and the point of the ſpeculum where the ray commences, is called the *point of Reflection*. Thus, the ray AB, proceeding from the radiant A, and ſtriking on the point of the ſpeculum B, being returned thence to C, BC repreſents the reflected ray, and B the point of Reflection; in reſpect of which, AB repreſents the incident ray, or ray of incidence, and B the point of incidence; alſo the angle CBE is the angle of Reflection, and ABD the angle of incidence; where DE is the reflecting ſurface, or at leaſt a tangent to it at the point B. Though ſome count the angle of incidence and of Reflection from the perpendicular BF.



General Laws of Reflection.—1. *When a ray of light is reflected from a ſpeculum of any form, the angle of incidence is always equal to the angle of Reflection.* This law obtains in the percuſſions of all kinds of bodies; and conſequently muſt do ſo in thoſe of light; and the proof of it may be ſeen at the article Incidence.

This law is confirmed alſo by experiments on all bodies; and on the rays of light in this manner: A ray from the ſun falling on a mirror, in a dark room, through a ſmall hole, you will have the pleaſure to ſee it rebound, ſo as to make the angle of Reflection equal to the angle of incidence. And the ſame may be ſhewn in various other ways: thus ex. gr. placing a ſemicircle DFE on a mirror DE, its centre on B, and its limb or plane perpendicular to the ſpeculum; and aſſuming equal arcs DG and EH; place an object in A, and the eye in C: then will the object be ſeen by a ray reflected from the point B. But by covering B, the object will ceaſe to be ſeen.

II. *Every point of a ſpeculum reflects rays falling on it, from every part of an object.*

III. *If the eye C and the radiant point A change places, the point will continue to radiate upon the eye, in the ſame courſe or path as before.*

IV. *The plane of Reflection is perpendicular to the ſurface of the ſpeculum; and it paſſes through the centre in ſpherical ſpecula.*

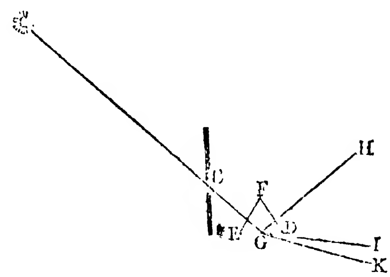
Reflection *of the Moon*, is a term uſed by ſome authors for what is otherwiſe called *her variation*; being the 3d inequality in her motion, by which her true place out of the quadratures differs from her place twice equated.

Reflection is alſo uſed in the Copernican ſyſtem, for the diſtance of the pole from the horizon of the diſc; which is the ſame thing as the ſun's declination in the Ptolomaic ſyſtem.

REFLECTOIRE Curve. See *Reflectoire* Curve.

REFLEXIBILITY *of the rays of light*, is that property by which they are diſpoſed to be reflected. Or, it is their diſpoſition to be turned back into the ſame medium, from any other medium on whoſe ſurface they fall. Hence thoſe rays are ſaid to be more or leſs reflexible, which are returned back more or leſs eaſily under the ſame incidence. Thus, if light paſs out of glaſs into air, and by being inclined more and more to the common ſurface of the glaſs and air, begins at length to be totally reflected by that ſurface, thoſe ſorts of rays which at like incidences are reflected moſt copiouſly, or the rays which by being inclined begin ſooneſt to be totally reflected, are the moſt reflexible rays.

That rays of light are of different colours, are endued with different degrees of reflexibility, was firſt diſcovered by Sir I. Newton; and it is ſhewn by the following experiment. Applying a priſm DFE to



the aperture C of a darkened room in ſuch manner that the light be reflected from the baſe in G; the violet rays are ſeen firſt reflected into HG; the other rays continuing ſtill refracted to I and K. After the violet, the blue are all reflected; then the green, &c.——Hence it appears, that the differently coloured rays differ in degree of Reflexibility. And from other experiments it appears, that thoſe rays which are moſt reflexible, are alſo moſt refrangible.

REFLUX *of the Sea*, is the ebbing of the water, or its return from the ſhore; being ſo called, becauſe it is the oppoſite motion to the flood or flux. See Tide.

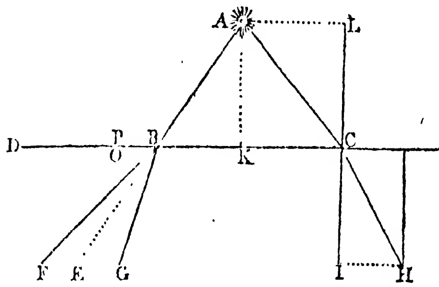
REFRACTED *Angle*, or *Angle of Refraction*, in Optics, is the angle which the refracted ray makes with the refracting ſurface; or ſometimes it denotes the complement of that, or the angle it makes with the perpendicular to the ſaid ſurface.

Refracted *Dials*, or *Refracting Dials*, are ſuch as ſhew the hour by means of ſome refracting tranſparent fluid.

Refracted *Ray*, or *Ray of* Refraction, is a ray

ray after it is broken or bent, at the common surface of two different mediums, where it passes from the one into the other. See RAY, and REFRACTION.

REFRACTION, in Mechanics, is the deviation of a moving body from its direct course, by reason of the different density of the medium it moves in; or a flexion and change of determination, occasioned by a body's passing obliquely out of one medium into another of a different density.



Thus a ball A, moving in the air in the line AB, and falling obliquely on the surface of the water CD, does not proceed straight in the same direction, as to E, but deviates or is deflected to F. Again, if the ball move in water in the line AB, and fall obliquely on a surface of air CD; it will in this case also deviate from the same continued direction BE, but now the contrary way, and will go to G, on the other side of it. Now the deflection in either case is called the *Refraction*, the Refraction being towards the denser surface BD in the former case, but from it in the latter.

These Refractions are supposed to arise from hence; that the ball arriving at B, in the first case finds more resistance or opposition on the one side O, or from the side of the water, than it did from the side P, or that of the air; and in the latter more resistance from the side P, which is now the side of the water, than the side O, which is that of the air. And so for any other different media: a visible instance of which is often perceived in the falling of shot or shells into the earth, as clay &c, when the perforation is found to rise a little upwards, toward the surface. However another reason is assigned for the Refraction of the rays of light, whose Refractions lie the contrary way to those above, as will be seen in what follows, viz, that water by its greater attraction accelerates the motion of the rays of light more than air does.

REFRACTION *of Light*, in Optics, is an inflection or deviation of the rays from their rectilinear course on passing obliquely out of one medium into another, of a different density.

That a body may be refracted, it is necessary that it should fall obliquely on the second medium: in perpendicular incidence there is no Refraction. Yet Vossius and Snellius imagined they had observed a perpendicular ray of light undergo a Refraction; a perpendicular object appearing in the water nearer than it really was: but this was attributing that to a Refraction of the perpendicular rays, which was owing to the divergency of the oblique rays after refraction, from a nearer point. Yet there is a manifest Refraction even of perpendicular rays found in island crystal.

Rohault adds, that though an oblique incidence be necessary in all other mediums we know of, yet the obliquity must not exceed a certain degree; if it do, the body will not penetrate the medium, but will be reflected instead of being refracted. Thus, cannon-balls, in sea engagements, falling very obliquely on the surface of the water, are observed to bound or rise from it, and to sweep the men from off the enemy's decks. And the same thing happens to the little stones with which children make their ducks and drakes along the surface of the water.

The ancients confounded Refraction with Reflection; and it was Newton who first taught the true difference between them. He shews however that there is a good deal of analogy between them, and particularly in the case of light.

The laws of Refraction of the rays of light in mediums differently terminated, i. e. whose surfaces are plane, concave, and convex, make the subject of Dioptrics.—By Refraction it is, that convex glasses, or lenses, collect the rays, magnify objects, burn, &c; and hence the foundation of microscopes, telescopes, &c.—And by Refraction it is, that all remote objects are seen out of their real places; particularly, that the heavenly bodies are apparently higher than they are in reality. The Refraction of the air has many times so uncertain an influence on the places of celestial objects, near the horizon, that wherever Refraction is concerned, the conclusions deduced from observations that are much affected by it, will always remain doubtful, and sometimes too precarious to be relied on. See Dr. Bradley in Philos. Trans. number 485.

As to the cause of Refraction, it does not appear that any person before Des Cartes attempted to explain it; this he undertook to do by the resolution of forces, on the principles of mechanics; in consequence of which, he was obliged to suppose that light passes with more ease through a dense medium than a rare one: thus, the ray AC falling obliquely on a denser medium at C is supposed to be acted on by two forces, one of them impelling it in the direction AL, and the other in AK, which alone can be affected by the change of medium: and since, after the ray has entered the denser medium, it approaches the perpendicular CI, it is plain that this force must have received an increase, whilst the other continued the same.

The first person who questioned the truth of this explanation of the cause of Refraction, was Fermat; he asserted, contrary to Des Cartes, that light suffers greater resistance in water than in air, and greater in glass than in water; and he maintained that the resistance of different mediums, with respect to light, is in proportion to their densities. Leibnitz also adopted the same general idea; and they reasoned upon the subject in the following manner. Nature, say they, accomplishes her ends by the shortest methods; and therefore light ought to pass from one point to another, either by the shortest course, or by that in which the least time is required. But it is plain that the path in which light passes, when it falls obliquely upon a denser

ſer medium, is not the moſt direct or the ſhorteſt; and therefore it muſt be that in which the leaſt time is ſpent. And whereas it is demonſtrable, that light falling obliquely upon a denſer medium (in order to take up the leaſt time poſſible, in paſſing from a point in one medium to a point in the other) muſt be refracted in ſuch a manner, that the ſine of the angles of incidence and Refraction muſt be to one another, as the different facilities with which light is tranſmitted in thoſe mediums; it follows that, ſince light approaches the perpendicular when it paſſes obliquely from air into water, the facility with which water ſuffers light to paſs through it, is leſs than that of the air; ſo that the light meets with greater reſiſtance in water than in air.

This method of arguing from final cauſes could not ſatisfy philoſophers. Dr. Smith obſerves, that it agrees only to the caſe of Refraction at a plane ſurface; and that the hypotheſis is altogether arbitrary.

Dechales, in explaining the law of Refraction, ſuppoſes that every ray of light is compoſed of ſeveral ſmaller rays, which adhere to one another; and that they are refracted towards the perpendicular, in paſſing into a denſer medium, becauſe one part of the ray meets with more reſiſtance than another part; ſo that the former traverſes a ſmaller ſpace than the latter; in conſequence of which the ray muſt neceſſarily bend a little towards the perpendicular. This hypotheſis was adopted by the celebrated Dr. Barrow, and indeed ſome ſay, he was the author of it. On this hypotheſis it is plain, that mediums of a greater refractive power, muſt give a greater reſiſtance to the paſſage of the rays of light, than mediums of a leſs refractive power; which is contrary to fact.

The Bernoullis, both father and ſon, have attempted to explain the cauſe of Refraction on mechanical principles; the former on the equilibrium of forces, and the latter on the ſame principles with the ſuppoſition of etherial vortices: but neither of theſe hypotheſes have gained much credit.

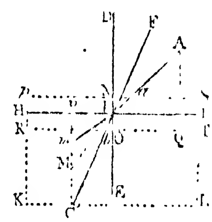
M. Mairan ſuppoſes a ſubtle fluid, filling the pores of all bodies, and extending, like an atmoſphere, to a ſmall diſtance beyond their ſurfaces; and then he ſuppoſes that the Refraction of light is nothing more than a neceſſary and mechanical effect of the incidence of a ſmall body in thoſe circumſtances. There is more, he ſays, of the refracting fluid, in water than in air, more in glaſs than in water, and in general more in a denſe medium than in one that is rarer.

Maupertuis ſuppoſes that the courſe which every ray takes, in paſſing out of one medium into another, is that which requires the leaſt quantity of action, which depends upon the velocity of the body and the ſpace it paſſes over; ſo that it is in proportion to the ſum of the products ariſing from the ſpaces multiplied by the velocities with which bodies paſs over them. From this principle he deduces the neceſſity of the ſine of the angle of incidence being in a conſtant proportion to that of Refraction; and alſo all the other laws relating to the propagation and reflection of light.

Dr. Smith, (in his Optics, Remarks, p. 70) obſerves, that all other theories for explaining the reflection and Refraction of light, except that of Newton, ſuppoſe that it ſtrikes upon bodies and is reſiſted by them; which has never been proved by any deduction from experience. On the contrary, it appears by various conſiderations, and might be ſhewn by the obſervations of Mr. Molyneux and Dr. Bradley on the parallax of the fixed ſtars, that their rays are not at all impeded by the rapid motion of the earth's atmoſphere, nor by the object glaſs of the teleſcope, through which they paſs. And by Newton's theory of Refraction, which is grounded on experience only, it appears that light is ſo far from being reſiſted and retarded by Refraction into any denſe medium, that it is ſwifter there than in vacuo in the ratio of the ſine of incidence in vacuo to the ſine of Refraction into the denſe medium. Prieſtley's Hiſt. of Light, &c, p. 102 and 333.

Newton ſhews that the Refraction of light is not performed by the rays falling on the very ſurface of bodies; but that it is effected, without any contact, by the action of ſome power belonging to bodies, and extending to a certain diſtance beyond their ſurfaces; by which ſame power, acting in other circumſtances, they are alſo emitted and reflected.

The manner in which Refraction is performed by mere attraction, without contact, may be thus accounted for: Suppoſe HI the boundary of two mediums, N and O; the firſt the rarer, ex. gr. air; the ſecond the denſer, ex. gr. glaſs; the attraction of the mediums here will be as their denſities. Suppoſe p S to be the diſtance to which the attracting force of the denſer medium exerts itſelf within the rarer. Now



let a ray of light Aa fall obliquely on the ſurface which ſeparates the mediums, or rather on the ſurface pS, where the action of the ſecond and more reſiſting medium commences: as the ray arrives at a, it will begin to be turned out of its rectilinear courſe by a ſuperior force, with which it is attracted by the medium O, more than by the medium N; hence the ray is bent out of its right line in every point of its paſſage between pS and RT, within which diſtance the attraction acts; and therefore between theſe lines it deſcribes a curve aBb; but beyond RT, being out of the ſphere of attraction of the medium N, it will proceed uniformly in a right line, according to the direction of the curve in the point b.

Again, ſuppoſe N the denſer and more attracting medium, O the rarer, and HI the boundary as before; and let RT be the diſtance to which the denſer medium exerts its attractive force within the rarer: even when the ray has paſſed the point B, it will be within the ſphere of the ſuperior attraction of the denſer medium; but that attraction acting in lines perpendicular to its ſurface, the ray will be continually drawn from its ſtraight courſe BM perpendicularly towards HI: thus, having two forces or directions, it will have a compound motion, by which, inſtead of BM, it will deſcribe Bm, which Bm will in ſtrictneſs be a curve. Laſtly, after it has arrived at m, being out of the influence of the medium N, it will perſiſt uniformly, in a right line, in the direction in which the extremity of the

the curve leaves it.—Thus we see how Refraction is performed, both towards the perpendicular DE, and from it.

Refraction *in Dioptrics*, is the inflexion or bending of the rays of light, in passing the surfaces of glasses, lenses, and other transparent bodies of different densities. Thus, a ray, as AB, falling obliquely from the radiant A, upon a point B, in a diaphanous surface HI, rarer or denser than the medium along which it was propagated from the radiant, has its direction there altered by the action of the new medium; and instead of proceeding to M, it deviates, as for ex. to C.

This deviation is called the *Refraction of the ray*; BC the *refracted ray*, or *line of Refraction*; and B the *point of Refraction*.—The line AB is also called the *line of incidence*; and in respect of it, B is also called the *point of incidence*. The plane in which both the incident and refracted ray are found, is called the *plane of Refraction*; also a right line BE drawn in the refracting medium perpendicular to the refracting surface at the point of Refraction B, is called the *axis of Refraction*; and its continuation DB along the medium through which the ray falls, is called the *axis of incidence*.—Farther, the angle ABI, made by the incident ray and the refracting surface, is usually called the *angle of incidence*; and the angle ABD, between the incident ray and the axis of incidence, is the *angle of inclination*. Moreover, the angle MBC, between the refracted and incident rays, is called the *angle of Refraction*; and the angle CBE, between the refracted ray and the axis of Refraction, is the *refracted angle*. But it is also very common to call the angles ABD and CBE made by the perpendicular with the incident and refracted rays, the *angles of incidence and Refraction*.

General Laws of Refraction.—I. *A ray of light in its passage out of a rarer medium into a denser*, ex. gr. *out of air into water or into glass, is refracted towards the perpendicular*, i. e. *towards the axis of Refraction*. Hence, the refracted angle is less than the angle of inclination; and the angle of Refraction less than that of incidence; as they would be equal were the ray to proceed straight from A to M.

II. *The ratio of the sines of the angles* ABD, CBF, *made by the perpendicular with the incident and refracted rays, is a constant and fixed ratio*; whatever be the obliquity of the incident ray, the mediums remaining. Thus, the Refraction out of air, into water, is nearly as 4 to 3, and into glass it is nearly as 3 to 2. As to air in particular, it is shewn by Newton, that a ray of light, in traversing quite through the atmosphere, is refracted the same as it would be, were it to pass with the same obliquity out of a vacuum immediately into air of equal density with that in the lowest part of the atmosphere.

The true law of Refraction was first discovered by Willebrord Snell, professor of Mathematics at Leyden; who found by experiment that the cosecants of the angles of incidence and Refraction, are always in the same ratio. It was commonly attributed however to Des Cartes; who, having seen it in a MS. of Snell's, first published it in his Dioptrics, without naming Snellius, as Huygens asserts; Des Cartes having only altered the form of the law, from the ratio of the cosecants, to that of the sines, which is the same thing.

It is to be observed however, that as the rays of light are not all of the same degree of refrangibility, this constant ratio must be different in different kinds: so that the ratio mentioned by authors, is to be understood of rays of the mean refrangibility, i. e of green rays. The difference of Refraction between the least and most refrangible rays, that is, between violet and red rays, Newton shews, is about the $\frac{1}{27}$ of the whole Refraction of the mean refrangible; which difference, he allows, is so small, that it seldom needs to be regarded.

Different transparent substances have indeed very different degrees of Refraction, and those not according to any regular law; as appears by many experiments of Newton, Euler, Hawksbee, &c. See Newton's Optics, 3d edit. pa. 247; Hawksbee's Experim. pa. 292; Act. Berlin. 1762, pa. 302; Priestley's Hist. of Light &c, pa. 479.

Whence the different refractive powers in different fluids arise, has not been determined. Newton shews, that in many bodies, as glass, crystal, selenites, pseudo-topaz, &c, the refractive power is indeed proportionable to their densities; whilst in sulphureous bodies, as camphor, linseed, and olive oil, amber, spirit of turpentine, &c, the power is two or three times greater than in other bodies of equal density; and yet even these have the refractive power with respect to each other, nearly as their densities. Water has a refractive power in a medium degree between those two kinds of substances; whilst salts and vitriols have refractive powers in a middle degree between those of earthy substances and water, and accordingly are composed of those two sorts of matter. Spirit of wine has a refractive power in a middle degree between those of water and oily substances; and accordingly it seems to be composed of both, united by fermentation. It appears therefore, that all bodies seem to have their refractive powers nearly proportional to their densities, excepting so far as they partake more or less of sulphureous oily particles, by which those powers are altered.

Newton suspected that different degrees of heat might have some effect on the refractive power of bodies; but his method of determining the general Refraction was not sufficiently accurate to ascertain this circumstance. Euler's method however was well adapted to this purpose: from his experiments he infers, that the focal distance of a single lens of glass diminishes with the heat communicated to it; which diminution is owing to a change in the refractive power of the glass itself, which is probably increased by heat, and diminished by cold, as well probably as that of all other translucent substances.

From the law above laid down it follows, that one angle of inclination, and its corresponding refracted angle, being found by observation, the refracted angles corresponding to the several other angles of inclination are thence easily computed. Now, Zahnius and Kircher have found, that if the angle of inclination be 70°, the refracted angle, out of air into glass, will be 38° 50'; on which principle Zahnius has constructed a table of those Refractions for the several degrees of the angle

angle of inclination; a ſpecimen of which here follows:

Angle of Inclination.	Refracted Angle.			Angle of Refraction.		
°	°	′	″	°	′	″
1	0	40	5	0	19	55
2	1	20	6	0	39	54
3	2	0	4	0	59	56
4	2	40	5	1	19	55
5	3	20	3	1	39	57
10	6	39	16	3	20	44
20	13	11	35	6	48	25
30	19	29	29	10	30	31
45	28	9	19	16	50	41
90	41	51	40	48	8	20

Hence it appears, that if the angle of inclination be leſs than 20°, the angle of Refraction out of air into glaſs is almoſt ⅓ of the angle of inclination; and therefore a ray is refracted to the axis of Refraction by almoſt a third part of the quantity of its angle of inclination. And on this principle it is that Kepler, and moſt other dioptrical writers, demonſtrate the Refractions in glaſſes; though in eſtimating the law of theſe Refractions he followed the example of Alhazen and Vitello, and ſought to diſcover it in the proportion of the angles, and not in that of the ſines, or coſecants, as diſcovered by Snellius, as mentioned above.

The refractive powers of ſeveral ſubſtances, as determined by different philoſophers, may be ſeen in the following tables; in which the ray is ſuppoſed to paſs out of air into each of the ſubſtances, and the annexed numbers ſhew the proportion to unity or 1, between the ſines of the angles of incidence and Refraction.

III. *When a ray paſſes out of a denſer medium into a rarer, it is refracted from the perpendicular, or from the axis of Refraction.*

This is exactly the reverſe of the 2d law, and the quantity of Refraction is equal in both caſes, or both forwards and backwards; ſo that a ray would take the ſame courſe back, by which another paſſed forward, viz, if a ray would paſs from A by B to C, another would paſs from C by B to A. Hence, in this caſe, the angle of Refraction is greater than the angle of inclination. Hence alſo, if the angle of inclination be leſs than 30°, MBC is nearly equal to ½ of MBE; therefore MBC is ½ of CBE; conſequently, if the Refraction be out of glaſs into air, and the angle of inclination leſs than 30°, the ray is refracted from the axis of Refraction by almoſt the half of the angle of inclination. And this is the other dioptrical principle uſed by moſt authors after Kepler, to demonſtrate the Refractions of glaſſes.

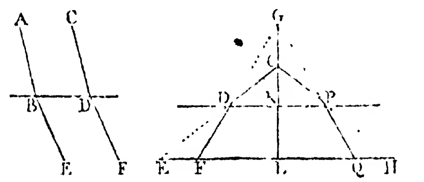
If the Refraction be out of air into glaſs, the ratio of the ſines of inclination and Refraction is as 3 to 2, or more accurately as 17 to 11; if out of air into water as 4 to 3; therefore if the courſe be the contrary way, viz, out of glaſs or water into air, the ratio of the ſines will be, in the former caſe as 2 to 3 or 11 to 17, and in the latter as 3 to 4. So that, if the Refraction be from water or glaſs into air, and the angle of incidence

dence or inclination be greater than about $48\frac{1}{2}$ degrees in water, or greater than about 40° in glass, the ray will not be refracted into air; but will be reflected into a line which makes the angle of reflection equal to the angle of incidence; because the sines of $48\frac{1}{2}$ and 40° are to the radius, as 3 to 4, and as 11 to 17 nearly; and therefore when the sine has a greater proportion to the radius than as above, the ray will not be refracted.

IV. *A ray falling on a curve surface, whether concave or convex, is refracted after the same manner as if it fell on a plane which is a tangent to the curve in the point of incidence.* Because the curve and its tangent have the point of contact common to both, where the ray is refracted.

Laws of REFRACTION *in Plane Surfaces.*

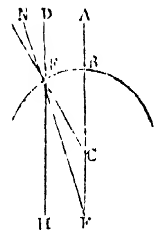
1. If parallel rays, AB and CD, be refracted out of one transparent medium into another of a different density, they will continue parallel after Refraction, as BE and DF. Hence a glass that is plane on both sides, being turned either directly or obliquely to the sun, &c. the light passing through it will be propagated in the same manner as if the glass were away.



2. If two rays CD and CP, proceeding from the same radiant C, and falling on a plane surface of a different density, so that the points of Refraction D and P be equally distant from the perpendicular of incidence GK, the refracted rays DF and PQ have the same virtual focus, or the same point of dispersion G.—Hence, when refracted rays, falling on the eye placed out of the perpendicular of incidence, are either equally distant from the perpendicular, or very near each other, they will flow upon the eye as if they came to it from the point G; consequently the point C will be seen by the refracted rays as in G. And hence also, if the eye be placed in a dense medium, objects in a rarer will appear more remote than they are; and the place of the image, in any case, may be determined from the ratio of Refraction: Thus, to fishes swimming under water, objects out of the water must appear farther distant than in reality they are. But, on the contrary, if the eye at E be placed in a rarer medium, then an object G placed in a denser, appears, at C, nearer than it is; and the place of the image may be determined in any given case by the ratio of Refraction: and thus the bottom of a vessel full of water is raised by Refraction a third part of its depth, with respect to an eye placed perpendicularly over the refracting surface; and thus also fishes and other bodies, under water, appear nearer than they really are.

3. If the eye be placed in a rarer medium; then an object seen in a denser, by a ray refracted in a plane surface, will appear larger than it really is. But if the eye be in a denser medium, and the object in a rarer, the object will appear less than it is. And, in each case, the apparent magnitude FQ is to the real one EH, as the rectangle CK · GL to GK · CL, or in the compound ratio of the distance CK of the point to which the rays tend before Refraction, from the refracting surface DP, to the distance GK of the eye from the same, and of the distance GL of the object EH from the eye, to its distance CL from the point to which the rays tend before Refraction.—Hence, if the object be very remote, CL will be physically equal to GL; and then the real magnitude EL is to the apparent magnitude FL, as GK to CK, or as the distance of the eye G from the refracting plane, to the distance of the point of convergence F from the same plane. And hence also, objects under water, to an eye in the air, appear larger than they are; and to fishes under water, objects in the air appear less than they are.

Laws of REFRACTION *in Spherical Surfaces, both concave and convex.*



1. A ray of light DE, parallel to the axis, after a single refraction at E, meets the axis in the point F, beyond the centre C.

2. Also in that case, the semidiameter CB or CE will be to the refracted ray EF, as the sine of the angle of refraction to the sine of the angle of inclination BCE. But the distance of the focus, or point of concurrence from the centre, CF, is to the refracted ray EF, as the sine of the refracted angle to the sine of the angle of inclination.

3. Hence also, in this case, the distance BF of the focus from the refracting surface, must be to CF its distance from the centre, in a ratio greater than that of the sine of the angle of inclination to the sine of the refracted angle. But those ratios will be nearly equal when the rays are very near the axis, and the angle of inclination BCE is only of a few degrees. And when the Refraction is out of air into glass, then

For rays near the axis,	For more distant rays,
BF : FC :: 3 : 2,	BF : FC $>$ 3 : 2,
BC : BF :: 1 : 3.	BC : BF $<$ 1 : 3.

But if the Refraction be out of air into water, then

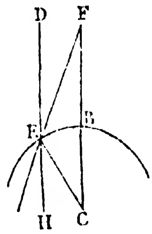
For rays near the axis,	For more distant rays,
BF : FC :: 4 : 3,	BF : FC $>$ 4 : 3,
BC : BF :: 1 : 4,	BC : BF $<$ 1 : 4.

Hence, as the sun's rays are parallel as to sense, if they fall on the surface of a solid glass sphere, or of a sphere full of water, they will not meet the axis within the sphere: so that Vitello was mistaken when he imagined that the sun's rays, falling on the surface of a crystalline sphere, were refracted to the centre.

4. If a ray HE fall parallel to the axis FA, out of a rarer medium, on the concave spherical surface BE of a denser one; the refracted ray EN will diverge from the point of the axis F, so that FE will be to FC, in the ratio of the sine of the angle of inclination, to the sine of the refracted angle. Consequently FB to FC is in a greater ratio than that; unless when the rays are very near the axis, and the angle BCE is very small.

for then FB will be to FC nearly in that ratio. And hence, in the cases of Refraction out of air into water or glass, the ratios of BC, BF and CF, will be the same as specified in the last article.

5. If a ray DE, parallel to the axis FC, pass out of a denser into a rarer spherical convex medium, it will diverge from the axis after Refraction; and the distance FC of the point of dispersion, or of the virtual focus F, from the centre of the sphere, will be to its semidiameter CE or CB, as the sine of the refracted angle is to the sine of the angle of Refraction; but to the portion of the refracted ray drawn back, FE, it will be in the ratio of the sine of the refracted angle to the sine of the angle of inclination. Consequently FC will be to FB, in a greater ratio than this last one: unless when the rays DE fall very near the axis FC, for then FC to FB will be very nearly in that ratio.



Hence, when the Refraction is out of glass into air; then,

For rays near the axis,	For more distant rays,
FC : FB :: 3 : 2,	FC : FB > 3 : 2,
BC : BF :: 1 : 2.	BC : BF > 1 : 2,

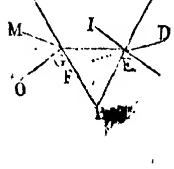
But when the Refraction is out of water into air; then,

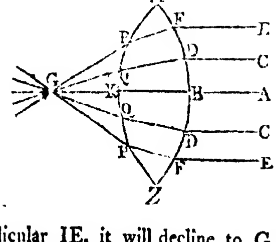
For rays near the axis,	For more distant rays,
FC : FB :: 4 : 3,	FC : FB > 4 : 3,
BC : BF :: 1 : 3.	BC : BF > 1 : 3.

6. If the ray HE fall parallel to the axis CF, from a denser medium, upon the surface of a spherically concave rarer one; the refracted ray will meet with the axis in the point F, so that the distance CF from the centre, will be to the refracted ray FE, as the sine of the refracted angle, to the sine of the angle of inclination. Consequently FC will be to FB, in a greater ratio than that above mentioned: unless when the rays are very near the axis, for then FC is to FB very nearly in that ratio; and the three FB, FC, BC are, in the cases of air, water and glass, in the numeral ratios as specified at the end of the last article. See Wolfius, Elem. Mathes. tom. 3 p. 179 &c.

Refraction *in a Glass Prism.*

ABC being the transverse section of a prism; if a ray of light DE fall obliquely upon it out of the air; instead of proceeding straight on to F, being refracted





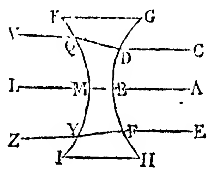
towards the perpendicular IE, it will decline to G. Again, since the ray EG, passing out of glass into air, falls obliquely on BC, it will be refracted to M, so as to recede from the perpendicular GO. And hence arise the various phenomena of the prism. See Colour.

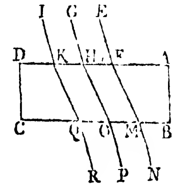
Refraction *in a Convex Lens.*

If parallel rays, AB, CD, EF, fall on the surface of a convex lens XBZ (the last fig. above); the perpendicular ray AB will pass unrefracted to K, where emerging, as before, perpendicularly, into air, it will proceed straight on to G. But the rays CD and EF, falling obliquely out of air into glass, at D and F, will be refracted towards the axis of Refraction, or towards the perpendiculars at D and F, and so decline to Q and P: where emerging again obliquely out of the glass into the surface of the air, they will be refracted from the perpendicular, and proceed in the directions QG and PG, meeting in G. And thus also will all the other rays be refracted so as to meet the rest near the place G. See Focus and Lens.—Hence the great property of convex glasses; viz, that they collect parallel rays, or make them converge into a point.

Refraction *in a Concave Lens.*

Parallel rays AB, CD, EF, falling on a concave lens GBHIMK, the ray AB falling perpendicularly on the glass at B, will pass unrefracted to M; where, being still perpendicular, it will pass into the air to L, with-





out Refraction. But the ray CD, falling obliquely on the surface of the glass, will be refracted towards the perpendicular at D, and proceed to Q; where again falling obliquely out of the glass upon the surface of air, it will be refracted from the perpendicular at Q, and proceed to V. After the same manner the ray EF is first refracted to Y, and thence to Z.—Hence the great property of concave glasses; viz, that they disperse parallel rays, or make them diverge. See Lens.

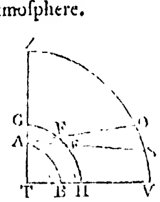
Refraction *in a Plane Glass.*

If parallel rays EF, GH, IK, (the last fig. above) fall obliquely on a plane glass ABCD; the obliquity being the same in all, by reason of their parallelism, they will be all equally refracted towards the perpendicular; and accordingly, being still parallel at M, O, and Q, they will pass out into the air equally refracted again from the perpendicular, and still parallel. Thus will the rays EF, GH, and IK, at their entering the glass, be inflected towards the right; and in their going out as much inflected to the left; so that the first Refraction is here undone by the second, thereby causing the rays on their emerging from the glass, to be parallel to their first direction before they entered it; though not so as that the object is seen in its true *place; for* the ray RQ, being produced back again, will not coincide with the ray IK, but will fall to the left of it; and this the more as the glass is thicker; however, as to

to the colour, the second Refraction does really undo the first. See Colour.

Refraction *in Astronomy*, or Refraction *of the Stars*, is an inflexion of the rays of those luminaries, in passing through our atmosphere; by which the apparent altitudes of the heavenly bodies are increased.

This Refraction arises from hence, that the atmosphere is unequally dense in different stages or regions; rarest of all at the top, and densest of all at the bottom; which inequality in the same medium, makes it equivalent to several unequal mediums, by which the course of the ray of light is continually bent into a continued curve line. See Atmosphere.——And Sir Isaac Newton has shewn, that a ray of light, in passing from the highest and rarest part of the atmosphere, down to the lowest and densest, undergoes the same quantity of Refraction that it would do in passing immediately, at the same obliquity, out of a vacuum into air of equal density with that in the lowest part of the atmosphere.



The effect of this Refraction may be thus conceived. Suppose ZV a quadrant of a vertical circle described from the centre of the earth T, under which is AB a quadrant of a circle on the surface of the earth, and GH a quadrant of the surface of the atmosphere. Then suppose SE a ray of light emitted by a star at S, and falling on the atmosphere at E: this ray coming out of the ethereal medium, which is much rarer than our air, or perhaps out of a perfect vacuum, and falling on the surface of the atmosphere, will be refracted towards the perpendicular, or inclined down more towards the earth; and since the upper air is again rarer than that near the earth, and grows still denser as it approaches the earth's surface, the ray in its progress will be continually refracted, so as to arrive at the eye in the curve line EA. Then supposing the right line AF to be a tangent to the arch at A, the ray will enter the eye at A in the direction of AF; and therefore the star will appear in the heavens at Q, instead of S, higher or nearer the zenith than the star really is.

Hence arise the phenomena of the crepusculum or twilight; and hence also it is that the moon is sometimes seen eclipsed, when she is really below the horizon, and the sun above it.

That there is a real Refraction of the stars &c, is deduced not only from physical considerations, and from arguments a priori, and a similitudine, but also from precise astronomical observation: for there are numberless observations by which it appears that the sun, moon, and stars rise much sooner, and appear higher, than they should do according to astronomical calculations. Hence it is argued, that as light is propagated in right lines, no rays could reach the eye from a luminary below the horizon, unless they were deflected out of their course, at their entrance into the atmosphere; and therefore it appears that the rays are refracted in passing through the atmosphere.

Hence the stars appear higher by Refraction than they really are; so that to bring the observed or apparent altitudes to the true ones, the quantity of Refraction must be subtracted. And hence, the ancients, as they were not acquainted with this Refraction, reckoned their altitudes too great, so that it is no wonder they sometimes committed considerable errors. Hence also, Refraction lengthens the day, and shortens the night, by making the sun appear above the horizon a little before his rising, and a little after his setting. Refraction also makes the moon and stars appear to rise sooner and set later than they really do. The apparent diameter of the sun or moon is about 32′; the horizontal refraction is about 33′; whence the sun and moon appear *wholly* above the horizon when they are entirely below it. Also, from observations it appears that the Refractions are greater nearer the pole than at lesser latitudes, causing the sun to appear some days above the horizon, when he is really below it; doubtless from the greater density of the atmosphere, and the greater obliquity of the incidence.

Stars in the zenith are not subject to any Refraction: those in the horizon have the greatest of all: from the horizon, the Refraction continually decreases to the zenith. All which follows from hence, that in the first case, the rays are perpendicular to the medium; in the second, their obliquity is the greatest, and they pass through the largest space of the lower and denser part of the air, and through the thickest vapours; and in the third, the obliquity is continually decreasing.

The air is condensed, and consequently Refraction is increased, by cold; for which reason it is greater in cold countries than in hot ones. It is also greater in cold weather than in hot, in the same country; and the morning Refraction is greater than that of the evening, because the air is rarefied by the heat of the sun in the day, and condensed by the coldness of the night. Refraction is also subject to some small variation at the same time of the day in the finest weather.

At the same altitudes, the sun, moon, and stars all undergo the same Refraction: for at equal altitudes the incident rays have the same inclinations; and the sines of the refracted angles are as the sines of the angles of inclination, &c.

Indeed Tycho Brahe, who first deduced the Refractions of the sun, moon, and stars, from observations, and whose table of the Refraction of the stars is not much different from those of Flamsteed and Newton, except near the horizon, makes the solar Refractions about 4′ greater than those of the fixed stars; and the lunar Refractions also sometimes greater than those of the stars, and sometimes less. But the theory of Refractions, found out by Snellius, was not fully understood in his time.

The horizontal Refraction, being the greatest, is the cause that the sun and moon appear of an oval form at their rising and setting; for the lower edge of each being more refracted than the upper edge, the perpendicular diameter is shortened, and the under edge appears more flatted also.—Hence also, if we take with an instrument the distance of two stars when they are *in the same vertical and near the horizon, we shall find* it considerably less than if we measure it when they are both at such a height as to suffer little or no Refraction; because the lower star is more elevated than the higher. There is also another alteration made by Refraction in the apparent distance of stars: when two stars are in the same almicantar, or parallel of declination, their apparent

parent distance is less than the true; for since Refraction makes each of them higher in the azimuth or vertical in which they appear, it must bring them into parts of the vertical where they come nearer to each other; because all vertical circles converge and meet in the zenith. This contraction of distance, according to Dr. Halley (Philos. Transf. numb. 368) is at the rate of at least one second in a degree; so that, if the distance between two stars in a position parallel to the horizon measure 30°, it is at most to be reckoned only 29° 59′ 30″.

The quantity of the Refraction at every altitude, from the horizon, where it is greatest, to the zenith where it is nothing, has been determined by observation, by many astronomers; those of Dr. Bradley and Mr. Mayer are esteemed the most correct of any, being nearly alike, and are now used by most astronomers. Doctor Bradley, from his observations, deduced this very simple and general rule for the Refraction r at any altitude a whatever; viz,

as rad. 1 : cotang. $\overline{a + 3r}$ :: 57″ : r'' the Refraction in seconds.

This rule, of Dr. Bradley's, is adapted to these states of the barometer and thermometer, viz,

either 29·6 ins. barom. and 50° thermometer,
or 30 — barom. and 55. thermometer,

for both which states it answers equally the same. But for any other states of the barometer and thermometer, the Refraction above-found is to be corrected in this manner; viz, if b denote any other height of the barometer in inches, and t the degrees of the thermometer, r being the Refraction uncorrected, as found in the manner above. Then

as $29 \cdot 6 : b :: r :$ R the Refraction corrected on account of the barometer,

and $400 : 450 - t :: \text{R} :$ the Refraction corrected both on account of the barometer and thermometer; which final corrected Refraction is therefore $= \frac{450 - t}{11840} br$.

Or, to correct the same Refraction r by means of the latter state, viz, barom. 30 and therm. 55, it will be

as $30 : b :: r : \text{R} = \frac{br}{30}$,

and $400 : 455 - t :: \text{R} : \frac{455 - t}{400}\text{R} = \frac{455 - t}{12000} br$ the correct Refraction.

From Dr. Bradley's rule, $r = 57'' \times \cot.\overline{a + 3r}$, the following Table of the mean astronom. Refrac. is computed.

Mean Astronomical Refractions in Altitude.

Apparent Altitude.		Refraction		Apparent Altitude.		Refraction.		Apparent Altitude.		Refraction.		Apparent Altitude.		Refraction.		Apparent Altitude.	Refraction.

Mr. Mayer says his rule was deduced from theory, and, when reduced from French meafure and Reaumur's thermometer, to Englifh meafure and Fahrenheit's thermometer, it is this,

$$r = \frac{74 \cdot 4b \times \text{cof. } a}{(1 + \cdot 00248t)^{\frac{1}{2}}} \left(\sqrt{1 + \frac{17 \cdot 14 \text{ fin. } a}{1 + \cdot 00248t}} - \frac{17 \cdot 14 \text{ fin. } a}{(1 + \cdot 00248t)^{\frac{1}{2}}} \right)$$

or $r = \dfrac{74 \cdot 4b \times \text{cof. } a \times \text{tang. } \frac{1}{2}A}{(1 + \cdot 00248t)^{\frac{1}{2}}}$ the Refraction in feconds, corrected for both barometer and thermometer: where the letters denote the fame things as before, except A, which denotes the angle whofe tangent is $\dfrac{\sqrt{1 + \cdot 00248t}}{17 \cdot 14 \text{ fin. } a}$.

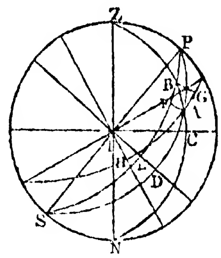
Mr. Simpfon too (Differt. pa. 46 &c) has ingeniously determined by theory the aftronomical Refractions, from which he brings out this rule, viz, As 1 to ·9986 or as radius to fine of 86° 58′ 30″, fo is the fine of any given zenith diftance, to the fine of an arc; then $\frac{1}{12}$ of the difference between this arc and the zenith diftance, is the Refraction fought for that zenith diftance. And by this rule Mr. Simpfon computed a Table of the mean Refractions, which are not much different from thofe of Dr. Bradley and Mr. Mayer, and are as in the following Table.

Mr. Simpfon's Table of Mean Refractions.

Apparent Altitude.	Refraction.		Apparent Altitude.	Refraction.		Apparent Altitude.	Refraction.	
0°	33′	0″	17°	2′	50″	38°	1′	7″
1	23	50	18	2	40	40	1	2
2	17	43	19	2	31	42	0	58
3	13	44	20	2	23	44	0	54
4	11	5	21	2	16	46	0	50
5	9	10	22	2	9	48	0	47
6	7	49	23	2	3	50	0	44
7	6	48	24	1	57	52	0	41
8	5	59	25	1	52	54	0	38
9	5	21	26	1	47	56	0	35
10	4	50	27	1	42	58	0	32
11	4	24	28	1	38	60	0	30
12	4	2	29	1	34	65	0	24
13	3	43	30	1	30	70	0	19
14	3	27	32	1	23	75	0	14
15	3	13	34	1	17	80	0	9
16	3	1	36	1	12	85	0	4

It is evident that all obferved altitudes of the heavenly bodies ought to be diminifhed by the numbers taken out of the foregoing Table. It is alfo evident that the Refraction diminifhes the right and oblique afcenfions of a ftar, and increafes the defcenfions: it increafes the northern declination and latitude, but decreafes the fouthern: in the eaftern part of the heavens it diminifhes the longitude of a ftar, but in the weftern part of the heavens it increafes the fame.

REFRACTION *of Altitude*, is an arc of a vertical circle, as AB, by which the altitude of a ftar AC is increafed by the Refraction.



REFRACTION *of Afcenfion and Defcenfion*, is an arc DE of the equator, by which the afcenfion and defcenfion of a ftar, whether right or oblique, is increafed or diminifhed by the Refraction.

REFRACTION *of Declination*, is an arc BF of a circle of declination, by which the declination of a ftar DA or EF is increafed or diminifhed by Refraction.

REFRACTION *of Latitude* is an arc AG of a circle of latitude, by which the latitude of a ftar AH is increafed or diminifhed by the Refraction.

REFRACTION *of Longitude* is an arc IH of the ecliptic, by which the longitude of a ftar is increafed or diminifhed by means of the Refraction.

Terreftrial REFRACTION, is that by which terreftrial objects appear to be raifed higher than they really are, in obferving their altitudes. The quantity of this Refraction is eftimated by Dr. Mafkelyne at one-tenth of the diftance of the object obferved, expreffed in degrees of a great circle. So, if the diftance be 10000 fathoms, its 10th part 1000 fathoms, is the 60th part of a degree of a great circle on the earth, or 1′, which therefore is the Refraction in the altitude of the object at that diftance. (Requifite Tables, 1766, pa. 134).

But M. Le Gendre is induced, he fays, by feveral experiments, to allow only $\frac{1}{14}$th part of the diftance for the Refraction in altitude. So that, upon the diftance of 10000 fathoms, the 14th part of which is 714 fathoms, he allows only 44″ of terreftrial Refraction, fo many being contained in the 714 fathoms. See his Memoir concerning the Trigonometrical operations, &c.

Again, M. de Lambre, an ingenious French aftronomer, makes the quantity of the Terreftrial Refraction to be the 11th part of the arch of diftance. But the Englifh meafurers, Col. Edw. Williams, Capt. Mudge, and Mr. Dalby, from a multitude of exact obfervations made by them, determine the quantity of the medium Refraction to be the 12th part of the faid diftance.

The quantity of this Refraction, however, is found to vary confiderably, with the different ftates of the weather and atmofphere, from the 15th part of the diftance, to the 9th part of the fame; the medium of which is the 12th part, as above mentioned.

Some whimfical effects of this Refraction are alfo related, arifing from peculiar fituations and circumftances. Thus, it is faid, any perfon ftanding by the fide of the river Thames at Greenwich, when it is high-

water

L

water there, he can see the cattle grazing on the Isle of Dogs, which is the marshy meadow on the other side of the river at that place; but when it is low-water there, he cannot see any thing of them, as they are hid from his view by the land wall or bank on the other side, which is raised higher than the marsh, to keep out the waters of the river. This curious effect is probably owing to the moist and dense vapours, just above and rising from the surface of the water, being raised higher or lifted up with the surface of the water at the time of high tide, through which the rays pass, and are the more refracted.

Again, a similar instance is related in a letter to me, from an ingenious friend, Mr. Abr. Crocker of Frome in Somersetshire, dated January 12, 1795. "My Devonshire friend," says he, (whose seat is in the vicinity of the town of Modbury, 12 miles in a geographical line from Maker tower near Plymouth) "being on a pleasure spot in his garden, on the 4th of December 1793, with some friends, viewing the surrounding country, with an achromatic telescope, descried an object like a perpendicular pole standing up in the chasm of a hedge which bounded their view at about 9 miles distance; which, from its direction, was conjectured to be the flagstaff on Maker tower.—Directing the glass, on the morning of the next day, to the same part of the horizon, a flag was perceived on the pole; which corroborated the conjecture of the preceding day. This day's view also discovered the pinnacles and part of the shaft of the tower.—Viewing the same spot at 8 in the morning on the 9th of January 1794, the whole tower and part of the roof of the church, with other remote objects not before noticed, became visible.

"It is necessary to give you the state of the weather there, on those days.

1793.	Barometer.	Thermom.	Wind	
Dec. 4	29'93, rising	36 0	N. E.	Frosty morning, a mist over the land below.
5	29'97, rising	35'2	W.	Ditto.
1794.				
Jan. 9	30'01, falling	29'8	W.	Hard white frost, a fog over the lowlands; clear in the surrounding country.

"The singularity of this phenomenon has occasioned repeated observations on it; from all which it appears that the summer season, and wet windy weather, are unfavourable to this refracted elevation; but that calm frosty weather, with the absence of the sun, are favourable to it.

"From hence a question arises; what is the principal or most general cause of atmospheric Refraction, which produces such extraordinary appearances?"

The following is also a copy of a letter to Mr. Crocker on this curious phenomenon, from his friend above mentioned, viz, Mr. John Andrews, of Traine, near Modbury, dated the 1st of February 1795.

"My good Friend,

"Finding, by your favour of last Sunday, the proceedings which are going on in respect to my observations on the phenomenon of *Looming*, I have thought it necessary to bestow about half this day in preparing, what I am obliged to call, in my way, *drawings*, illustrative of those observations.—I have endeavoured to distinguish, by different tints and shades, the grounds which lie nearer or more remote; but this will perhaps be better explained by the letters of reference, which I have inserted as they may be serviceable in future correspondence.—I believe the drawings, rough as they are, give a tolerably exact representation of the scenes: they may be properly copied to send to London by one of your ingenious sons.—I have been attentive in my observations, or rather in looking out for observations, during the late hard frosts, which you will be surprised to learn, have (except on one or two days) been very unpropitious to the phenomenon; but they have compensated for that disappointment, by a discovery, that a dry frost, though ever so intense, has no tendency to produce it. A hoar frost, or that kind of dewy vapour which, in a sufficient degree of cold, occasions a hoar frost, appears essentially necessary. This took place pretty favourably on the 6th of January, when the elevation was equal to that represented in the third drawing (*see plate* 25, *fig.* 3), much like what it was on the 9th of January 1794, and confirmed me as to the certainty of some peculiar appearances, hinted at in my letter of the 14th of that month, but not there described. What I allude to, was a fluctuating appearance of two horizons, one above the other, with a complete vacancy between them, exactly like what may be often observed looking through an uneven pane of glass. Divers instances of this were seen by my brother and myself on the 6th of last January; continually varying and intermitting, but not rapidly, so that they were capable of distinct observation.—Till that day I had formed, as I thought, a plausible theory, to account for, as well this latter, as all the other phenomena; but now, unless my imagination deceives me, I am left in impenetrable darkness. The vacant line of separation, you will take notice, would often increase so much in breadth, as to efface entirely the upper of the two horizons; forming then a kind of dent or gap in the remaining horizon, which horizon at the places contiguous to the extremities of the vacancy, seemed of the same height as the upper horizon was, before effaced. This vacancy was several times seen to approach and take in the tower, and immediately to admit a view of the whole or most part of its body (like that in the third drawing) which was not the case before: exactly, to all appearance, as if it had opened a gap for that purpose in the intercepted ground.—It remains therefore to be determined by future observations, whether the separation is effected by an elevation of the upper, or depression of the lower horizon; and if the latter, why the vacancy does not cause the tower to disappear, as well as the intervening ground?—As an opportunity for this purpose may not soon occur, I hope you will not wait for it, in your communications to him who is, Dear Sir, yours very truly,

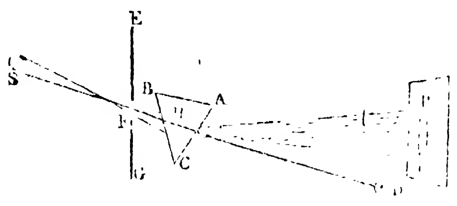
John Andrews."

See the representations in plate 25, of the appearances, in three different states of the atmosphere, with the explanations of them.

REFRAN-

REFRANGIBILITY *of Light*, the difpofition of the rays to be refracted. And a greater or lefs Refrangibility, is a difpofition to be more or lefs refracted, in paffing at equal angles of incidence into the fame medium.

That the rays of light are differently refrangible, is the foundation of Newton's whole theory of light and colours; and the truth and circumftances of the principle he evinced from fuch experiments as the following.



Let EG reprefent the window-fhutter of a dark room, and F a hole in it, through which the light paffes, from the luminous object S, to the glafs prifm ABC within the room, which refracts it towards the oppofite fide, or a fcreen, at PT, where it appears of an oblong form; its length being about five times the breadth, and exhibiting the various colours of the rainbow; whereas without the interpofition of the prifm, the ray of light would have proceeded on in its firft direction to D. Hence then it follows,

1. That the rays of light are refrangible. This appears by the ray being refracted from its original direction SHD, into another one, HP or HT, by paffing through a different medium.

2. That the ray SFH is a compound one, which, by means of the prifm, is decompounded or feparated into its parts, HP, HT, &c, which it hence appears are all endued with different degrees of Refrangibility, as they are tranfmitted to all the intermediate points from T to P, and there painting all the different colours.

From this, and a great variety of other experiments, Newton proved, that the blue rays are more refracted than the red ones, and that there is likewife unequal refraction in the intermediate rays; and upon the whole it appears that the fun's rays have not all the fame Refrangibility, and confequently are not of the fame nature. It is alfo obferved that thofe rays which are moft refrangible, are alfo moft reflexible. See Reflexibility; alfo Newton's Optics, pa. 22 &c, 3d edit.

The difference between Refrangibility and reflexibility was firft difcovered by Sir Ifaac Newton, in 1671-2, and communicated to the Royal Society, in a letter dated Feb. 6 of that year, which was publifhed in the Philof. Tranf. numb. 80, pa. 3075; and from that time it was vindicated by him, from the objections of feveral authors; particularly Pardies, Mariotte, Lucas or Lin, and other gentlemen of the Englifh college at Liege; and at length it was more fully laid down, illuftrated, and confirmed, by a great variety of experiments, in his excellent treatife on Optics.

But farther, as not only thefe colours of light produced by refraction in a prifm, but alfo thofe reflected from opaque bodies, have their different degrees of Refrangibility and reflexibility; and as a white light arifes from a mixture of the feveral coloured rays together, the fame great author concluded that all homogeneous light has its proper colour, correfponding to its degree of Refrangibility, and not capable of being changed by any reflexions, or any refractions; that the fun's light is compofed of all the primary colours; and that all compound colours arife from the mixture of the primary ones, &c.

The different degrees of Refrangibility, he conjectures to arife from the different magnitude of the particles compofing the different rays. Thus, the moft refrangible rays, that is the red ones, he fuppofes may confift of the largeft particles; the leaft refrangible, i. e. the violet rays, of the fmalleft particles; and the intermediate rays, yellow, green, and blue, of particles of intermediate fizes. See Colour.

For the method of correcting the effect of the different Refrangibility of the rays of light in glaffes, fee Aberration and Telescope.

REGEL, or Rigel, a fixed ftar of the firft magnitude, in the left foot of Orion.

REGIOMONTANUS. See *John* Muller.

REGION, of the Air or Atmofphere. Authors divide the atmofphere into three ftages, called the upper, middle, and lower Regions.—The loweft Region is that in which we breathe, and is bounded by the reflexion of the fun's rays, that is, by the height to which they rebound from the earth.—The middle Region is that in which the clouds refide, and where meteors are formed, &c; extending from the extremity of the loweft, to the tops of the higheft mountains.—The upper Region commences from the tops of the mountains, and reaches to the utmoft limits of the atmofphere. In this Region there probably reigns a perpetual equable calmnefs, clearnefs, and ferenity.

Elementary Region, according to the Ariftotelians, is a fphere terminated by the concavity of the moon's orb, comprehending the earth's atmofphere.

Ethereal Region, is the whole extent of the univerfe, comprifing all the heavens with the orbs of the fixed ftars and other celeftial bodies.

Region, in Geography, a country or particular divifion of the earth, or a tract of land inhabited by people of the fame nation.

Regions *of the Moon*. Modern aftronomers divide the moon into feveral Regions, or provinces, to each of which they give its proper name.

Regions *of the Sea*, are the two parts into which the whole depth of the fea is conceived to be divided. The upper of thefe extends from the furface of the water, down as low as the rays of the fun penetrate, and extend their influence; and the lower Region extends from thence to the bottom of the fea.

Subterranean Regions. Thefe are three, into which the earth is divided, at different depths below the furface, according to different degrees of cold or warmth; and it is imagined that the 2d or middlemoft of thefe Regions is the coldeft of the three.

REGIS (Peter Sylvain), a French philofopher, and great propagator of Cartefianifm, was born in Agenois 1632.

He ftudied the languages and philofophy under the

Jesuits at Cahors, and afterwards divinity in the university of that town, being designed for the church. His progress in learning was so uncommon, that at the end of four years he was offered a doctor's degree without the usual charges; but he did not think it became him till he should study also in the Sorbonne at Paris. He accordingly repaired to the capital for that purpose; but he soon became disgusted with theology; and, as the philosophy of Des Cartes began at that time to make a noise through the lectures of Rohault, he conceived a taste for it, and gave himself up entirely to it.

Having, by attending those lectures, and by close study, become an adept in that philosophy, he went to Toulouse in 1665, where he set up lectures in it himself. Having a clear and fluent manner, and a happy way of explaining his subject, he drew all sorts of people to his discourses; the magistrates, the literati, the ecclesiastics, and the very women, who all now affected to renounce the ancient philosophy.

In 1671, he received at Montpellier the same applauses for his lectures as at Toulouse. Finally, in 1680 he returned to Paris; where the concourse about him was such, that the sticklers for Peripateticism began to be alarmed. These applying to the archbishop of Paris, he thought it expedient, in the name of the king, to put a stop to the lectures; which accordingly were discontinued for several months. Afterwards his whole life was spent in propagating the new philosophy, both by lectures, and by publishing books. In defence of his system, he had disputes with Huet, Du Hamel, Malbranche, and others. His works, though abounding with ingenuity and learning, have been neglected in consequence of the great discoveries and advancement in philosophic knowledge that has been since made.—He was chosen a member of the Academy of Sciences in 1699; and died in 1707, at 75 years of age.

His works, which he published, are,

1. *A System of Philosophy;* containing Logic, Metaphysics, and Morals; in 1690, 3 vols in 4to. being a compilation of the different ideas of Des Cartes.—It was reprinted the year after at Amsterdam, with the addition of a Discourse upon Ancient and Modern Philosophy.

2. *The Use of Reason and of Faith.*

3. An Answer to Huet's Censures of the Cartesian Philosophy; and an Answer to Du Hamel's Critical Reflections.

4. Some pieces against Malbranche, to shew that the apparent magnitude of an object depends solely on the magnitude of its image, traced on the retina.

5. A small piece upon the question, Whether Pleasure makes our present happiness?

REGRESSION, or RETROGRADATION *of Curves*, &c. See RETROGRADATION.

REGULAR *Figure*, in Geometry, is a figure that is both equilateral and equiangular, or having all its sides and angles equal to one another.

For the dimensions, properties, &c, of regular figures, see POLYGON.

REGULAR *Body*, called also *Platonic Body*, is a body or solid comprehended by like, equal, and regular plane figures, and whose solid angles are all equal.

The plane figures by which the solid is contained, are the faces of the solid. And the sides of the plane figures are the edges, or linear sides of the solid.

There are only five Regular Solids, viz,

The tetraedron, or regular triangular pyramid, having 4 triangular faces;

The hexaedron, or cube, having 6 square faces;

The octaedron, having 8 triangular faces;

The dodecaedron, having 12 pentagonal faces;

The icosaedron, having 20 triangular faces.

Besides these five, there can be no other Regular Bodies in nature.

PROB. 1. *To construct or form the Regular Solids.*—See the method of describing these figures under the article BODY.

2. *To find either the Surface or the Solid Content of any of the Regular Bodies.*—Multiply the proper tabular area or surface (taken from the following Table) by the square of the linear edge of the solid, for the superficies. And

Multiply the tabular solidity, in the last column of the Table, by the cube of the linear edge, for the solid content.

Surfaces and Solidities of Regular Bodies, the side being unity or 1.

No. of sides.	Name.	Surface.	Solidity.
4	Tetraedron	1·7320508	0·1178513
6	Hexaedron	6·0000000	1·0000000
8	Octaedron	3·4641016	0·4714045
12	Dodecaedron	20·6457788	7·6631189
20	Icosaedron	8·6602540	2·1816950

3. The Diameter of a Sphere being given, to find the side of any of the Platonic bodies, that may be either inscribed in the sphere, or circumscribed about the sphere, or that is equal to the sphere.

Multiply the given diameter of the sphere by the proper or corresponding number, in the following Table, answering to the thing sought, and the product will be the side of the Platonic body required.

The diam. of a sphere being 1, the side of a	That may be inscribed in the sphere, is	That may be circumscribed about the sphere, is	That is equal to the sphere, is
Tetraedron	0·816497	2·44948	1·64417
Hexaedron	0·577350	1·00000	0·88610
Octaedron	0·707107	1·22474	1·03576
Dodecaedron	0·525731	0·66158	0·62153
Icosaedron	0·356822	0·44903	0·40883

4. The side of any of the five Platonic bodies being given, to find the diameter of a sphere, that may either be inscribed in that body, or circumscribed about it, or that is equal to it.—As the respective number in the Table above, under the title, *inscribed*, *circumscribed*, or *equal*, is to 1, so is the side of the given Platonic body,

body, to the diameter of its inscribed, circumscribed, or equal sphere.

5. The side of any one of the five Platonic bodies being given; to find the side of any of the other four bodies, that may be equal in solidity to that of the given body.—As the number under the title *equal* in the last column of the table above, against the given Platonic body, is to the number under the same title, against the body whose side is sought, so is the side of the given Platonic body, to the side of the body sought.

See demonstrations of many other properties of the Platonic bodies, in my Mensuration, part 3 sect. 2 pa. 249, &c, 2d edition.

REGULAR *Curve*. See CURVE.

REGULATOR *of a Watch*, is a small spring belonging to the balance, serving to adjust the going, and to make it go either faster or slower.

REGULUS, in Astronomy, a star of the first magnitude, in the constellation Leo; called also, from its situation, *Cor Leonis*, or the *Lion's Heart*; by the Arabs, *Alhabor*; and by the Chaldeans, *Kalbeleced*, or *Karbeleced*; from an opinion of its influencing the affairs of the heavens; as Theon observes.

The longitude of Regulus, as fixed by Flamsteed, is 25° 31′ 21″, and its latitude 0° 26′ 38″ north. See LEO.

REINFORCE, in Gunnery, is that part of a gun next the breech, which is made stronger to resist the force of the powder. There are usually two Reinforces in each piece, called the first and second Reinforce. The second is somewhat smaller than the first, because the inflamed powder in that part is less strong.

REINFORCE *Rings* of a cannon, are flat mouldings, like iron hoops, placed at the breech end of the first and second Reinforce, projecting beyond the rest of the metal about a quarter of an inch.

REINHOLD (ERASMUS), an eminent astronomer and mathematician, was born at Salfeldt in Thuringia, a province in Upper Saxony, the 11th of October 1511. He studied mathematics under James Milichi at Wittemberg, in which university he afterwards became professor of those sciences, which he taught with great applause. After writing a number of useful and learned works, he died the 19th of February 1553, at 42 years of age only. His writings are chiefly the following:

1. *Theoriæ novæ Planetarum G. Purbachii*, augmented and illustrated wirh diagrams and Scholia in 8vo, 1542; and again in 1580.—In this work, among other things worthy of notice, he teaches (pa. 75 and 76) that the centre of the lunar epicycle describes an *oval figure* in each monthly period, and that the orbit of Mercury is also of the same oval figure.

2. *Ptolomy's Almagest*, the first book, in Greek, with a Latin version, and Scholia, explaining the more obscure passages; in 8vo, 1549.—At the end of pa. 123 he promises an edition of Theon's Commentaries, which are very useful for understanding Ptolomy's meaning; but his immature death prevented Reinhold from giving this and other works which he had projected.

3. *Prutenicæ Tabulæ Cœlestium Motuum*, in 4to, 1551; again in 1571; and also in 1585.—Reinhold spent seven years labour upon this work, in which he was assisted by the munificence of Albert, duke of Prussia, from whence the tables had their name. Reinhold compared the observations of Copernicus with those of Ptolomy and Hipparchus, from whence he constructed these new tables, the uses of which he has fully explained in a great number of precepts and canons, forming a complete introduction to practical astronomy.

4. *Primus liber Tabularum Directionum*; to which are added, the *Canon Fœcundus*, or Table of Tangents, to every minute of the quadrant; and New Tables of Climates, Parallels and Shadows, with an Appendix containing the second Book of the Canon of Directions; in 4to, 1554.—Reinhold here supplies what was omitted by Regiomontanus in his Table of Directions, &c; shewing the finding of the sines, and the construction of the tangents, the sines being found to every minute of the quadrant, to the radius 10,000,000; and he produced the Oblique Ascensions from 60 degrees to the end of the quadrant. He teaches also the use of these tables in the solution of spherical problems.

Reinhold prepared likewise an edition of many other works, which are enumerated in the Emperor's Privilege, prefixed to the Prutenic Tables. Namely, Ephemerides for several years to come, computed from the new tables. Tables of the Rising and Setting of several Fixed Stars, for many different climates and times. The illustration and establishment of Chronology, by the eclipses of the luminaries, and the great conjunctions of the planets, and by the appearance of comets, &c. The Ecclesiastical Calendar. The History of Years, or Astronomical Calendar. *Isagoge Spherica*, or Elements of the Doctrine of the Primum Mobile. *Hypotyposes Orbium Cœlestium*, or the Theory of Planets. Construction of a New Quadrant. The Doctrine of Plane and Spherical Triangles. Commentaries on the work of Copernicus. Also Commentaries on the 15 books of Euclid, on Ptolomy's Geography, and on the Optics of Alhazen the Arabian.—Reinhold also made Astronomical Observations, but with a wooden quadrant, which observations were seen by Tycho Brahe when he passed through Wittemberg in the year 1575, who wondered that so great a cultivator of astronomy was not furnished with better instruments.

Reinhold left a son, named also Erasmus after himself, an eminent mathematician and physician at Salfeldt. He wrote a small work in the German language, on Subterranean Geometry, printed in 4to at Erfurt 1575.—He wrote also concerning the New Star which appeared in Cassiopeia in the year 1572; with an Astrological Prognostication, published in 1574, in the German language.

RELAIS, in Fortification, a French term, the same with berme.

RELATION, in Mathematics, is the habitude or respect of quantities of the same kind to each other, with regard to their magnitude; more usually called *ratio*.—And the equality, identity, or sameness of two such Relations, is called proportion.

RELATION, *Inharmonical*, in Musical Composition, is

is that whose extremes form a false or unnatural interval, incapable of being sung.—This is otherwise called a *false Relation*, and stands opposed to a just or true one.

RELATIVE *Gravity*, *Levity*, *Motion*, *Necessity*, *Place*, *Space*, *Time*, *Velocity*, &c. See the several substantives.

RELIEVO, in Architecture, denotes the sally or projecture of any ornament.

REMAINDER, is the difference between two quantities, or that which is left after subtracting one from the other.

RENDERING, in Building. See PARGETING.

REPELLING *Power*, in Physics, is a certain power or faculty, residing in the minute particles of natural bodies, by which, under certain circumstances, they mutually fly from each other. This is the reverse or opposite of the attractive power. Newton shews, from observation, that such a force does really exist; and he argues, that as in algebra, where positive quantities cease, there negative ones begin; so in physics, where the attractive force ceases, there a Repelling force must begin.

As the Repelling power seems to arise from the same principle as the attractive, only exercised under different circumstances, it is governed by the same laws. Now the attractive power we find is stronger in small bodies, than in great ones, in proportion to the masses; therefore the Repelling is so too. But the rays of light are the most minute bodies we know of; and therefore their Repelling force must be the greatest. It is computed by Newton, that the attractive force of the rays of light is above 1000000000000000, or one thousand million of millions of times stronger than the force of gravity on the surface of the earth: hence arises that inconceivable velocity with which light must move to reach from the sun to the earth in little more than 7 minutes of time. For the rays emitted from the body of the sun, by the vibrating motion of its parts, are no sooner got without the sphere of attraction of the sun, than they come within the action of the Repelling power.

The elasticity or springiness of bodies, or that property by which, after having their figure altered by an external force, they return to their former shape again, follows from the Repelling power. See REPULSION.

REPERCUSSION. See REFLECTION.

REPETEND, in Arithmetic, denotes that part of an infinite decimal fraction, which is continually repeated ad infinitum. Thus in the numbers 2·13 13 13 &c. the figures 13 are the Repetend, and marked thus $\dot{1}\dot{3}$.

These Repetends chiefly arise in the reduction of vulgar fractions to decimals. Thus, $\frac{1}{3} = 0{\cdot}333$ &c $= 0{\cdot}\dot{3}$; and $\frac{1}{6} = 0{\cdot}1666$ &c $= 0{\cdot}1\dot{6}$; and $\frac{1}{7} = 0{\cdot}142857\ 142857$ &c $= 0{\cdot}\dot{1}4285\dot{7}$. Where it is to be observed, that a point is set over the figure of a single Repetend, and a point over the first and last figure when there are several that repeat.

Repetends are either *single* or *compound*.

A *Single* REPETEND is that in which only one figure repeats; as $0{\cdot}\dot{3}$, or $0{\cdot}\dot{6}$, &c.

A *Compound* REPETEND, is that in which two or more figures are repeated; as $\cdot\dot{1}\dot{3}$, or $\cdot\dot{2}1\dot{5}$, or $\cdot\dot{1}4285\dot{7}$, &c.

Similar REPETENDS are such as begin at the same place, and consist of the same number of figures: as $\cdot\dot{3}$ and $\cdot\dot{6}$, or $1{\cdot}\dot{3}4\dot{1}$ and $2{\cdot}\dot{1}5\dot{6}$.

Dissimilar REPETENDS begin at different places, and consist of an unequal number of figures.

To find the finite Value of any Repetend, or to reduce it to a Vulgar Fraction. Take the given repeating figure or figures for the numerator; and for the denominator, take as many 9's as there are recurring figures or places in the given Repetend.

So $\cdot\dot{3} = \frac{3}{9} = \frac{1}{3}$; and $\cdot0\dot{5} = \cdot0\frac{5}{9} = \frac{5}{90} = \frac{1}{18}$;

and $\cdot\dot{1}2\dot{3} = \frac{123}{999} = \frac{41}{333}$; and $2{\cdot}\dot{6}\dot{3} = 2\frac{63}{99} = 2\frac{7}{11}$;

and $\cdot0\dot{5}9440\dot{5} = \frac{594405}{9999990} = \frac{17}{280}$;

and $\cdot\dot{7}6923\dot{0} = \frac{769230}{999999} = \frac{10}{13}$.

Hence it follows, that every such infinite Repetend has a certain determinate and finite value, or can be expressed by a terminate vulgar fraction. And consequently, that an infinite decimal which does not repeat or circulate, cannot be completely expressed by a finite vulgar fraction.

It may farther be observed, that if the numerator of a vulgar fraction be 1, and the denominator any prime number, except 2 and 5, the decimal which shall be equal to that vulgar fraction, will always be a Repetend, beginning at the first place of decimals; and this Repetend must necessarily be a submultiple, or an aliquot part of a number expressed by as many 9's as the Repetend has figures; that is, if the Repetend have six figures, it will be a submultiple of 999999; if four figures, a submultiple of 9999 &c. From whence it follows, that if any prime number be called p, the series 9999 &c, produced as far as is necessary, will always be divisible by p, and the quotient will be the Repetend of the decimal fraction $= \frac{1}{p}$.

RESIDUAL *Figure*, in Geometry, the figure remaining after subtracting a less from a greater.

RESIDUAL *Root*, is a root composed of two parts or members, only connected together with the sign $-$ or minus. Thus, $a-b$, or $5-3$, is a residual root; and is so called, because its true value is no more than the residue, or difference between the parts a and b, or 5 and 3, which in this case is 2.

RESIDUUM *of a Charge*, in Electricity, first discovered by Mr. Gralath, in Germany, in 1746, is that part of the charge that lay on the uncoated part of a Leyden phial, which does not part with all its electricity at once; so that it is afterwards gradually diffused to the coating.

RESISTANCE, or RESISTING *Force*, in Physics, any power which acts in opposition to another, so as to destroy or diminish its effect.

There

There are various kinds of Resistance, arising from the various natures and properties of the resisting bodies, and governed by various laws: as, the Resistance of solids, the Resistance of fluids, the Resistance of the air, &c. Of each of these in their order, as below.

Resistance *of Solids*, in Mechanics, is the force with which the quiescent parts of solid bodies oppose the motion of others contiguous to them.

Of these, there are two kinds. The first where the resisting and the resisted parts, i. e the moving and quiescent bodies, are only contiguous, and do not cohere; constituting separate bodies or masses. This Resistance is what Leibnitz calls *Resistance of the surface*, but which is more properly called *friction*: for the laws of which, see the article Friction.

The second case of Resistance, is where the resisting and resisted parts are not only contiguous, but cohere, being parts of the same continued body or mass. This Resistance was first considered by Galileo, and may properly be called *tenacity*.

As to what regards the Resistance of bodies when struck by others in motion, see Percussion, and Collision.

Theory of the Resistance of the Fibres of Solid Bodies.—To conceive an idea of this Resistance, or tenacity of the parts, suppose a cylindrical body suspended vertically by one end. Here all its parts, being heavy, tend downwards, and endeavour to separate the two contiguous planes or surfaces where the body is the weakest; but all the parts of them resist this separation by the force with which they cohere, or are bound together. Here then are two opposite powers; viz, the weight of the cylinder, which tends to break it; and the force of cohesion of the parts, which resists the fracture.

If now the base of the cylinder be increased, without increasing its length; it is evident that both the Resistance and the weight will be increased in the same ratio as the base; and hence it appears that all cylinders of the same matter and length, whatever their bases be, have an equal Resistance, when vertically suspended.

But if the length of the cylinder be increased, without increasing its base, its weight is increased, while the Resistance or strength continues unaltered; consequently the lengthening has the effect of weakening it, or increases its tendency to break.

Hence to find the greatest length a cylinder of any matter may have, when it just breaks with the addition of another given weight, we need only take any cylinder of the same matter, and fasten to it the least weight that is just sufficient to break it; and then consider how much it must be lengthened, so that the weight of the part added, together with the given weight, may be just equal to that weight, and the thing is done. Thus, let l denote the first length of the cylinder, c its weight, g the given weight the lengthened cylinder is to bear, and w the least weight that breaks the cylinder l, also x the length sought;

then as $l : x :: c : \frac{cx}{l} =$ the weight of the longest cylinder sought; and this, together with the given weight g, must be equal to c together with the weight w; hence then

$\frac{cx}{l} + g = c + w$; therefore $x = \frac{c + w - g}{c} l =$ the whole length of the cylinder sought. If the cylinder must just break with its own weight, then is $g = 0$, and in that case $x = \frac{c + w}{c} l$ is the whole length that just breaks by its own weight. By this means Galileo found that a copper wire, and of consequence any other cylinder of copper, might be extended to 4801 braccios or fathoms of 6 feet each.

If the cylinder be fixed by one end into a wall, with the axis horizontally; the force to break it, and its Resistance to fracture, will here be both different; as both the weight to cause the fracture, and the Resistance of the fibres to oppose it, are combined with the effects of the lever; for the weight to cause the fracture, whether of the weight of the beam alone, or combined with an additional weight hung to it, is to be supposed collected into the centre of gravity, where it is considered as acting by a lever equal to the distance of that centre beyond the face of the wall where the cylinder or other prism is fixed; and then the product of the said whole weight and distance, will be the momentum or force to break the prism. Again, the Resistance of the fibres may be supposed collected into the centre of the transverse section, and all acting there at the end of a lever equal to the vertical semidiameter of the section, the lowest point of that diameter being immoveable, and about which the whole diameter turns when the prism breaks; and hence the product of the adhesive force of the fibres multiplied by the said semidiameter, will be the momentum of Resistance, and must be equal to the former momentum when the prism just breaks.

Hence, to find the length a prism will bear, fixed so horizontally, before it breaks, either by its own weight, or by the addition of any adventitious weight; take any length of such a prism, and load it with weights till it just break. Then, put

$l =$ the length of this prism,
$c =$ its weight,
$w =$ the weight that breaks it,
$a =$ distance of weight w,
$g =$ any given weight to be borne,
$d =$ its distance,
$x =$ the length required to break.

Then $l : x :: c : \frac{cx}{l}$ the weight of the prism x, and $\frac{cx}{l} \times \frac{1}{2} x = \frac{cx^2}{2l} =$ its momentum; also $dg =$ the momentum of the weight g; therefore $\frac{cx^2}{2l} + dg$ is the momentum of the prism x and its added weight. In like manner $\frac{1}{2}cl + aw$ is that of the former or short prism and the weight that brake it; consequently $\frac{cx^2}{2l} + dg = \frac{1}{2}cl + aw$, and $x = \sqrt{\frac{aw + \frac{1}{2}cl - dg}{c} \times 2l}$ is the length sought, that just

breaks

breaks with the weight g at the diſtance d. If this weight g be nothing, then $x = \sqrt{\frac{aw + \frac{1}{2}cl}{c}} \times 2l$ is the length of the priſm that juſt breaks with its own weight.

If two priſms of the ſame matter, having their baſes and lengths in the ſame proportion, be ſuſpended horizontally; it is evident that the greater has more weight than the leſſer, both on account of its length, and of its baſe; but it has leſs Reſiſtance on account of its length, conſidered as a longer arm of a lever, and has only more Reſiſtance on account of its baſe; therefore it exceeds the leſſer in its momentum more than it does in its Reſiſtance, and conſequently it muſt break more eaſily.

Hence appears the reaſon why, in making ſmall machines and models, people are apt to be miſtaken as to the Reſiſtance and ſtrength of certain horizontal pieces, when they come to execute their deſigns in large, by obſerving the ſame proportions as in the ſmall.

When the priſm, fixed vertically, is juſt about to break, there is an equilibrium between its poſitive and relative weight; and conſequently thoſe two oppoſite powers are to each other reciprocally as the arms of the lever to which they are applied, that is, as half the diameter to half the axis of the priſm. On the other hand, the Reſiſtance of a body is always equal to the greateſt weight which it will juſt ſuſtain in a vertical poſition, that is, to its abſolute weight. Therefore, ſubſtituting the abſolute weight for the Reſiſtance, it appears, that the abſolute weight of a body, ſuſpended horizontally, is to its relative weight, as the diſtance of its centre of gravity from the fixed point or axis of motion, is to the diſtance of the centre of gravity of its baſe from the ſame.

The diſcovery of this important truth, at leaſt of an equivalent to it, and to which this is reducible, we owe to Galileo. On this ſyſtem of Reſiſtance of that author, Mariotte made an ingenious remark, which gave birth to a new ſyſtem. Galileo ſuppoſes that where the body breaks, all the fibres break at once; ſo that the body always reſiſts with its whole abſolute force, or the whole force that all its fibres have in the place where it breaks. But Mariotte, finding that all bodies, even glaſs itſelf, bend before they break, ſhews that fibres are to be conſidered as ſo many little bent ſprings, which never exert their whole force, till ſtretched to a certain point, and never break till entirely unbent. Hence thoſe neareſt the fulcrum of the lever, or loweſt point of the fracture, are ſtretched leſs than thoſe farther off, and conſequently employ a leſs part of their force, and break later.

This conſideration only takes place in the horizontal ſituation of the body: in the vertical, the fibres of the baſe all break at once; ſo that the abſolute weight of the body muſt exceed the united Reſiſtance of all its fibres; a greater weight is therefore required here than in the horizontal ſituation, that is, a greater weight is required to overcome their united Reſiſtance, than to overcome their ſeveral Reſiſtances one after another.

Varignon has improved on the ſyſtem of Mariotte, and ſhewn that to Galileo's ſyſtem, it adds the conſideration of the centre of percuſſion. In each ſyſtem, the ſection, where the body breaks, moves on the axis of equilibrium, or line at the lower extremity of the ſame ſection; but in the ſecond, the fibres of this ſection are continually ſtretching more and more, and that in the ſame ratio, as they are ſituated farther and farther from the axis of equilibrium, and conſequently are ſtill exerting a greater and greater part of their whole force.

Theſe unequal extenſions, like all other forces, muſt have ſome common centre where they are united, making equal efforts on each ſide of it; and as they are preciſely in the ſame proportion as the velocities which the ſeveral points of a rod moved circularly would have to one another, the centre of extenſion of the ſection where the body breaks, muſt be the ſame as its centre of percuſſion. Galileo's hypotheſis, where fibres ſtretch equally, and break all at once, correſponds to the caſe of a rod moving parallel to itſelf, where the centre of extenſion or percuſſion does not appear, as being confounded with the centre of gravity.

Hence it follows, that the Reſiſtance of bodies in Mariotte's ſyſtem, is to that in Galileo's, as the diſtance of the centre of percuſſion, taken on the vertical diameter of the fracture, is to the whole of that diameter. Hence alſo, the Reſiſtance being leſs than what Galileo imagined, the relative weight muſt alſo be leſs, and in the ratio juſt mentioned. So that, after conceiving the relative weight of a body, and its Reſiſtance equal to its abſolute weight, as two contrary powers applied to the two arms of a lever, in the hypotheſis of Galileo, there needs nothing to change it into that of Mariotte, but to imagine that the Reſiſtance, or the abſolute weight, is become leſs, in the ratio above mentioned, every thing elſe remaining the ſame.

One of the moſt curious, and perhaps the moſt uſeful queſtions in this reſearch, is to find what figure a body muſt have, that its Reſiſtance may be equal or proportional in every part to the force tending to break it. Now to this end, it is neceſſary, ſome part of it being conceived as cut off by a plane parallel to the fracture, that the momentum of the part retrenched be to its Reſiſtance, in the ſame ratio as the momentum of the whole is to its Reſiſtance; theſe four powers acting by arms of levers peculiar to themſelves, and are proportional in the whole, and in each part, of a ſolid of equal Reſiſtance. From this proportion, Varignon eaſily deduces two ſolids, which ſhall reſiſt equally in all their parts, or be no more liable to break in one part than in another: Galileo had found one before. That diſcovered by Varignon is in the form of a trumpet, and is to be fixed into a wall at its greater end; ſo that its magnitude or weight is always diminiſhed in proportion as its length, or the arm of the lever by which its weight acts, is increaſed. It is remarkable that, howſoever different the two ſyſtems may be, the ſolids of equal Reſiſtance are the ſame in both.

For the Reſiſtance of a ſolid ſupported at each end, as of a beam between two walls, ſee Beam.

Resistance *of Fluids*, is the force with which bodies,

bodies, moving in fluid mediums, are impeded and retarded in their motion.

A body moving in a fluid is resisted from two causes. The first of these is the cohesion of the parts of the fluid. For a body, in its motion, separating the parts of a fluid, must overcome the force with which those parts cohere. The second is the inertia, or inactivity of matter, by which a certain force is required to move the particles from their places, in order to let the body pass.

The retardation from the first cause is always the same in the same space, whatever the velocity be, the body remaining the same; that is, the Resistance is as the space run through, in the same time: but the velocity is also in the same ratio of the space run over in the same time: and therefore the Resistance, from this cause, is as the velocity itself.

The Resistance from the second cause, when a body moves through the same fluid with different velocities, is as the square of the velocity. For, first the Resistance increases according to the number of particles or quantity of the fluid struck in the same time; which number must be as the space run through in that time, that is, as the velocity: but the Resistance also increases in proportion to the force with which the body strikes against every part; which force is also as the velocity of the body, so as to be double with a double velocity, and triple with a triple one, &c: therefore, on both these accounts, the Resistance is as the velocity multiplied by the velocity, or as the square of the velocity. Upon the whole therefore, on account of both causes, viz, the tenacity and inertia of the fluid, the body is resisted partly as the velocity and partly as the square of the velocity.

But when the same body moves through different fluids with the same velocity, the Resistance from the second cause follows the proportion of the matter to be removed in the same time, which is as the density of the fluid.

Hence therefore, if d denote the density of the fluid,
v the velocity of the body,
and a and b constant coefficients:
then $adv^2 + bv$ will be proportional to the whole Resistance to the same body, moving with different velocities, in the same direction, through fluids of different densities, but of the same tenacity.

But, to take in the consideration of different tenacities of fluids; if t denote the tenacity, or the cohesion of the parts of the fluid, then $adv^2 + btv$ will be as the said whole Resistance.

Indeed the quantity of Resistance from the cohesion of the parts of fluids, except in glutinous ones, is very small in respect of the other Resistance; and it also increases in a much lower degree, being only as the velocity, while the other increases as the square of the velocity, and rather more. Hence then the term btv is very small in respect of the other term adv^2; and consequently the Resistance is nearly as this latter term; or nearly as the square of the velocity. Which rule has been employed by most authors, and is very near the truth in slow motions; but in very rapid ones, it differs considerably from the truth, as we shall perceive below; not indeed from the omission of the small term btv, due to the cohesion, but from the want of the full counter pressure on the hinder part of the body, a vacuum, either perfect or partial, being left behind the body in its motion; and also perhaps to some compression or accumulation of the fluid against the fore part of the body. Hence,

To conceive the Resistance of fluids to a body moving in them, we must distinguish between those fluids which, being greatly compressed by some incumbent weight, always close up the space behind the body in motion, without leaving any vacuity there; and those fluids which, not being much compressed, do not quickly fill up the space quitted by the body in motion, but leave a kind of vacuum behind it. These differences, in the resisting fluids, will occasion very remarkable varieties in the laws of their Resistance, and are absolutely necessary to be considered in the determination of the action of the air on shot and shells; for the air partakes of both these affections, according to the different velocities of the projected body.

In treating of these Resistances too, the fluids may be considered either as continued or discontinued, that is, having their particles contiguous or else as separated and unconnected; and also either as elastic or non-elastic. If a fluid were so constituted, that all the particles composing it were at some distance from each other, and having no action between them, then the Resistance of a body moving in it would be easily computed, from the quantity of motion communicated to those particles; for instance, if a cylinder moved in such a fluid in the direction of its axis, it would communicate to the particles it met with, a velocity equal to its own, and in its own direction, when neither the cylinder nor the parts of the fluid are elastic: whence, if the velocity and diameter of the cylinder be known, and also the density of the fluid, there would thence be determined the quantity of motion communicated to the fluid, which (as action and reaction are equal) is the same with the quantity lost by the cylinder, and consequently the Resistance would thus be ascertained.

In this kind of discontinued fluid, the particles being detached from each other, every one of them can pursue its own motion in any direction, at least for some time, independent of the neighbouring ones; so that, instead of a cylinder moving in the direction of its axis, if a body with a surface oblique to its direction be supposed to move in such a fluid, the motion which the parts of the fluid will hence acquire, will not be in the direction of the resisted body, but perpendicular to its oblique surface; whence the Resistance to such a body will not be estimated from the whole motion communicated to the particles of the fluid, but from that part of it only which is in the direction of the resisted body. In fluids then, where the parts are thus discontinued from each other, the different obliquities of that surface which goes foremost, will occasion considerable changes in the Resistance; although the transverse section of the solid should in all cases be the same: And Newton has particularly determined that, in a fluid thus constituted, the Resistance of a globe is but half the Resistance of a cylinder of the same diameter, moving, in the direction of its axis, with the same velocity.

But though the hypothesis of a fluid thus constituted be

be of great use in explaining the nature of Resistances, yet we know of no such fluid existing in nature; all the fluids with which we are conversant being so formed, that their particles either lie contiguous to each other, or at least act on each other in the same manner as if they did: consequently, in these fluids, no one particle that is contiguous to the resisted body, can be moved, without moving at the same time a great number of others, some of which will be distant from it; and the motion thus communicated to a mass of the fluid, will not be in any one determined direction, but different in all the particles, according to the different positions in which they lie in contact with those from which they receive their impulse; whence, great numbers of the particles being diverted into oblique directions, the Resistance of the moving body, which will depend on the quantity of motion communicated to the fluid in its own direction, will be different in quantity from what it would be in the foregoing supposition, and its estimation becomes much more complicated and operose.

If the fluid be compressed by the incumbent weight of its upper parts (as all fluids are with us, except at their very surface), and if the velocity of the moving body be much less than that with which the parts of the fluid would rush into a void space, in consequence of their compression; it is evident, that in this case the space left by the moving body will be instantaneously filled up by the fluid; and the parts of the fluid against which the foremost part of the body presses in its motion, will, instead of being impelled forwards in the direction of the body, in some measure circulate towards the hinder part of the body, in order to restore the equilibrium, which the constant influx of the fluid behind the body would otherwise destroy; whence the progressive motion of the fluid, and consequently the Resistance of the body, which depends upon it, would in this instance be much less, than in the hypothesis where each particle is supposed to acquire, from the stroke of the resisting body, a velocity equal to that with which the body moved, and in the same direction. Newton has determined, that the Resistance of a cylinder, moving in the direction of its axis, in such a compressed fluid as we have here treated of, is but one-fourth part of the Resistance to the same cylinder, if it moved with the same velocity in a fluid constituted in the manner described in the first hypothesis, each fluid being supposed of the same density.

But again, it is not only in the quantity of their Resistance that these fluids differ, but also in the different manner in which they act upon solids of different forms moving in them. In the discontinued fluid, first described, the obliquity of the foremost surface of the moving body would diminish the Resistance; but the same thing does not hold true in compressed fluids, at least not in any considerable degree; for the chief Resistance in compressed fluids arises from the greater or less facility with which the fluid, impelled by the fore part of the body, can circulate towards its hinder part; and this being little, if at all, affected by the form of the moving body, whether it be cylindrical, conical, or spherical, it follows, that while the transverse section of the body is the same, and consequently the quantity of impelled fluid also, the change of figure in the body will scarcely affect the quantity of its Resistance.

And this case, viz. the Resistance of a compressed fluid to a solid, moving in it with a velocity much less than what the parts of the fluid would acquire from their compression, has been very fully considered by Newton, who has ascertained the quantity of such a Resistance, according to the different magnitudes of the moving body, and the density of the fluid. But he expressly informs us that the rules he has laid down, are not generally true, but only upon a supposition that the compression of the fluid be increased in the greater velocities of the moving body: however, some unskilful writers, who have followed him, overlooking this caution, have applied his determination to bodies moving with all sorts of velocities, without attending to the different compressions of the fluids they are resisted by; and by this means they have accounted the Resistance, for instance, of the air to musket and cannon shot, to be but about one-third part of what it is found to be by experience.

It is indeed evident that the resisting power of the medium must be increased, when the resisted body moves so fast that the fluid cannot instantaneously press in behind it, and fill the deserted space; for when this happens, the body will be deprived of the pressure of the fluid behind it; which in some measure balanced its Resistance, or at least the fore pressure, and must support on its fore part the whole weight of a column of the fluid, over and above the motion it gives to the parts of the same; and besides, the motion in the particles driven before the body, is less affected in this case by the compression of the fluid, and consequently they are less deflected from the direction in which they are impelled by the resisted surface; whence it happens that this species of Resistance approaches more and more to that described in the first hypothesis, where each particle of the fluid being unconnected with the neighbouring ones, pursued its own motion, in its own direction, without being interrupted or deflected by their contiguity; and therefore, as the Resistance of a discontinued fluid to a cylinder moving in the direction of its axis, is 4 times greater than the Resistance of a fluid sufficiently compressed of the same density, it follows that the Resistance of a fluid, when a vacuity is left behind the moving body, may be near 4 times greater than that of the same fluid, when no such vacuity is formed; for when a void space is thus left, the Resistance approaches in its nature to that of a discontinued fluid.

This then may probably be the case in a cylinder moving in the same compressed fluid, according to the different degrees of its velocity; so that if it set out with a great velocity, and moves in the fluid till that velocity be much diminished, the resisting power of the medium may be near 4 times greater in the beginning of its motion than in the end.

In a globe, the difference will not be so great, because, on account of its oblique surface, its Resistance in a discontinued medium is but about twice as much as in one properly compressed; for its oblique surface diminishes its Resistance in one case, and not in the other: however, as the compression of the medium, even

even when a vacuity is left behind the moving body, may yet confine the oblique motion of the parts of the fluid, which are driven before the body, and as in an elastic fluid, such as our air is, there will be some degree of condensation in those parts; it is highly probable that the Resistance of a globe, moving in a compressed fluid with a very great velocity, may greatly exceed the proportion of the Resistance to slow motions.

And as this increase of the resisting power of the medium will take place, when the velocity of the moving body is so great, that a perfect vacuum is left behind it, so some degree of augmentation will be sensible in velocities much short of this; for even when, by the compression of the fluid, the space left behind the body is instantaneously filled up; yet, if the velocity with which the parts of the fluid rush in behind, is not much greater than that with which the body moves, the same reasons that have been urged above, in the case of an absolute vacuity, will hold in a less degree in this instance; and therefore it is not to be supposed that, in the increased Resistance which has been hitherto treated of, it immediately vanishes when the compression of the fluid is just sufficient to prevent a vacuum behind the resisted body; but we must consider it as diminishing only according as the velocity, with which the parts of the fluid follow the body, exceeds that with which the body moves.

Hence then it may be concluded, that if a globe sets out in a resisting medium, with a velocity much exceeding that with which the particles of the medium would rush into a void space, in consequence of their compression, so that a vacuum is necessarily left behind the globe in its motion; the Resistance of this medium to the globe will be much greater, in proportion to its velocity, than what we are sure, from Sir I. Newton, would take place in a slower motion. We may farther conclude, that the resisting power of the medium will gradually diminish as the velocity of the globe decreases, till at last, when it moves with velocities which bear but a small proportion to that with which the particles of the medium follow it, the Resistance becomes the same with what is assigned by Newton in the case of a compressed fluid.

And from this determination may be seen, how false that position is, which asserts the Resistance of any medium to be always in the duplicate ratio of the velocity of the resisted body; for it plainly appears, by what has been said, that this can only be considered as nearly true in small variations of velocity, and can never be applied in comparing together the Resistances to all velocities whatever, without incurring the most enormous errors. See Robins's Gunnery, chap. 2 prop. 1, and my Select Exercises pa. 235 &c. See also the articles Resistance *of the Air*, Projectile, and Gunnery.

Resistance and retardation are used indifferently for each other, as being both in the same proportion, and the same Resistance always generating the same retardation. But with regard to different bodies, the same Resistance frequently generates different retardations; the Resistance being as the quantity of motion, and the retardation that of the celerity. For the difference and measure of the two, see Retardation.

The retardations from this Resistance may be compared together, by comparing the Resistance with the gravity or quantity of matter. It is demonstrated that the Resistance of a cylinder, which moves in the direction of its axis, is equal to the weight of a column of the fluid, whose base is equal to that of the cylinder, and its altitude equal to the height through which a body must fall in vacuo, by the force of gravity, to acquire the velocity of the moving body. So that, if a denote the area of the face or end of the cylinder, or other prism, v its velocity, and n the specific gravity of the fluid; then, the altitude due to the velocity v being $\frac{v^2}{4g}$, the whole Resistance, or motive force m, will be $a \times n \times \frac{v^2}{4g} = \frac{anv^2}{4g}$; the quantity g being $= 16\frac{1}{12}$ feet, or the space a body falls, in vacuo, in the first second of time. And the Resistance to a globe of the same diameter would be the half of this.—Let a ball, for instance, of 3 inches diameter, be moved in water with a celerity of 16 feet per second of time: now from experiments on pendulums, and on falling bodies, it has been found, that this is the celerity which a body acquires in falling from the height of 4 feet; therefore the weight of a cylinder of water of 3 inches diameter, and 4 feet high, that is a weight of about 12 lb 4 oz, is equal to the Resistance of the cylinder; and consequently the half of it, or 6 lb 2 oz is that of the ball. Or, the formula

$$\frac{anv^2}{4g} \text{ gives } \frac{\cdot 7854 \times 9 \times 1000 \times 16 \times 16}{144 \times 4 \times 16} = 196 \text{ oz},$$

or 12 lb 4 oz, for the Resistance of the cylinder, or 6 lb 2 oz for that of the ball, the same as before.

Let now the Resistance, so discovered, be divided by the weight of the body, and the quotient will shew the ratio of the retardation to the force of gravity. So if the said ball, of 3 inches diameter, be of cast iron, it will weigh nearly 61 ounces, or $3\frac{4}{5}$ lb; and the Resistance being 6 lb 2 oz, or 98 ounces; therefore, the Resistance being to the gravity as 98 to 61, the retardation, or retarding force, will be $\frac{98}{61}$ or $1\frac{3}{5}$, the force of gravity being 1. Or thus; because a the area of a great circle of the ball, is $= pd^2$, where d is the diameter, and $p = \cdot 7854$, therefore the Resistance to the ball is $m = \frac{pnd^2 v^2}{8g}$; and because its solid content is $w = \frac{2}{3} pd^3$, and its weight $\frac{2}{3} Npd^3$, where N denotes its specific gravity; therefore, dividing the Resistance or motive force m by the weight w, gives $\frac{m}{w} = \frac{3nv^2}{16Ndg} = f$ the retardation, or retarding force, that of gravity being 1; which is therefore as the square of the velocity directly, and as the diameter inversely; and this is the reason why a large ball overcomes the Resistance better than a small one, of the same density. See my Select Exercises, pa. 225 &c.

Resistance *of Fluid Mediums to the Motion of Falling Bodies*.—A body freely descending in a fluid, is accelerated by the relative gravity of the body, (that is, the difference between its own absolute gravity and that of a like bulk of the fluid), which continually acts upon it, yet not equably, as in a vacuum: the Resistance of the fluid occasions a retardation, or diminution of

of acceleration, which diminution increases with the velocity of the body. Hence it happens, that there is a certain velocity, which is the greatest that a body can acquire by falling; for if its velocity be such, that the Resistance arising from it becomes equal to the relative weight of the body, its motion can be no longer accelerated; for the motion here continually generated by the relative gravity, will be destroyed by the Resistance, or the force of Resistance is equal to the relative gravity, and the body forced to go on equably: for after the velocity is arrived at such a degree, that the resisting force is equal to the weight that urges it, it will increase no longer, and the globe must afterward continue to descend with that velocity uniformly. A body continually comes nearer and nearer to this greatest celerity, but can never attain accurately to it. Now, N and n being the specific gravities of the globe and fluid, $N - n$ will be the relative gravity of the globe in the fluid, and therefore $w = \frac{2}{3}pd^3(N - n)$ is the weight by which it is urged downward; also $m = \frac{pnd^2v^2}{8g}$ is the Resistance, as above; therefore these two must be equal when the velocity can be no farther increased, or $m = w$, that is $\frac{pnd^2v^2}{8g} = \frac{2}{3}pd^3(N - n)$, or $nv^2 = \frac{16}{3}dg\,(N - n)$; and hence $v = \sqrt{\frac{16}{3}dg \times \frac{N-n}{n}}$ is the said uniform or greatest velocity to which the body may attain; which is evidently the greater in the subduplicate proportion of v the diameter of the ball. But v is always $= \sqrt{4gfs}$, the velocity generated by any accelerative force f in describing the space s; which being compared with the former, it gives $s = \frac{4}{3}d$, when f is $= \frac{N-n}{n}$; that is, the greatest velocity is that which is generated by the accelerating force $\frac{N-n}{n}$ in passing over the space $\frac{4}{3}d$ or $\frac{4}{3}$ of the diameter of the ball, or it is equal to the velocity generated by gravity in describing the space $\frac{N-n}{n} \times \frac{4}{3}d$. For ex. if the ball be of lead, which is about $11\frac{1}{4}$ times the density of water; then $N = 11\frac{1}{4}$, $n = 1$, $N - n = \frac{N-n}{n} = 10\frac{1}{4} = \frac{41}{4}$, and $\frac{N-n}{n} \times \frac{4}{3}d = \frac{41}{3}d = 13\frac{2}{3}d$; that is, the uniform or greatest velocity of a ball of lead, descending in water, is equal to that which a heavy body acquired by falling in vacuo through a space equal to $13\frac{2}{3}$ of the diameter of the ball, which velocity is $v = 2\sqrt{\frac{4}{3}dg \times \frac{N-n}{n}} = 2\sqrt{13\frac{2}{3}dg} = 8\sqrt{13\frac{2}{3}d}$ nearly, or 8 times the root of the same space.

Hence it appears, how soon small bodies come to their greatest or uniform velocity in descending in a fluid, as water, and how very small that velocity is: which explains the reason of the slow precipitation of mud, and small particles, in water, as also why, in precipitations, the larger and gross particles descend soonest, and the lowest.

Farther, where $N = n$, or the density of the fluid is equal to that of the body, then $N - n = 0$, consequently the velocity and distance descended are each nothing, and the body will just float in any part of the fluid.

Moreover, when the body is lighter than the fluid, then N is less than n, and $N - n$ becomes a negative quantity, or the force and motion tend the contrary way, that is, the ball will ascend up towards the top of the fluid by a motive force which is as $n - N$. In this case then, the body ascending by the action of the fluid, is moved exactly by the same laws as a heavier body falling in the fluid. Wherever the body is placed, it is sustained by the fluid, and carried up with a force equal to the difference of the weight of a quantity of the fluid of the same bulk as the body, from the weight of the body; there is therefore a force which continually acts equably upon the body; by which not only the action of gravity of the body is counteracted, so as that it is not to be considered in this case; but the body is also carried upwards by a motion equably accelerated, in the same manner as a body heavier than a fluid descends by its relative gravity: but the equability of acceleration is destroyed in the same manner by the Resistance, in the ascent of a body lighter than the fluid, as it is destroyed in the descent of a body that is heavier.

For the circumstances of the correspondent velocity, space, and time, &c, of a body moving in a fluid in which it is projected with a given velocity, or descending by its own weight, &c, see my Select Exercises, prop. 29, 30, 31, and 32, pag. 221 &c.

Resistance *of the Air*, in Pneumatics, is the force with which the motion of bodies, particularly of projectiles, is retarded by the opposition of the air or atmosphere. See Gunnery, Projectiles, &c.

The air being a fluid, the general laws of the Resistance of fluids obtain in it; subject only to some variations and irregularities from the different degrees of density in the different stations or regions of the atmosphere.

The Resistance of the air is chiefly of use in military projectiles, in order to allow for the differences caused in their flight and range by it. Before the time of Mr. Robins, it was thought that this Resistance to the motion of such heavy bodies as iron balls and shells, was too inconsiderable to be regarded, and that the rules and conclusions derived from the common parabolic theory, were sufficiently exact for the common practice of gunnery. But that gentleman shewed, in his New Principles of Gunnery, that, so far from being inconsiderable, it is in reality enormously great, and by no means to be rejected without incurring the grossest errors; so much so, that balls or shells which range, at the most, in the air, to the distance of two or three miles, would in a vacuum range to 20 or 30 miles, or more. To determine the quantity of this Resistance, in the case of different velocities, Mr. Robins discharged musket balls, with various degrees of known velocity, against his ballistic pendulums, placed at several different distances, and so discovered by experiment the quantity of velocity lost, when passing through those distances or

or spaces of air, with the several known degrees of celerity. For having thus known, the velocity lost or destroyed, in passing over a certain space, in a certain time, (which time is very nearly equal to the quotient of the space divided by the medium velocity between the greatest and least, or between the velocity at the mouth of the gun and that at the pendulum); that is, knowing the velocity v, the space s, and time t, the resisting force is thence easily known, being equal to $\frac{vb}{2gt}$ or $\frac{vVb}{2gs}$, where b denotes the weight of the ball, and V the medium velocity above-mentioned. The balls employed upon this occasion by Mr. Robins, were leaden ones, of $\frac{1}{12}$ of a pound weight, and $\frac{3}{4}$ of an inch diameter; and to the medium velocity of

1600 feet the Resistance was 11 lb,
1065 feet - - - - - - - it was $2\frac{4}{7}$;

but by the theory of Newton, before laid down, the former of these should be only $4\frac{1}{2}$ lb, and the latter 2 lb: so that, in the former case the real Resistance is more than double of that by the theory, being increased as 9 to 22; and in the lesser velocity the increase is from 2 to $2\frac{4}{7}$, or as 5 to 7 only.

Mr. Robins also invented another machine, having a whirling or circular motion, by which he measured the Resistances to larger bodies, though with much smaller velocities: it is described, and a figure of it given, near the end of the 1st vol. of his works.

That this resisting power of the air to swift motions is very sensibly increased beyond what Newton's theory for slow motions makes it, seems hence to be evident. By other experiments it appears that the Resistance is very sensibly increased, even in the velocity of 400 feet. However, this increased power of Resistance diminishes as the velocity of the resisted body diminishes, till at length, when the motion is sufficiently abated, the actual Resistance coincides with that supposed in the theory nearly. For these varying Resistances Mr. Robins has given a rule, extending to 1670 feet velocity.

Mr. Euler has shewn, that the common doctrine of Resistance answers pretty well when the motion is not very swift, but in swift motions it gives the Resistance less than it ought to be, on two accounts. 1. Because in quick motions, the air does not fill up the space behind the body fast enough to press on the hinder parts, to counterbalance the weight of the atmosphere on the fore part. 2. The density of the air before the ball being increased by the quick motion, will press more strongly on the fore part, and so will resist more than lighter air in its natural state. He has shewn that Mr. Robins has restrained his rule to velocities not exceeding 1670 feet per second; whereas had he extended it to greater velocities, the result must have been erroneous; and he gives another formula himself, and deduces conclusions differing from those of Mr. Robins. See his Principles of Gunnery investigated, translated by Brown in 1777, pa. 224 &c.

Mr. Robins having proved that, in very great changes of velocity, the Resistance does not accurately follow the duplicate ratio of the velocity, lays down two positions, which he thought might be of some service in the practice of artillery, till a more complete and accurate theory of Resistance, and the changes of its augmentation, may be obtained. The first of these is, that till the velocity of the projectile surpass 1100 or 1200 feet in a second, the Resistance may be esteemed to be in the duplicate ratio of the velocity: and the second is, that when the velocity exceeds 1100 or 1200 feet, then the absolute quantity of the Resistance will be near 3 times as great as it should be by a comparison with the smaller velocities. Upon these principles he proceeds in approximating to the actual ranges of pieces with small angles of elevation, viz, such as do not exceed 8° or 10°, which he sets down in a table, compared with their corresponding potential ranges. See his Mathematical Tracts, vol. 1 pa. 179 &c. But we shall see presently that these positions are both without foundation; that there is no such thing as a sudden or abrupt change in the law of Resistance, from the square of the velocity to one that gives a quantity three times as much; but that the change is slow and gradual, continually from the smallest to the highest velocities; and that the increased real Resistance no where rises higher than to about double of that which Newton's theory gives it.

Mr. Glenie, in his History of Gunnery, 1776, pa. 49, observes, in consequence of some experiments with a rifled piece, properly fitted for experimental purposes, that the Resistance of the air to a velocity somewhat less than that mentioned in the first of the above propositions, is considerably greater than in the duplicate ratio of the velocity; and that, to a celerity somewhat greater than that stated in the second, the Resistance is considerably less than that which is treble the Resistance in the said ratio. Some of Robins's own experiments seem necessarily to make it so; since, to a velocity no quicker than 400 feet in a second, he found the Resistance to be somewhat greater than in that ratio. But the true value of the ratio, and other circumstances of this Resistance, will more fully appear from what follows.

The subject of the Resistance of the air, as begun by Robins, has been prosecuted by myself, to a very great extent and variety, both with the whirling machine, and with cannon balls of all sizes, from 1 lb to 6 lb weight, as well as with figures of many other different shapes, both on the fore part and hind part of them, and with planes set at all varieties of angles of inclination to the path or motion of the same; from all which I have obtained the real Resistance to bodies for all velocities, from 1 up to 2000 feet per second; together with the law of the Resistance to the same body for all different velocities, and for different sizes with the same velocity, and also for all angles of inclination; a full account of which would make a book of itself, and must be reserved for some other occasion. In the mean time, some general tables of conclusions may be taken as below.

TABLE I. *Resistances of different Bodies.*

In this Table are contained the Resistances to several forms of bodies, when moved with several degrees of velocity, from 3 feet per second to 20. The names of the bodies are at the tops of the columns, as also which end went foremost through the air; the different velocities are in the first column, and the Resistances on the same line, in their several columns, in avoirdupois ounces and decimal parts. So on the first line are contained the Resistances when the bodies move with a velocity of 3 feet in a second, viz, in the 2d column for the small hemisphere, of $4\frac{3}{4}$ inches diameter, its Resistance ·028 oz when the flat side went foremost; in the 3d and 4th columns the Resistances to a larger hemisphere, first with the flat side, and next the round side foremost, the diameter of this, as well as all the following figures being $6\frac{3}{8}$ inches, and therefore the area of the great circle = 32 sq. inches, or $\frac{2}{9}$ of a sq. foot; then in the 5th and 6th columns are the Resistances to a cone, first its vertex and then its base foremost, the altitude of the cone being $6\frac{5}{8}$ inches, the same as the diameter of its base; in the 7th column the Resistance to the end of the cylinder, and in the 8th that against the whole globe or sphere. All the numbers shew the real weights which are equal to the Resistances; and at the bottoms of the columns are placed proportional numbers, which shew the mean proportions of the Resistances of all the figures to one another, with any velocity. Lastly, in the 9th column are placed the exponents of the power of the velocity which the Resistances in the 8th column bear to each other, viz, which that of the 10 feet velocity bears to each of the following ones, the medium of all of them being as the 2·04 power of the velocity, that is, very little above the square or second power of the velocity, so far as the velocities in this Table extend.

From this Table the following inferences are easily deduced.

1. That the Resistance is nearly in the same proportion as the surfaces; a small increase only taking place in the greater surfaces, and for the greater velocities. Thus, by comparing together the numbers in the 2d and 3d columns, for the bases of the two hemispheres, the areas of which bases are in the proportion of $17\frac{3}{4}$ to 32, or 5 to 9 very nearly, it appears that the numbers in those two columns, expressing the Resistances, are nearly as 1 to 2 or 5 to 10, as far as the velocity of 12 feet; but after that, the Resistances on the greater surface increase gradually more and more above that proportion.

2. The Resistance to the same surface, with different velocities, is, in these slow motions, nearly as the square of the velocity; but gradually increases more and more above that proportion as the velocity increases. This is manifest from all the columns; and the index of the power of the velocity is set down in the 9th column, for the Resistances in the 8th, the medium being 2·04; by which it appears that the Resistance to the same body is, in these slow motions, as the 2·04 power of the velocity, or nearly as the square of it.

3. The round ends, and sharp ends, of solids, suffer less Resistance than the flat or plane ends, of the same diameter; but the sharper end has not always the less Resistance. Thus, the cylinder, and the flat ends of the hemisphere and cone, have more Resistance, than the round or sharp ends of the same; but the round side of the hemisphere has less Resistance than the sharper end of the cone.

4. The Resistance on the base of the hemisphere, is to that on the round, or whole sphere, as $2\frac{1}{3}$ to 1, instead of 2 to 1, as the theory gives that relation. Also the experimented Resistance, on each of these, is nearly $\frac{1}{4}$ more than the quantity assigned by the theory.

5. The Resistance on the base of the cone, is to that on the vertex, nearly as $2\frac{3}{10}$ to 1; and in the same ratio is radius to the sine of the angle of inclination of the side of the cone to its path or axis. So that, in this instance, the Resistance is directly as the sine of the angle of incidence, the transverse section being the same.

6. When the hinder parts of bodies are of different forms, the Resistances are different, though the foreparts be exactly alike and equal; owing probably to the different pressures of the air on the hinder parts. Thus, the Resistance to the fore part of the cylinder, is less than on the equal flat surface of the cone, or of the hemisphere; because the hinder part of the cylinder is more pressed or pushed, by the following air than those of the other two figures; also, for the same reason, the base of the hemisphere suffers a less Resistance than that of the cone, and the round side of the hemisphere less than the whole sphere.

2000	1569	786	2·00	2·098

In the firft column of this Table are contained the feveral velocities, gradually from o up to the great velocity of 2000 feet per fecond, with which a ball or globe moved. In the 2d column are the experimented Refiftances, in averdupois ounces. In the 3d column are the correfpondent Refiftances, as computed by the foregoing theory. In the 4th column are the ratios of thefe two Refiftances, or the quotients of the former divided by the latter. And in the 5th or laft, the indexes of the power of the velocity which is proportional to the experimented Refiftance; which are found by comparing the Refiftance of 20 feet velocity with each of the following ones.

From the 2d, 3d and 4th columns it appears, that at the beginning of the motion, the experimented Refiftance is nearly equal to that computed by theory; but that, as the velocity increafes, the experimented Refiftance gradually exceeds the other more and more, till at the velocity of 1300 feet the former becomes juft double the latter; after which the difference increafes a little farther, till at the velocity of 1600 or 1700, where that excefs is the greateft, and is rather lefs than $2\frac{1}{10}$; after this, the difference decreafes gradually as the velocity increafes, and at the velocity of 2000, the former Refiftance again becomes juft double the latter.

From the laft column it appears that, near the beginning, or in flow motions, the Refiftances are nearly as the fquare of the velocities; but that the ratio gradually increafes, with fome fmall variation, till at the velocity of 1500 or 1600 feet it becomes as the $2\frac{1}{9}$ power of the velocity nearly, which is its higheft afcent; and after that it gradually decreafes again, as the velocity goes higher. And fimilar conclufions have alfo been derived from experiments with larger balls or globes.

And hence we perceive that Mr. Robins's pofitions are erroneous on two accounts, viz, both in ftating that the Refiftance changes fuddenly, or all at once, from being as the fquare of the velocity, fo as then to become as fome higher and conftant power; and alfo when he ftates the Refiftance as rifing to the height of 3 times that which is given by the theory: fince the ratio of the Refiftance both increafes gradually from the beginning, and yet never afcends higher than $2\frac{1}{10}$ of the theory.

Table III. *Refiftance to a Plane, fet at various Angles of Inclination to its Path.*

In the 2d column of this Table are contained the actual experimerted Refiftances, in ounces, to a plane of 32 fquare inches, or $\frac{2}{9}$ of a fquare foot, moved through the air with a velocity of exactly 12 feet per fecond, when the plane was fet fo as to make, with the direction of its path, the correfponding angles in the firft column.

And from thefe I have deduced this formula, or theorem, viz, $\cdot 84 s^{1\cdot 84 c}$, which brings out very nearly the fame numbers, and is a general theorem for every angle, for the fame plane of $\frac{2}{9}$ of a foot, and moved with the fame velocity of 12 feet in a fecond of time; where s is the fine, and c the cofine of the angles of inclination in the firft column.

If

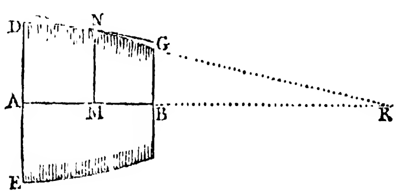
If a theorem be desired for any other velocity v, and any other plane whose area is a, it will be this: $\frac{1}{35}av^2s^{1.842c}$, or more nearly $\frac{1}{72}av^{2.04}s^{1.842c}$; which denotes the Resistance nearly to any plane surface whose area is a, moved through the air with the velocity v, in a direction making with that plane an angle, whose sine is s, and cosine c.

If it be water or any other fluid, different from air, this formula will be varied in proportion to the density of it.

By this theorem were computed the numbers in the 3d column; which it is evident agree very nearly with the experiment Resistances in the 2d column, excepting in two or three of the small numbers near the beginning, which are of the least consequence. In all other cases, the theorem gives the true Resistance very nearly. In the 4th or last column are entered the sines of the angles of the first column, to the radius ·84, in order to compare them with the Resistances in the other columns. From whence it appears, that those Resistances bear no sort of analogy to the sines of the angles, nor yet to the squares of the sines, nor to any other power of them whatever. In the beginning of the columns, the sines much exceed the Resistances all the way till the angle be between 55 and 60 degrees; after which the sines are less than the Resistances all the way to the end, or till the angle become of 90 degrees.

Mr. James Bernoulli gave some theorems for the Resistances of different figures, in the Acta Erud. Lips. for June 1693, pa. 252 &c. But as these are deduced from theory only, which we find to be so different from experiment, they cannot be of much use. Messieurs Euler, D'Alembert, Gravesande, and Simpson, have also written pretty largely on the theory of Resistances, besides what had been done by Newton.

Solid of Least Resistance. Sir Isaac Newton, from his general theory of Resistance, deduces the figure of a solid which shall have the least Resistance of the same base, height and content.



The figure is this. Suppose DNG to be a curve of such a nature, that if from any point N the ordinate NM be drawn perpendicular to the axis AB; and from a given point G there be drawn GR parallel to a tangent at N, and meeting the axis produced in R; then if MN be to GR, as GR^3 to $4BR \times BG^2$, a solid described by the revolution of this figure about its axis AB, moving in a medium from A towards B, is less resisted than any other circular solid of the same base, &c.

This theorem, which Newton gave without a demonstration, has been demonstrated by several mathematicians, as Facio, Bernoulli, Hospital, &c. See Maclaurin's Flux. sect. 606 and 607; also Horsley's edit. of Newton, vol. 2, pag. 390. See also Act. Erud. 1699, pa. 514; and Mem. de l'Acad. &c; also Robins's View of Newton's method for comparing the Resistance of Solids, 8vo, 1734; and Simpson's Fluxions, art. 413; or my Principles of Bridges, prop. 11 and 12.

M. Bouguer has resolved this problem in a very general manner; not in supposing the solid to be formed by a revolution, of any figure whatever. The problem, as enunciated and resolved by M. Bouguer, is this: Any base being given, to find what kind of solid must be formed upon it, so that the impulse upon it may be the least possible. Properly however it ought to be the retardive force, or the impulse divided by the weight or mass of matter in the body, that ought to be the minimum.

RESOLUTION, in Physics, the reduction of a body into its original or natural state, by a dissolution or separation of its aggregated parts. Thus, snow and ice are said to be resolved into water; water resolves in vapour by heat; and vapour is again resolved into water by cold; also any compound is resolved into its ingredients, &c.

Some of the modern philosophers, particularly Boyle, Mariotte, Boerhaave, &c, maintain, that the natural state of water is to be congealed, or in ice; in as much as a certain degree of heat, which is a foreign and violent agent, is required to make it fluid: so that near the pole, where this foreign agent is wanting, it constantly retains its fixed or icy state.

Resolution, or Solution, in Mathematics, is an orderly enumeration of several things to be done, to obtain what is required in a problem.

Wolfius makes a problem to consist of three parts: The *proposition* (or what is properly called the *problem*), the *Resolution*, and the *demonstration*.

As soon as a problem is demonstrated, it is converted into a theorem; of which the Resolution is the hypothesis; and the proposition the thesis.

For the process of a mathematical Resolution, see the following article.

Resolution in *Algebra*, or *Algebraical* Resolution, is of two kinds; the one practised in numerical problems, the other in geometrical ones.

In Resolving a Numerical Problem Algebraically, the method is this. First, the given quantities are distinguished from those that are sought; and the former denoted by the initial letters of the alphabet, but the latter by the last letters.—2. Then as many equations are formed as there are unknown quantities. If that cannot be done from the proposition or data, the problem is indeterminate; and certain arbitrary assumptions must be made, to supply the defect, and which can satisfy the question. When the equations are not contained in the problem itself, they are to be found by particular theorems concerning equations, ratios, proportions, &c.—Since, in an equation, the known and unknown quantities are mixed together, they must be separated in such a manner, that the unknown one remain alone on one side, and the known ones on the other. This reduction, or separation, is made by addition, subtraction, multiplication, division, extraction of

of roots, and raising of powers; resolving every kind of combination of the quantities, by their counter or reverse ones, and performing the same operation on all the quantities or terms, on both sides of the equation, that the equality may still be preserved.

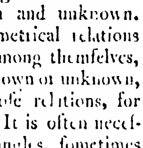
To Resolve a Geometrical Problem Algebraically.—The same sort of operations are to be performed, as in the former article; besides several others, that depend upon the nature of the diagram, and geometrical properties. As 1st, the thing required or proposed, must be supposed done, the diagram being drawn or constructed in all its parts, both known and unknown. 2. We must then examine the geometrical relations which the lines of the figure have among themselves, without regarding whether they are known or unknown, to find what equations arise from those relations, for finding the unknown quantities. 3. It is often necessary to form similar triangles and rectangles, sometimes by producing of lines, or drawing parallels and perpendiculars, and forming equal angles, &c; till equations can be formed, from them, including both the known and unknown quantities.

If we do not thus arrive at proper equations, the thing is to be tried in some other way. And sometimes the thing itself, that is required, is not to be sought directly, but some other thing, bearing certain relations to it, by means of which it may be found.

The final equation being at last arrived at, the geometrical construction is to be deduced from it, which is performed in various ways according to the different kinds of equations.

RESOLUTION *of Forces*, or *of Motion*, is the resolving or dividing of any one force or motion, into several others, in other directions, but which, taken together, shall have the same effect as the single one; and it is the reverse of the composition of forces or motions. See these articles.

Any single direct force AD, may be resolved into two oblique forces, whose quantities and directions are AB, AC, having the same effect, by describing any parallelogram ABDC, whose diagonal is AD. And each of these may, in like manner, be resolved into two others; and so on, as far as we please. And all these new forces, or motions, so found, when acting together, will produce exactly the same effect as the single original one. See also COLLISION, PERCUSSION, MOTION, &c.



REST, in Physics, the continuance of a body in the same place; or its continual application or contiguity to the same parts of the ambient and contiguous bodies.—See SPACE.

Rest is either *absolute* or *relative*, as place is.

Some define Rest to be the state of a thing without motion; and hence again Rest becomes either absolute or relative, as motion is.

Newton defines true or absolute Rest to be the continuance of a body in the same part of absolute and immoveable space; and relative Rest to be the continuance of a body in the same part of relative space.

Thus, in a ship under sail, relative Rest is the continuance of a body in the same part of the ship. But true or absolute Rest is its continuance in the same part of universal space in which the ship itself is contained.

Hence, if the earth be really and absolutely at Rest, the body relatively at Rest in the ship will really and absolutely move, and that with the same velocity as the ship itself. But if the earth do likewise move, there will then arise a real and absolute motion of the body at Rest; partly from the real motion of the earth in absolute space, and partly from the relative motion of the ship on the sea. Lastly, if the body be likewise relatively moved in the ship, its real motion will arise partly from the real motion of the earth in immoveable space, and partly from the relative motion of the ship on the sea, and of the body in the ship.

It is an axiom in philosophy, that matter is indifferent as to Rest or motion. Hence Newton lays it down, as a law of nature, that every body perseveres in its state, either of Rest or uniform motion, except so far as it is disturbed by external causes.

The Cartesians assert, that firmness, hardness, or solidity of bodies, consists in this, that their parts are at Rest with regard to each other; and this Rest they establish as the great nexus, or principle of cohesion, by which the parts are connected together. On the other hand, they make fluidity to consist in a perpetual motion of the parts, &c. But the Newtonian philosophy furnishes us with much better solutions.

Maupertuis asserts, that when bodies are in equilibrio, and any small motion is impressed on them, the quantity of action resulting will be the least possible. This he calls the law of *Rest*; and from this law he deduces the fundamental proposition of statics. See Berlin Mem. tom. 2, pa. 294. And from the same principle too he deduces the laws of percussion.

RESTITUTION, in Physics, the returning of elastic bodies, forcibly bent, to their natural state; by some called the *motion of Restitution*.

RETARDATION, in Physics, the act of retarding, that is, of delaying the motion or progress of a body, or of diminishing its velocity.

The Retardation of moving bodies arises from two great causes, the resistance of the medium, and the force of gravity.

The RETARDATION *from the Resistance* is often confounded with the resistance itself; because, with respect to the same moving body, they are in the same proportion.

But with respect to different bodies, the same resistance often generates different Retardations. For if bodies of equal bulk, but different densities, be moved through the same fluid with equal velocity, the fluid will act equally on each; so that they will have equal resistances, but different Retardations; and the Retardations will be to each other, as the velocities which might be generated by the same forces in the bodies proposed; that is, they are inversely as the quantities of matter in the bodies, or inversely as the densities.

Suppose then bodies of equal density, but of unequal bulk, to move equally fast through the same fluid; then their resistances increase according to their superficies, that is as the squares of their diameters; but the quantities of matter are increased according to their mass or magnitude, that is as the cubes of their diameters: the resistances are the quantities of motion; the

the Retardations are the celerities arising from them; and dividing the quantities of motion by the quantities of matter, we shall have the celerities; therefore the Retardations are directly as the squares of the diameters, and inversely as the cubes of the diameters, that is inversely as the diameters themselves.

If the bodies be of equal magnitude and density, and moved through different fluids, with equal celerity, their Retardations are as the densities of the fluids. And when equal bodies are carried through the same fluid with different velocities, the Retardations are as the squares of the velocities.

So that, if s denote the superficies of a body, w its weight, d its diameter, v the velocity, and n the density of the fluid medium, and N that of the body; then, in similar bodies, the resistance is as nsv^2 or as nd^2v^2, and the Retardation, or retarding force,

as $\frac{nsv^2}{w}$, or as $\frac{nd^2v^2}{Nd^3} = \frac{nv^2}{Nd}$.

The RETARDATION *from Gravity* is peculiar to bodies projected upwards. A body thrown upwards is retarded after the same manner as a falling body is accelerated; only in the one case the force of gravity conspires with the motion acquired, and in the other it acts contrary to it.

As the force of gravity is uniform, the Retardation from that cause will be equal in equal times. Hence, as it is the same force which generates motion in the falling body, and diminishes it in the rising one, a body rises till it lose all its motion; which it does in the same time in which a body falling would have acquired a velocity equal to that with which the body was thrown up.

Also, a body thrown up, will rise to the same height from which, in falling, it would acquire the same velocity with which it was thrown up: therefore the heights which bodies can rise to, when thrown up with different velocities, are to each other as the squares of the velocities.

Hence, the Retardations of motions may be compared together. For they are, first, as the squares of the velocities; 2dly, as the densities of the fluids through which the bodies are moved; 3dly, inversely as the diameters of those bodies; 4thly, inversely as the densities of the bodies themselves; as expressed by the theorem above, viz, $\frac{nv^2}{Nd}$.

The Laws of RETARDATION, are the very same as those for acceleration; motion and velocity being destroyed in the one case, in the very same quantity and proportion as it is generated in the other.

RETICULA, or RETICULE, in Astronomy, a contrivance for measuring very nicely the quantity of eclipses, &c.

This instrument, introduced some years since by the Paris Acad. of Sciences, is a little frame, consisting of 13 fine silken threads, parallel to, and equidistant from each other; placed in the focus of object-glasses of telescopes; that is, in the place where the image of the luminary is painted in its full extent. Consequently the diameter of the sun or moon is thus seen divided into 12 equal parts or digits: so that, to find the quantity of the eclipse, there is nothing to do but to number the parts that are dark, or that are luminous.

As a square Reticule is only proper for the diameter of the luminary, not for the circumference of it, it is sometimes made circular, by drawing 6 concentric equidistant circles; which represents the phases of the eclipse perfectly.

But it is evident that the Reticule, whether square or circular, ought to be perfectly equal to the diameter or circumference of the sun or star, such as it appears in the focus of the glass; otherwise the division cannot be just. Now this is no easy matter to effect, because the apparent diameter of the sun and moon differs in each eclipse; nay that of the moon differs from itself in the progress of the same eclipse.—Another imperfection in the Reticule is, that its magnitude is determined by that of the image in the focus; and of consequence it will only fit one certain magnitude.

But M. de la Hire has found a remedy for all these inconveniences, and contrived that the same Reticule shall serve for all telescopes, and all magnitudes of the luminary in the same eclipse. The principle upon which his invention is founded, is that two object-glasses applied against each other, having a common focus, and these forming an image of a certain magnitude, this image will increase in proportion as the distance between the two glasses is increased, as far as to a certain limit. If therefore a Reticule be taken of such a magnitude, as just to comprehend the greatest diameter the sun or moon can ever have in the common focus of two object-glasses applied to each other, there needs nothing but to remove them from each other, as the star comes to have a less diameter, to have the image still exactly comprehended in the same Reticule.

Farther, as the silken threads are subject to swerve from the parallelism, &c, by the different temperature of the air, another improvement is, to make the Reticule of a thin looking-glass, by drawing lines or circles upon it with the fine point of a diamond. See MICROMETER.

RETIRED FLANK, in Fortification. See FLANK.

RETROCESSION *of Curves, &c.* See RETROGRADATION.

RETROCESSION *of the Equinox.* See PRECESSION.

RETROGRADATION, or RETROGRESSION, in Astronomy, is an apparent motion of the planets, by which they seem to go backwards in the ecliptic, and to move contrary to the order or succession of the signs.

When a planet moves in consequentia, or according to the order of the signs, as from Aries to Taurus, from Taurus to Gemini, &c, which is from west to east, it is said to be *direct*.—When it appears for some days in the same place, or point of the heavens, it is said to be *stationary*.—And when it goes in antecedentia, or backwards to the following signs, or contrary to the order of the signs, which is from east to west, it is said to be *retrograde*. All these different affections or circumstances, may happen in all the planets, except the sun and moon, which are seen to go direct only. But the times of the superior and inferior planets being retrograde are different; the former appearing so about their opposition, and the latter about their conjunction.

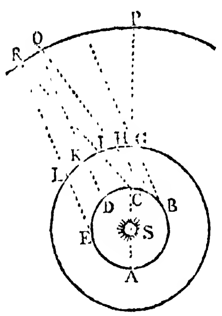
tion. The intervals of time alfo between two Retrogradations of the feveral planets, are very unequal:

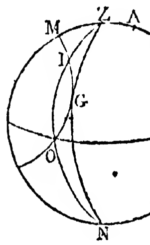
In Saturn it is	1 year	13 days,
In Jupiter - -	1 - -	43
In Mars - -	2 - -	50
In Venus - -	1 - -	220
In Mercury -	0 - -	115

Again, Saturn continues retrograde 140 days, Jupiter 120, Mars 73, Venus 42, and Mercury 22; or nearly fo; for the feveral Retrogradations of the fame planet are not conftantly equal.

Thefe various circumftances however in the motions of the planets are not real, but only apparent; as the inequalities arife from the motion and pofition of the earth, from whence they are viewed; for when they are confidered as feen from the fun, their motions appear always uniform and regular. Thefe inequalities are thus explained:

Let S denote the fun; and ABCD &c the path or orbit of the earth, moving from weft to eaft, and in that order; alfo GK &c the orbit of a fuperior planet, as Saturn for inftance, moving the fame way, or in the direction GKLG, but with a much lefs celerity than





the earth's motion. Now when the earth is at the point A of its orbit, let Saturn be at G, in conjunction with the fun, when it will be feen at P in the zodiac, or among the ftars; and when the earth has moved from A to B, let Saturn have moved from G to H in its orbit, when it will be feen in the line BHQ, and will appear to have moved from P to Q in the zodiac; alfo when the earth has got to C, let Saturn be arrived at I, but found at R in the zodiac, where being feen in the line CIR, it appears ftationary, or without motion in the zodiac at R. But after this, Saturn will appear for fome time in Retrogradation, viz, moving backwards, or the contrary way: for when the earth has moved to D, Saturn will have got to K, and, being feen in the line DKQ, will appear to have moved retrograde in the zodiac from R to Q; about which place the planet, ceafing to recede any farther, again becomes ftationary, and afterward proceeds forward again; for while the earth moves from D to E, and Saturn from K to L, this latter, being now feen in the line ELR, appears to have moved forward in the zodiac from Q to R. And fo on; the fuperior planets always becoming retrograde a little before they are in oppofition to the fun, and continuing fo till fome time after the oppofition: the retrograde motion being fwifteft when the planet is in the very oppofition itfelf; and the direct motion fwifteft when in the conjunction. The arch RQ which the planet defcribes while thus retrograde, is called the arch of Retrogradation. Thefe arches are unequal in all the planets, being greateft in the moft diftant, and gradually lefs in the nearer ones.

In like manner may be fhewn the circumftances of the Retrogradations of the inferior planets; by which it will appear, they become ftationary a little before their inferior conjunction, and go retrograde till a little time after it; moving the quickeft retrograde juft at that conjunction, and the quickeft direct juft at the fuperior or further conjunction.

Retrogradation *of the Nodes of the Moon*, is a motion of the line of the nodes of her orbit, by which it continually fhifts its fituation from eaft to weft, contrary to the order of the figns, completing its retrograde circulation in the period of about 19 years: after which time, either of the nodes, having receded from any point of the ecliptic, returns to the fame again.—Newton has demonftrated, in his Principia, that the Retrogradation of the moon's nodes is caufed by the action of the fun, which continually drawing this planet from her orbit, deflects this orbit from a plane, and caufes its interfection with the ecliptic continually to vary; and his determinations on this point have been confirmed by obfervation.

Retrogradation *of the Sun*, a motion by which in fome fituations, in the torrid zone, he feems to move retrograde or backwards.

When the fun is in the torrid zone, and has his declination AM greater than the latitude of the place AZ, but either northern or fouthern as that is, (laft fig. above), the fun will appear to go retrograde, or backwards, both before and after noon. For draw the vertical circle ZGN to be a tangent to the fun's diurnal circle MGO in G, and another ZON through the fun's rifing, at O: then it is evident, that all the intermediate vertical circles cut the fun's diurnal circle twice; firft in the arc GO, and the fecond time in the arc GI. So that, as the fun afcends through the arc GO, he continually arrives at farther and farther verticals. But as he continues his afcent through the arc GI, he returns to his former verticals; and therefore is feen retrograde for fome time before noon. And in like manner it may be fhewn that he does the fame thing for fome time after noon. Hence, as the fhadow always tends oppofite to the fun, the fhadow will be retrograde twice every day in all places of the torrid zone, where the fun's declination exceeds the latitude.

But the fame thing can never happen without the tropics, in a natural way.

Retrogradation, or Retrogression, in the Higher Geometry, is the fame with what is otherwife called *contrary flexion* or *flexure*. See Flexure, and Inflexion.

RETROGRADE, denotes backward, or contrary to the forward or natural direction. See RETROGRADATION.

RETROGRESSION, or RETROCESSION. The same with RETROGRADATION.

RETURNING *Stroke*, in Electricity, is an expression used by lord Mahon (now earl Stanhope) to denote the effect produced by the return of the electric fire into a body from which, in certain circumstances, it has been expelled.

To understand properly the meaning of these terms, it must be premised that, according to the noble author's experiments, an insulated smooth body, immerged within the electrical atmosphere, but beyond the striking distance of another body, charged positively, is at the same time in a state of threefold electricity. The end next to the charged body acquires negative electricity, the farther end is positively electrified; while a certain part of the body, somewhere between its two extremes, is in a natural, unelectrified, or neutral state; so that the two contrary electricities balance each other. It may farther be added, that if the body be not insulated, but have a communication with the earth, the whole of it will be in a negative state. Suppose then a brass ball, which may be called A, to be constantly placed at the striking distance of a prime conductor; so that the conductor, the instant when it becomes fully charged, explodes into it. Let another large or second conductor be suspended, in a perfectly insulated state, farther from the prime conductor than the striking distance, but within its electrical atmosphere: let a person standing on an insulated stool touch this second conductor very lightly with a finger of his right hand; while, with a finger of his left hand, he communicates with the earth, by touching very lightly a second brass ball fixed at the top of a metallic stand, on the floor, which may be called B. Now while the prime conductor is receiving its electricity, sparks pass (at least if the distance between the two conductors is not too great) from the second conductor to the right hand of the insulated person; while similar and simultaneous sparks pass out from the finger of his left hand into the second metallic ball B, communicating with the earth. At length however the prime conductor, having acquired its full charge, suddenly strikes into the ball A, of the first metallic stand, placed for that purpose at the striking distance. The explosion being made, and the prime conductor suddenly robbed of its elastic atmosphere, its pressure or action on the second conductor, and on the insulated person, as suddenly ceases; and the latter instantly feels a smart Returning Stroke, though he has no direct or visible communication (except by the floor) with either of the two bodies, and is placed at the distance of 5 or 6 feet from both of them. This Returning Stroke is evidently occasioned by the sudden re-entrance of the electric fire naturally belonging to his body and to the second conductor, which had before been expelled from them by the action of the charged prime conductor upon them; and which returns to its former place in the instant when that action or elastic pressure ceases. When the second conductor and the insulated person are placed in the densest part of the electrical atmosphere of the prime conductor, or just beyond the striking distance, the effects are still more considerable; the Returning Stroke being extremely severe and pungent, and appearing considerably sharper than even the main stroke itself, received directly from the prime conductor. Lord Mahon observes, that persons and animals may be destroyed, and particular parts of buildings may be much damaged, by an electrical Returning Stroke, occasioned even by some very distant explosion from a thunder cloud; possibly at the distance of a mile or more. It is certainly not difficult to conceive that a charged extensive thunder cloud must be productive of effects similar to those produced by the prime conductor; but perhaps the effects are not so great, nor the danger so terrible, as it seems have been apprehended. If the quantity of electric fluid naturally contained, for example, in the body of a man, were immense or indefinite, then the estimate between the effects producible by a cloud, and those caused by a prime conductor, might be admitted; but surely no electrical cloud can expel from a body more than the natural quantity of electricity which this contains. On the sudden removal therefore of the pressure by which this natural quantity had been expelled, in consequence of the explosion of the cloud into the earth, no more (at the utmost) than his whole natural stock of electricity can re-enter his body, provided it be so situated, that the returning fire of other bodies must necessarily pass through his body. But perhaps we have no reason to suppose that this quantity is so great, as that its sudden re-entrance into his body should destroy or injure him.

Allowing therefore the existence of the Returning Stroke, as sufficiently ascertained, and well illustrated, in a variety of circumstances, by the author's experiments, the magnitude and danger of it do not seem to be so alarming as he apprehends. See Lord Mahon's Principles of Electricity, &c. 4to. 1779, pa. 76, 113, and 131. Also Monthly Review, vol. 62, pa. 436.

REVERSION *of Series*, in Algebra, is the finding the value of the root, or unknown quantity, whose powers enter the terms of an infinite series, by means of another infinite series in which it is not contained. As, in the infinite series $z = ax + bx^2 + cx^3 + dx^4$ &c; then if there be found $x = Az + Bz^2 + Cz^3$ &c, that series is inverted, or its root x is found in an infinite series of other terms.

This was one of Newton's improvements in analysis, the first specimen of which was given in his Analysis per Æquationes Numero Terminorum Infinitas; and it is of great use in resolving many problems in various parts of the mathematics.

The most usual and general way of Reversion, is to assume a series, of a proper form, for the value of the required unknown quantity; then substitute the powers of this value, instead of those of that quantity into the given series; lastly compare the resulting terms with the said given series, and the values of the assumed coefficients will thus be obtained. So, to revert the series $z = ax + bx^2 + cx^3$, &c, or to find the value of x in terms of z; assume it thus, $x = Az + Bz^2 + Cz^3$ &c;

&c; then by involving this ſeries, for the ſeveral powers of x, and multiplying the correſpoñding powers by a, b, c, &c, there reſults

$$\begin{aligned} z = aAz &+ aBz^2 + aCz^3 + aDz^4, \text{ \&c.} \\ &+ bA^2z^2 + 2bABz^3 + 2bACz^4 \\ &\qquad\qquad\qquad + bB^2z^4 \\ &\qquad + cA^3z^3 + 3cA^2Bz^4 \\ &\qquad\qquad\qquad + dA^4z^4 \end{aligned}$$

Then by comparing the correſponding terms of this laſt ſeries, or making their coefficients equal, there are obtained theſe equations, viz,

$aA - 1$, and $aB + bA^2 = 0$, and $aC + 2bAB + cA^3 = 0$, &c, which give theſe values of the aſſumed coefficients, viz,

$$A = \frac{1}{a};\ B = -\frac{bA^2}{a} = -\frac{b}{a^3};$$

$$C = -\frac{2bAB + cA^3}{a} = \frac{2bb - ac}{a^5};$$

$$D = -\frac{2bAC + bB^2 + 3cA^2B + dA^4}{a}$$

$$= -\frac{5abc - 5b^3 - a^2d}{a^7};\ \text{\&c.}$$

and conſequently

$$x = \frac{1}{a}z - \frac{b}{a^3}z^2 + \frac{2bb - ac}{a^5}z^3 - \frac{5abc - 5b^3 - a^2d}{a^7}z^4$$

&c; which is therefore a general formula or theorem for every ſeries of the ſame kind, as to the powers of the quantity x. Thus, for

Ex. Suppoſe it were required to revert the ſeries $z = x - x^2 + x^3 - x^4$, &c.

Here $a = 1$, $b = -1$, $c = 1$, $d = -1$, &c; which values of theſe letters being ſubſtituted in the theorem, there reſults $x = z + z^2 + z^3 + z^4$, &c, which is that ſeries reverted, or the value of x in it.

In the ſame way it will be found that the theorem for reverting the ſeries

$z = ax + bx^3 + cx^5 + dx^7$ &c, is

$$x = \frac{1}{a}z - \frac{b}{a^4}z^3 + \frac{3bb - ac}{a^7}z^5 - \frac{a^2d + 12b^3 - 8abc}{a^{10}},$$
&c.

And if $z = ax^m + bx^{m+n} + cx^{m+2n} + \text{\&c}$, then is

$$x = y^{\frac{1}{m}} - \frac{b}{ma}y^{\frac{1+n}{m}} + \frac{(1 + 2n + m)\,bb - 2mac}{2mmaa}$$

$$\times\, y^{\frac{1+2n}{m}}\ \text{\&c. where } y \text{ is } = \frac{z}{a}.$$

Tranſ. number 240; or Maclaurin's Algebra pa. 263; or Stuart's Explanation of Newton's Analyſis, &c. pa. 455; or Coulſon's Comment on Newton's Flux. pa. 219; or Horſley's ed. of Newton's works vol. 1, pa. 291; or Simpſon's Flux. vol. 2, pa. 362: or moſt authors on Algebra.

REVETEMENT, in Fortification, a ſtrong wall built on the outſide of the rampart and parapet, to ſupport the earth, and prevent its rolling into the ditch.

REVOLUTION, in Geometry, the motion of rotation of a line about a fixed point or centre, or of any figure about a fixed axis, or upon any line or ſurface. Thus, the Revolution of a given line about a fixed centre, generates a circle; and that of a right-angled triangle about one ſide, as an axis, generates a cone; and that of a ſemicircle about its diameter, generates a ſphere or globe, &c.

Revolution, in Aſtronomy, is the period of a ſtar, planet, or comet, &c; or its courſe from any point of its orbit, till it return to the ſame again.

The planets have a twofold Revolution. The one about their own axis, uſually called their *diurnal rotation*, which conſtitutes their day. The other about the ſun, called their *annual Revolution*, or *period*, conſtituting their year.

REYNEAU (Charles-René), commonly called Father Reyneau, a noted French mathematician, was born at Briſſac in the province of Anjou, in the year 1656. At 20 years of age he entered himſelf among the Oratorians, a kind of religious order, in which the members lived in community without making any vows, and applied themſelves chiefly to the education of youth. He was ſoon after ſent, by his ſuperiors, to teach philoſophy at Pezenas, and then at Toulon. This requiring ſome acquaintance with geometry, he contracted a great affection for this ſcience, which he cultivated and improved to a great extent; in conſequence he was called to Angers in 1683, to fill the mathematical chair; and the Academy of Angers elected him a member in 1694.

In this occupation Father Reyneau, not content with making himſelf maſter of every thing worth knowing, which the modern analyſis, ſo fruitful in ſublime ſpeculations and ingenious diſcoveries, had already produced, undertook to reduce into one body, for the uſe of his ſcholars, the principal theories ſcattered here and there in Newton, Deſcartes, Leibnitz, Bernoulli, the Leipſic Acts, the Memoirs of the Paris Academy, and in other works; treaſures which by being ſo widely diſperſed, proved much leſs uſeful than they otherwiſe might have been. The fruit of this undertaking, was his *Analyſe Demontrée*, or Analyſis Demonſtrated, which he publiſhed in 2 volumes 4to, 1708.

Father Reyneau called this uſeful work, Analyſis Demonſtrated, becauſe he demonſtrates in it ſeveral methods which had not been demonſtrated by the authors of them, or at leaſt not with ſufficient perſpicuity and exactneſs; for it often happens that, in matters of this kind, a perſon is clear in a thing, without being able to demonſtrate it. Some perſons too have been ſo miſtakingly fond of glory as to make a ſecret of their demonſtrations, in order to perplex thoſe, whom it would become them much better to inſtruct. This book of Reyneau's was ſo well approved, that it ſoon became a maxim, at leaſt in France, that to follow him was the beſt, if not the only way, to make any extra-

 ordinary

ordinary progreſs in the mathematics. This was conſidering him as the firſt maſter, as the Euclid of the ſublime geometry.

Reyneau, after thus giving leſſons to thoſe who underſtood ſomething of geometry, thought proper to draw up ſome for ſuch as were utterly unacquainted with that ſcience. This was in ſome meaſure a condeſcenſion in him, but his paſſion to be uſeful made it eaſy and agreeable. In 1714 he publiſhed a volume in 4to on calculation, under the title of *Science du Calcul des Grandeurs*, of which the then Cenſor Royal, a moſt intelligent and impartial judge, ſays, in his approbation of it, that "though ſeveral books had already appeared upon the ſame ſubject, ſuch a treatiſe as that before him was ſtill wanting, as in it every thing was handled in a manner ſufficiently extenſive, and at the ſame time with all poſſible exactneſs and perſpicuity." In fact, though moſt branches of the mathematics had been well treated of before that period, there were yet no good elements, even of practical geometry. Thoſe who knew no more than what preciſely ſuch a book ought to contain, knew too little to complete a good one; and thoſe who knew more, thought themſelves probably above the taſk; whereas Reyneau poſſeſſed at once all the learning and modeſty neceſſary to undertake and execute ſuch a work.

As ſoon as the Royal Academy of Sciences at Paris, in conſequence of a regulation made in the year 1716, opened its doors to other learned men, under the title of *Free Aſſociates*, Father Reyneau was admitted of the number. The works however which we have already mentioned, beſides a ſmall piece upon *Logic*, are the only ones he ever publiſhed, or probably ever compoſed, except moſt of the materials for a ſecond volume of his *Science du Calcul*, which he left behind him in manuſcript. The laſt years of his life were attended with too much ſickneſs to admit of any extraordinary application. He died in 1728, at 72 years of age, not more regretted on account of his great learning, than of his many virtues, which all conſpired in an eminent degree to make that learning agreeable to thoſe about him, and uſeful to the world. The firſt men in France deemed it an honour and a happineſs to count him among their friends. Of this number were the chancellor of that kingdom, and Father Mallebranche, of whom Reyneau was a zealous and faithful diſciple.

RHABDOLOGY, or RABDOLOGY, in Arithmetic, a name given by Napier to a method of performing ſome of the more difficult operations of numbers by means of certain ſquare little rods. Upon theſe are inſcribed the ſimple numbers; then by ſhifting them according to certain rules, thoſe operations are performed by ſimply adding or ſubtracting of the numbers as they ſtand upon the rods. See Napier's Rabdologia, printed in 1617. See alſo the article NAPIER's *Bones*.

RHEO-STATICS, is uſed by ſome for the ſtatics, or the ſcience of the equilibrium of fluids.

RHETICUS (GEORGE JOACHIM), a noted German aſtronomer and mathematician, who was the colleague of Reinhold in the univerſity of Wittemberg, being joint profeſſors of mathematics there together. He was born at Feldkirk in Tyrol the 15th of February 1514. After imbibing the elements of the mathematics at Tiguri with Oſwald Mycone, he went to Wittemberg, where he diligently cultivated that ſcience. Here he was made maſter of philoſophy in 1535, and profeſſor in 1537. He quitted this ſituation however two years after, and went to Fruenburg to put him under the aſſiſtance of the celebrated Copernicus, being induced to this ſtep by his zeal for aſtronomical purſuits, and the great fame which Copernicus had then acquired. Rheticus aſſiſted this aſtronomer for ſome years, and conſtantly exhorted him to perfect his work, *De Revolutionibus*, which he publiſhed after the death of Copernicus, viz, in 1543, folio, at Noremberg, together with an illuſtration of the ſame in a narration, dedicated to Schoner. Here too, to render aſtronomical calculations more accurate, he began his very elaborate canon of ſines, tangents and ſecants, to 15 places of figures, and to every 10 ſeconds of the quadrant, a deſign which he did not live quite to complete. The canon of ſines however to that radius, for every 10 ſeconds, and for every ſingle ſecond in the firſt and laſt degree of the quadrant, computed by him, was publiſhed in folio at Francfort 1613 by Pitiſcus, who himſelf added a few of the firſt ſines computed to 22 places of figures. But the larger work, or canon of ſines, tangents and ſecants, to every 10 ſeconds, was perfected and publiſhed after his death, viz, in 1596, by his diſciple Valentine Otho, mathematician to the Electoral Prince Palatine; a particular account and analyſis of which work may be ſeen in the Hiſtorical Introduction to my Logarithms, pa. 9.

After the death of Copernicus, Rheticus returned to Wittemberg, viz, in 1541 or 1542, and was again admitted to his office of profeſſor of mathematics. The ſame year, by the recommendation of Melancthon, he went to Norimberg, where he found certain manuſcripts of Werner and Regiomontanus. He afterwards taught mathematics at Leipſic. From Saxony he departed a ſecond time, for what reaſon is not known, and went to Poland; and from thence to Caſſovia in Hungary, where he died December the 4th, 1576, near 63 years of age.

His *Narratio de Libris Revolutionum Copernici*, was firſt publiſhed at Gedunum in 4to, 1540; and afterwards added to the editions of Copernicus's work. He alſo compoſed and publiſhed *Ephemerides*, according to the doctrine of Copernicus, till the year 1551.

Rheticus alſo projected other works, and partly executed them, though they were never publiſhed, of various kinds, aſtronomical, aſtrological, geographical, chemical, &c; as they are more particularly mentioned in his letter to Peter Ramus in the year 1568, which Adrian Romanus inſerted in the preface to the firſt part of his Idea of Mathematics.

RHOMB SOLID, conſiſts of two equal and right cones joined together at their baſes.

RHOMBOID, or RHOMBOIDES, in Geometry, a quadrilateral figure, whoſe oppoſite ſides and angles are equal; but which is neither equilateral nor equiangular.

RHOMBUS, is an oblique equilateral parallelogram; or

or a quadrilateral figure, whose sides are equal and parallel, but the four angles not all equal, two of the opposite ones being obtuse, and the other two opposite ones acute.

The two diagonals of a Rhombus interfect at right angles; but not of a rhomboides.

As to the area of the Rhombus or rhomboides, it is found, like that of all other parallelograms, by multiplying the length or base by the perpendicular breadth.

Rhombus-*Sail*. See Rhomb-*Sail*.

RHUMB, Rumb, or Rum, in Navigation, a vertical circle of any given place; or the intersection of a part of such a circle with the horizon. Rhumbs therefore coincide with points of the world, or of the horizon. And hence mariners distinguish the Rhumbs by the same names as the points and winds. But we may observe, that the Rhumbs are denominated from the points of the compass in a different manner from the winds: thus, at sea, the north-east wind is that which blows from the north east point of the horizon towards the ship in which we are; but we are said to sail upon the north-east Rhumb, when we go towards the north-east.

They usually reckon 32 Rhumbs, which are represented by the 32 lines in the rose or card of the compass.

Aubin defines a Rhumb to be a line on the terrestrial globe, or sea-compass, or sea-chart, representing one of the 32 winds which serve to conduct a vessel. So that the Rhumb a vessel pursues is conceived as its route, or course.

Rhumbs are divided and subdivided like points of the compass. Thus, the whole Rhumb answers to the cardinal point. The half Rhumb to a collateral point, or makes an angle of 45 degrees with the former. And the quarter Rhumb makes an angle of 22° 30′ with it. Also the half-quarter Rhumb makes an angle of 11° 15′ with the same.

For a table of the Rhumbs, or points, and their distances from the meridian, see Wind.

Rhumb-Line, *Loxodromia*, in Navigation, is a line prolonged from any point of the compass in a nautical chart, except the four cardinal points: or it is the line which a ship, keeping in the same collateral point, or rhumb, describes throughout its whole course.

The chief property of the Rhumb-line, or loxodromia, and that from which some authors define it, is, that it cuts all the meridians in the same angle.

This angle is called the *angle of the Rhumb*, or the *loxodromic* angle. And the angle which the Rhumb-line makes with any parallel to the equator, is called the *complement of the Rhumb*.

An idea of the origin and properties of the Rhumb-line, the great foundation of Navigation, may be conceived thus: a vessel beginning its course, the wind by which it is driven makes a certain angle with the meridian of the place; and as we shall suppose that the vessel runs exactly in the direction of the wind, it makes the same angle with the meridian which the wind makes. Supposing then the wind to continue the same, as each point or instant of the progress may be esteemed the beginning, the vessel always makes the same angle with the meridian of the place where it is each moment, or in each point of its course which the wind makes.

Now a wind, for example, that is north-east, and which consequently makes an angle of 45 degrees with the meridian, is equally north-east wherever it blows, and makes the same angle of 45 degrees with all the meridians it meets. And therefore a vessel, driven by the same wind, always makes the same angle with all the meridians it meets with on the surface of the earth.

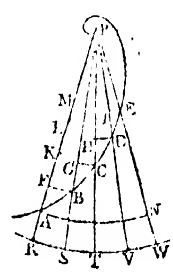
If the vessel sail north or south, it describes the great circle of a meridian. If it runs east or west, it cuts all the meridians at right angles, and describes either the circle of the equator, or else a circle parallel to it.

But if the vessel sails between the two, it does not then describe a circle; since a circle, drawn obliquely to a meridian, would cut all the meridians at unequal angles, which the vessel cannot do. It describes therefore another curve, the essential property of which is, that it cuts all the meridians in the same angle, and it is called the *loxodromy*, or *loxodromic curve*, or *Rhumb-line*.

This curve, on the globe, is a kind of spiral, tending continually nearer and nearer to the pole, and making an infinite number of circumvolutions about it, but without ever arriving exactly at it. But the spiral Rhumbs on the globe become proportional spirals in the stereographic projection on the plane of the equator.

The length of a part of this Rhumb-line, or spiral, then, is the distance run by the ship while she keeps in the same course. But as such a spiral line would prove very perplexing in the calculation, it was necessary to have the ship's way in a right line; which right line however must have the essential properties of the curve line, viz, to cut all the meridians at right angles. The method of effecting which, see under the article Chart.

The arc of the Rhumb-line is not the shortest distance between any two places through which it passes; for the shortest distance, on the surface of the globe, is an arc of the great circle passing through those places; so that it would be a shorter course to sail on the arc of this great circle: but then the ship cannot be kept in the great circle, because the angle it makes with the meridians is continually varying, more or less.



Let P be the pole, RW the equator, ABCDEP a spiral Rhumb, divided into an indefinite number of equal parts at the points B, C, D, &c; through which are drawn the meridians, PS, PT, PV, &c, and the parallels FB, KC, LD, &c, also draw the parallel AN. Then, as a ship sails along the Rhumb-line towards the pole, or in the direction ABCD &c, from A to E, the distance sailed AE is

is made up of all the small equal parts of the Rhumb AB + BC + CD + DE; and

the sum of all the small differences of latitude AF + BG + CH + DI make up the whole difference of latitude AM or EN; and

the sum of all the small parallels FB + GC + HD + IE is what is called the departure in plane sailing; and ME is the meridional distance, or distance between the first and last meridians, measured on the last parallel; also RW is the difference of longitude, measured on the equator. So that these last three are all different, viz, the departure, the meridional distance, and the difference of longitude.

If the ship sail towards the equator, from E to A; the departure, difference of latitude, and difference of longitude, will be all three the same as before; but the meridional distance will now be AN, instead of ME; the one of these AN being greater than the departure FB + GC + HD + IE, and the other ME is less than the same; and indeed that departure is nearly a mean proportional between the two meridional distances ME, AN. Other properties are as below.

1. All the small elementary triangles ABF, BCG, CDH, &c, are mutually similar and equal in all their parts. For all the angles at A, B, C, D, &c are equal, being the angles which the Rhumb makes with the meridians, or the angles of the course; also all the angles F, G, H, I, are equal, being right angles; therefore the third angles are equal, and the triangles all similar. Also the hypotenuses AB, BC, CD, &c, are all equal by the hypothesis; and consequently the triangles are both similar and equal.

2. As radius : distance run AE
:: sine of course $\angle$ A : departure FB + GC &c,
:: cosin. of course $\angle$ A : dif. of lat. AM.

For in any one ABF of the equal elementary triangles, which may be considered as small right-angled plane triangles, it is, as rad. or sin. $\angle$ F : sin. course A :: AB : FB :: (by composition) the sum of all the distances AB + BC + CD &c : the sum of all the departures FB + GC + HD &c.

And, in like manner, as radius : cos. course A :: AB : AF :: AB + BC &c : AF + BG &c.

Hence, of these four things, the course, the difference of latitude, the departure, and the distance run, having any two given, the other two are found by the proportions above in this article.

By means of the departure, the length of the Rhumb, or distance run, may be connected with the longitude and latitude, by the following two theorems.

3. As radius : half the sum of the cosines of both the latitudes, of A and E :: dif. of long. RW : departure.

Because RS : FB :: radius : sine of PA or cos. RA,
and VW : IE :: radius : sine of PE or cos. EW.

4. As radius : cos. middle latitude :: dif. of longitude : departure.—Because cosine of middle latitude is nearly equal to half the sum of the cosines of the two extreme latitudes.

RICCIOLI (JOANNES BAPTISTA), a learned Italian astronomer, philosopher, and mathematician, was born in 1598, at Ferrara, a city in Italy, in the dominions of the Pope. At 16 years of age he was admitted into the society of the Jesuits. He was endowed with uncommon talents, which he cultivated with extraordinary application; so that the progress he made in every branch of literature and science was surprising. He was first appointed to teach rhetoric, poetry, philosophy, and scholastic divinity, in the Jesuits' colleges at Parma and Bologna; yet applied himself in the mean time to making observations in geography, chronology, and astronomy. This was his natural bent, and at length he obtained leave from his superiors to quit all other employment, that he might devote himself entirely to those sciences

He projected a large work, to be divided into three parts, and to contain as it were a complete system of philosophical, mathematical, and astronomical knowledge. The first of these parts, which regards astronomy, came out at Bologna in 1651, 2 vols. folio, with this title, *J. B. Riccioli Almagestum Novum, Astronomiam veterem novamque complectens, observationibus aliorum et propriis, novisque theorematibus, problematibus ac tabulis promotam.* Riccioli imitated Ptolomy in this work, by collecting and digesting into proper order, with observations, every thing ancient and modern, which related to his subject; so that Gassendus very justly called his work, "Promptuarium et thesaurum ingentem Astronomiæ."

In the first volume of this work, he treats of the sphere of the world, of the sun and moon, with their eclipses; of the fixed stars, of the planets, of the comets and new stars, of the several mundane systems, and six sections of general problems serving to astronomy, &c. —In the second volume, he treats of trigonometry, or the doctrine of plane and spherical triangles; proposes to give a treatise of astronomical instruments, and the optical part of astronomy (which part was never published); treats of geography, hydrography, with an epitome of chronology.—The third, comprehends observations of the sun, moon, eclipses, fixed stars and planets, with precepts and tables of the primary and secondary motions, and other astronomical tables.

Riccioli printed also, two other works, in folio, at Bologna, viz,

2. *Astronomia Reformata*, 1665: the design of which was, that of considering the various hypotheses of several astronomers, and the difficulty thence arising of concluding any thing certain, by comparing together all the best observations, and examining what is most certain in them, thence to reform the principles of astronomy.

3. *Chronologia Reformata*, 1669.

Riccioli died in 1671, at 73 years of age.

RICOCHET Firing, in the Military Art, is a method of firing with small charges, and pieces elevated but in a small degree, as from 3 to 6 degrees. The word signifies duck-and drake, or rebounding, because the ball or shot, thus discharged, goes bounding and rolling along, and killing or destroying every thing in its way, like the bounding of a flat stone along the surface of water when thrown almost horizontally.

RIDEAU,

RIDEAU, in Fortification, a ſmall elevation of earth, extending itſelf lengthways on a plain; ſerving to cover a camp, or give an advantage to a poſt.

Rideau is ſometimes alſo uſed for a trench, the earth of which is thrown up on its ſide, to ſerve as a parapet for covering the men.

RIFLE Guns, in the Military Art, are thoſe whoſe barrels, inſtead of being ſmooth on the inſide, are formed with a number of ſpiral channels, making each about a turn and a half in the length of the barrel. Theſe carry their balls both farther and truer than the common pieces. For the nature and qualities of them, ſee Robins's Tracts, vol. 1 pa 328 &c.

RIGEL, in Aſtronomy. See Regel.

RIGHT, in Geometry, ſomething that lies evenly or equally, without inclining or bending one way or another. Thus, a Right-line is that whoſe ſmall parts all tend the ſame way. In this ſenſe, Right means the ſame as ſtraight, as oppoſed to curved or crooked.

Right-*Angle*, that which one line makes with another upon which it ſtands ſo as to incline neither to one ſide nor the other. And in this ſenſe the word Right ſtands oppoſed to oblique.

Right-*angled*, is ſaid of a figure when its ſides are at Right angles or perpendicular to each other.—This ſometimes holds in all the angles of the figure, as in ſquares and rectangles; ſometimes only in part, as in right-angled triangles.

Right *Cone*, or *Cylinder*, or priſm, or pyramid, one whoſe axis is at right-angles to the baſe.

Right-*lined Angle*, one formed by Right lines.

Right *Sine*, one that ſtands at Right-angles to the diameter; as oppoſed to verſed ſine.

Right *Sphere*, is that where the equator cuts the horizon at Right angles; or that which has the poles in the horizon, and the equinoctial in the zenith.

Such is the poſition of the ſphere with regard to thoſe who live at the equator, or under the equinoctial. The conſequences of which are; that they have no latitude, nor elevation of the pole; they ſee both poles of the world, and all the ſtars riſe, culminate and ſet; alſo the ſun always riſes and deſcends at Right angles, and makes their days and nights equal. In a Right ſphere, the horizon is a meridian; and if the ſphere be ſuppoſed to revolve, all the meridians ſucceſſively become horizons, one after another.

Right Aſcenſion, Deſcenſion, Parallax, &c. See the reſpective Articles.

Right *Circle*, in the Stereographic Projection of the Sphere, is a circle at Right angles to the plane of projection, or that is projected into a Right line.

Right *Sailing*, is that in which a voyage is performed on ſome one of the four cardinal points, eaſt, weſt, north, or ſouth.

If the ſhip ſail on a meridian, that is, north or ſouth, ſhe does not alter her longitude, but only changes the latitude, and that juſt as much as the number of degrees ſhe has run.

But if ſhe ſail on the equator, directly eaſt or weſt, ſhe varies not her latitude, but only changes the longitude, and that juſt as much as the number of degrees ſhe has run.

And if ſhe ſail directly eaſt or weſt upon any parallel, ſhe again does not change her latitude, but only the longitude; yet not the ſame as the number of degrees of a great circle ſhe hath ſailed, as on the equator, but more, according as the parallel is remoter from the equinoctial towards the pole. For the leſs any parallel is, the greater is the difference of longitude anſwering to the diſtance run.

RIGIDITY, a brittle hardneſs; or that kind of hardneſs which is ſuppoſed to ariſe from the mutual indentation of the component particles within one another. Rigidity is oppoſed to ductility, malleability, &c.

RING, in Aſtronomy and Navigation, an inſtrument uſed for taking the ſun's altitude &c. It is uſually of braſs, about 9 inches diameter, ſuſpended by a little ſwivel, at the diſtance of 45° from the point of which is a perforation, which is the centre of a quadrant of 90° divided in the inner concave ſurface.

To uſe it, let it be held up by the ſwivel, and turned round to the ſun, till his rays, falling through the hole, make a ſpot among the degrees, which marks the altitude required.

This inſtrument is preferred before the aſtrolabe, becauſe the diviſions are here larger than on that inſtrument.

Ring, of Saturn, is a thin, broad, opaque circular arch, encompaſſing the body of that planet, like the wooden horizon of an artificial globe, without touching it, and appearing double, when ſeen through a good teleſcope.

This Ring was firſt diſcovered by Huygens, who, after frequent obſervation of the planet, perceived two lucid points, like anſæ or handles, ariſing out from the body in a right line. Hence as in ſubſequent obſervations he always found the ſame appearance, he concluded that Saturn was encompaſſed with a permanent Ring; and accordingly produced his New Syſtem of Saturn, in 1659. However, Galileo firſt diſcovered that the figure of Saturn was not round.

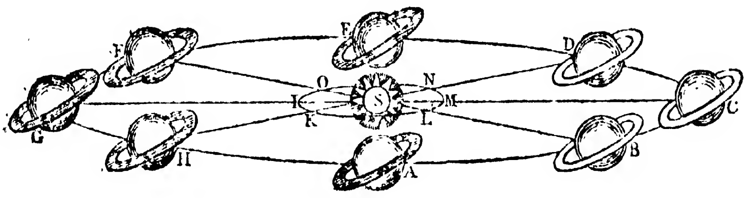
Huygens makes the ſpace between the globe of Saturn and the Ring equal to the breadth of the Ring, or rather more, being about 22000 miles broad; and the greateſt diameter of the Ring, in proportion to that of the globe, as 9 to 4 But Mr. Pound, by an excellent micrometer applied to the Huygenian glaſs of 123 feet, determined this proportion, more exactly, to be as 7 to 3.

Obſervations have alſo determined, that the plane of the Ring is inclined to the plane of the ecliptic in an angle of 30 degrees; that the Ring probably turns, in the direction of its plane, round its axis, becauſe when it is almoſt edgewiſe to us, it appears rather thicker on one ſide of the planet than on the other; and the thickeſt edge has been ſeen on different ſides at different times: the ſun ſhines almoſt 15 of our years together on one ſide of Saturn's Ring without ſetting, and as long on the other in its turn; ſo that the Ring is viſible to the inhabitants of that planet for almoſt 15 of

of our years, and as long invisible, by turns, if its axis has no inclination to its Ring; but if the axis of the planet be inclined to the Ring, ex. gr. about 30 degrees, the Ring will appear and disappear once every natural day to all the inhabitants within 30 degrees of the equator, on both sides, frequently eclipsing the sun in a Saturnian day. Moreover, if Saturn's axis be so inclined to his Ring, it is perpendicular to his orbit; by which the inconvenience of different seasons to that planet is avoided.

This Ring, seen from Saturn, appears like a large luminous arch in the heavens, as if it did not belong to the planet.

When we see the Ring most open, its shadow upon the planet is broadest; and from that time the shadow grows narrower, as the Ring appears to do to us; until, by Saturn's annual motion, the sun comes to the plane of the Ring, or even with its edge; which, being then directed towards us, becomes invisible, on account of its thinness.



The phenomena of Saturn's Ring are illustrated by a view of this figure. Let S be the sun, ABCDEFGH Saturn's orbit, and IKLMNO the earth's orbit. Both Saturn and the earth move according to the order of the letters; and when Saturn is at A, his Ring is turned edgewise to the sun S, and he is then seen from the earth as if he had lost his Ring, let the earth be in any part of its orbit whatever, except between N and O; for whilst it describes that space, Saturn is apparently so near the sun as to be hid in his beams. As Saturn goes from A to C, his Ring appears more and more open to the earth; at C the Ring appears most open of all; and seems to grow narrower and narrower as Saturn goes from C to E; and when he comes to E, the Ring is again turned edgewise both to the sun and earth; and as neither of its sides is illuminated, it is invisible to us, because its edge is too thin to be perceptible; and Saturn appears again as if he had lost his Ring. But as he goes from E to G, his Ring opens more and more to our view on the under side; and seems just as open at G as it was at C, and may be seen in the night time from the earth in any part of its orbit, except about M, when the sun hides the planet from our view.

As Saturn goes from G to A, his Ring turns more and more edgewise to us, and, therefore, it seems to grow narrower and narrower; and at A it disappears as before.

Hence, while Saturn goes from A to E, the sun shines on the upper side of his Ring, and the under side is dark; and whilst he goes from E to A, the sun shines on the under side of his Ring, and the upper side is dark. The Ring disappears twice in every annual revolution of Saturn, viz, when he is in the 19th degree of Pisces and of Virgo, and when Saturn is in the middle between these points, or in the 19th degree either of Gemini or of Sagittarius, his Ring appears most open to us; and then its longest diameter is to its shortest, as 9 to 4. Ferguson's Astr. sect. 204.

There are various hypotheses concerning this Ring. Kepler, in his Epitom. Astron. Copern. and after him Dr. Halley, in his Enquiry into the Causes of the Variation of the Needle, Phil. Transf. No 195, suppose our earth may be composed of several crusts or shells, one within another, and concentric to each other. If this be the case, it is possible the Ring of Saturn may be the fragment or remaining ruin of his formerly exterior shell, the rest of which is broken or fallen down upon the body of the planet. And some have supposed that the Ring may be a congeries or series of moons revolving about the planet.

Later observations have thrown much more light upon this curious phenomenon, especially respecting its dimensions, and rotation, and division into two or more parts. De la Lande and De la Place say, that Cassini saw the breadth of the Ring divided into two separate parts that are equal, or nearly so. Mr. Short assured M. De la Lande, that he had seen many divisions upon the Ring, with his 12 feet telescope. And Mr. Hadley, with an excellent $5\frac{1}{2}$ feet reflector, saw the Ring divided into two parts. Several excellent theories have been given in the French Memoirs, particularly by De la Place, contending for the division of the Ring into many parts. But finally the observations of Dr. Herschel, in several volumes of the Philos. Transf. seem to confirm the division into two concentric parts only. The dimensions of these two Rings, and the space between them, he states in the following proportion to each other.

	Miles.
Inner diam. of smaller Ring	146345
Outside diam. of ditto	184393
Inner diam. of larger Ring	190248
Outside diam. of ditto	204883
Breadth of the inner Ring	20000
Breadth of the outer Ring	7200
Breadth of the vacant space	2839
Ring revolves in its own plane, in $10^h\ 32'\ 15''.4$.	

So that the outside diameter of the larger Ring is almost 26 times the diameter of the earth.

Dr. Herschel adds, Some theories and observations of

of other persons, "lead us to consider the question, whether the construction of this Ring is of a nature so as permanently to remain in its present state? or whether it be liable to continual and frequent changes, in such a manner as in the course of not many years, to be seen subdivided into narrow slips, and then again as united into one or two circular planes only. Now, without entering into a discussion, the mind seems to revolt, even at first sight, against an idea of the chaotic state in which so large a mass as the Ring of Saturn must needs be, if phenomena like these can be admitted. Nor ought we to indulge a suspicion of this being a reality, unless repeated and well-confirmed observations had proved, beyond a doubt, that this Ring was actually in so fluctuating a condition." But from his own observations he concludes, "It does not appear to me that there is a sufficient ground for admitting the Ring of Saturn to be of a very changeable nature, and I guess that its phenomena will hereafter be so fully explained, as to reconcile all observations. In the mean while, we must withhold a final judgment of its construction, till we can have more observations. Its division however into two very unequal parts, can admit of no doubt." See Philos. Trans. vol. 80 pa. 4, 481 &c, and the vol. for 1792, pa. 1 &c. also Hist. de l'Acad. des Scienc. de Paris, 1787, pa. 249 &c.

RINGS *of Colours*, in Optics, a phenomenon first observed in thin plates of various substances, by Boyle, and Hook, but afterwards more fully explained by Newton.

Mr. Boyle having exhibited a variety of colours in colourless liquors, by shaking them till they rose in bubbles, as well as in bubbles of soap and water, and also in turpentine, procured glass blown so thin as to exhibit similar colours; and he observes, that a feather of a proper shape and size, and also a black ribband, held at a proper distance between his eye and the sun, shewed a variety of little rainbows, as he calls them, with very vivid colours. Boyle's Works by Shaw, vol. 2, p. 70. Dr. Hook, about nine years after the publication of Mr. Boyle's Treatise on Colours, exhibited the coloured bubbles of soap and water, and observed, that though at first it appeared white and clear, yet as the film of water became thinner, there appeared upon it all the colours of the rainbow. He also described the beautiful colours that appear in thin plates of Muscovy glass; which appeared, through the microscope, to be ranged in Rings surrounding the white specks or flaws in them, and with the same order of colours as those of the rainbow, and which were often repeated ten times. He also took two thin pieces of glass, ground plane and polished, and putting them one upon another, pressed them till there began to appear a red coloured spot in the middle; and pressing them closer, he observed several Rings of colours encompassing the first place, till, at last, all the colours disappeared out of the middle of the circles, and the central spot appeared white. The first colour that appeared was red, then yellow, then green, then blue, then purple; then again red, yellow, green, blue, and purple; and again in the same order; so that he sometimes counted nine or ten of these circles, the red immediately next to the purple; and the last colour that appeared before the white was blue; so that it began with red, and ended with purple. These Rings, he says, would change their places, by changing the position of the eye, so that, the glasses remaining the same, that part which was red in one position of the eye, was blue in a second, green in the third, &c. Birch's Hist. of the Royal Society, vol. 3, pa. 54.

Newton, having demonstrated that every different colour consists of rays which have a different and specific degree of refrangibility, and that natural bodies appear of this or that colour, according to their disposition to reflect this or that species of rays (see COLOUR), pursued the hint suggested by the experiments of Dr. Hook, already recited, and casually noticed by himself, with regard to thin transparent substances. Upon compressing two prisms hard together, in order to make their sides touch one another, he observed, that in the place of contact they were perfectly transparent, which appeared like a dark spot, and when it was looked through, it seemed like a hole in that air, which was formed into a thin plate, by being impressed between the glasses. When this plate of air, by turning the prisms about their common axis, became so little inclined to the incident rays, that some of them began to be transmitted, there arose in it many slender arcs of colours, which increased, as the motion of the prisms was continued, and bended more and more about the transparent spot, till they were completed into circles, or Rings, surrounding it; and afterwards they became continually more and more contracted.

By another experiment, with two object glasses, he was enabled to observe distinctly the order and quality of the colours from the central spot, to a very considerable distance. Next to the pellucid central spot, made by the contact of the glasses, succeeded blue, white, yellow, and red. The next circuit immediately surrounding these, consisted of violet, blue, green, yellow, and red. The third circle of colours was purple, blue, green, yellow, and red. The fourth circle consisted of green and red. All the succeeding colours became more and more imperfect and dilute, till, after three or four revolutions, they ended in perfect whiteness.

When these Rings were examined in a darkened room, by the coloured light of a prism cast on a sheet of white paper, they became more distinct, and visible to a far greater number than in the open air. He sometimes saw more than twenty of them, whereas in the open air he could not discern above eight or nine.

From other curious observations on these Rings, made by different kinds of light thrown upon them, he inferred, that the thicknesses of the air between the glasses, where the Rings are successively made, by the limits of the seven colours, red, orange, yellow, green, blue, indigo, and violet, in order, are one to another as the cube roots of the squares of the eight lengths of a chord, which sound the notes in an octave, sol, la, fa, sol, la, mi, fa, sol; that is, as the cube roots of the squares of the numbers $1, \frac{8}{9}, \frac{5}{6}, \frac{3}{4}, \frac{2}{3}, \frac{3}{5}, \frac{9}{16}, \frac{1}{2}$. These Rings appeared of that prismatic colour, with which they were illuminated, and by projecting the prismatic colours immediately upon the glasses, he found that the light, which fell on the dark spaces between the

the coloured Rings, was tranfmitted through the glaffes without any change of colour. From this circumftance he thought that the origin of thefe Rings is manifeft; becaufe the air between the glaffes is difpofed according to its various thicknefs, in fome places to reflect, and in others to tranfmit the light of any particular colour, and in the fame place to reflect that of one colour, where it tranfmits that of another.

In examining the phenomena of colours made by a denfer medium furrounded by a rarer, fuch as thofe which appear in plates of Mufcovy glafs, bubbles of foap and water, &c, the colours were found to be much more vivid than the others, which were made with a rarer medium furrounded by a denfer.

From the preceding phenomena it is an obvious deduction, that the tranfparent parts of bodies, according to their feveral feries, reflect rays of one colour and tranfmit thofe of another; on the fame account that thin plates, or bubbles, reflect or tranfmit thofe rays, and this Newton fuppofed to be the reafon of all their colours. Hence alfo he has inferred, that the fize of thofe component parts of natural bodies that affect the light, may be conjectured by their colours. See Colour and Reflection.

Newton, purfuing his difcoveries concerning the colours of thin fubftances, found that the fame were alfo produced by plates of a confiderable thicknefs, divifible into leffer thickneffes. The Rings formed in both cafes have the fame origin, with this difference, that thofe of the thin plates are made by the alternate reflexions and tranfmiffions of the rays at the fecond furface of the plate, after one paffage through it; but that, in the cafe of a glafs fpeculum, concave on one fide, and convex on the other, and quickfilvered over on the convex fide, the rays go through the plate and return before they are alternately reflected and tranfmitted. Newton's Optics, p. 169, &c. or Newton's Opera, Horfley's edit. vol. 4, p. 121, &c. p. 184, &c.

The abbé Mazeas, in his experiments on the Rings of colours that appear in thin plates, has difcovered feveral important circumftances attending them, which were overlooked by the fagacious Newton, and which tend to invalidate his theory for explaining them. In rubbing the flat fide of an object glafs againft another piece of flat and fmooth glafs, he found that they adhered very firmly together after this friction, and that the fame colours were exhibited between thefe plane glaffes, which Newton had obferved between the convex object glafs of a telefcope, and another that was plane; and that the colours were in proportion to their adhefion. When the furfaces of pieces of glafs, that are tranfparent and well polifhed, are equally preffed, a refiftance will be perceived; and wherever this is felt, two or three very fine curve lines will be difcovered, fome of a pale red, and others of a faint green. If the friction be continued, the red and green lines increafe in number at the place of contact; the colours being fometimes mixed without any order, and fometimes difpofed in a regular manner; in which cafe the coloured lines are generally concentric circles, or ovals, more or lefs elongated, as the furfaces are more or lefs united.

When the colours are formed, the glaffes adhere with confiderable force; but if the glaffes be feparated fuddenly, the colours will appear immediately upon their being put together, without the leaft friction. Beginning with the flighteft touch, and increafing the preffure by infenfible degrees, there firft appears an oval plate of a faint red, and in the centre of it a fpot of light green, which enlarges by the preffure, and becomes a green oval, with a red fpot in the centre; and this enlarging in its turn, difcovers a green fpot in its centre. Thus the red and green fucceed one another in turns, affuming different fhades, and having other colours mixed with them. The greateft difference between thefe colours exhibited between plane furfaces, and thofe by curve ones, is, that, in the former cafe, preffure alone will not produce them, except in the cafe above mentioned.

In rubbing together two prifms, with very fmall refracting angles, which were joined fo as to form a parallelopiped, the colours appeared with a furprifing luftre at the places of contact, and differently coloured ovals appeared.

In the centre there was a black fpot, bordered by a deep purple; next to this appeared violet, blue, orange, red tinged with purple, light green, and faint purple.

The other Rings appeared to the naked eye to confift of nothing but faint reds and greens. When thefe coloured glaffes were fufpended over the flame of a candle, the colours difappeared fuddenly, though they ftill adhered; but being fuffered to cool, the colours returned to their former places, in the fame order as before. At firft the abbé Mazeas had no doubt but that thefe colours were owing to a thin plate of air between the glaffes, to which Newton has afcribed them; but the remarkable difference in the circumftances attending thofe produced by the flat plates and thofe produced by the object glaffes of Newton, convinced him that the air was not the caufe of this appearance. The colours of the flat plates vanifhed at the approach of flame, but thofe of the object glaffes did not. Nor was this difference owing to the plane glaffes being lefs compreffed than the convex ones; for though the former were compreffed ever fo much by a pair of forceps, it did not in the leaft hinder the effect of the flame. Afterwards he put both the plane glaffes and the convex ones into the receiver of an air-pump, fufpending the former by a thread, and keeping the latter compreffed by two ftrings; but he obferved no change in the colours of either of them, in the moft perfect vacuum that he could make. Sufpecting ftill that the air adhered to the furface of the glaffes, fo as not to be feparated from them by the force of the pump, he had recourfe to other experiments, which rendered it ftill more improbable that the air fhould be the caufe of thefe colours. Having laid the coloured plates, after warming them gradually, on burning coals; and thus, when they were nearly red, rubbing them together, he obferved the fame coloured circles and ovals as before. When he ceafed to prefs upon them, the colours feemed to vanifh; but they returned, as he renewed the friction. In order to determine whether the colours were owing to the thicknefs of fome matter interpofed between the glaffes, he rubbed them together

ther with ſuet and other ſoft ſubſtances between them; yet his endeavour to produce the colours had no effect. However by continuing the friction with ſome degree of violence, he obſerved, that a candle appeared through them encompaſſed with two or three concentric circles, and with a lively red inclining to yellow, and a green like that of an emerald, and at length the Rings acquired the colours of blue, yellow, and violet. The abbé was confirmed in his opinion that there muſt be ſome error in Newton's hypotheſis, by conſidering that, according to his meaſures, the colours of the plates varied with the difference of a millionth part of an inch; whereas he was ſatiſfied that there muſt have been much greater differences in the diſtance between his glaſſes, when the colours remained unchanged. From other experiments he concluded, that the plate of water introduced between the glaſſes was not the cauſe of their colours, as Newton apprehended; and that the coloured Rings could not be owing to the compreſſion of the glaſſes. After all, he adds, that the theory of light, thus reflected from thin plates, is too delicate a ſubject to be completely aſcertained by a ſmall number of obſervations. Berlin Mem. for 1752, or Memoires Preſentes, vol. 2, pa. 28—43. M. du Tour repeated the experiments of the abbé Mazeas, and added ſome obſervations of his own. See Mem. Preſ. vol. 4, pa. 288.

Muſſchenbroeck is alſo of opinion, that the colours of thin plates do not depend upon the air; but as to the cauſe of them, he acknowledges that he could not ſatisfy himſelf about it. Introd. ad Phil. Nat. vol. 2, p. 738.

See on this ſubject Prieſtley's Hiſt. of Light, &c. per. 6, ſect. 5, pa. 498, &c.

For an account of the Rings of colours produced by electrical exploſions, ſee *Colours* of *natural bodies*, CIRCULAR *ſpots*, and FAIRY *circles*.

RISING, in Aſtronomy, the appearance of the ſun, or a ſtar, or other luminary, above the horizon, which before was hid beneath it.

By reaſon of the refraction of the atmoſphere, the heavenly bodies always appear to riſe before their time; that is, they are ſeen above the horizon, while they are really below it, by about 33′ of a degree.

There are three poetical kinds of Riſing of the ſtars. See ACRONICAL, COSMICAL, and HELIACAL.

RIVER, in Geography, a ſtream or current of freſh water, flowing in a bed or channel, from a ſource or ſpring, into the ſea.

When the ſtream is not large enough to bear boats, or ſmall veſſels, loaden, it is properly called by the diminutive, *rivulet* or *brook;* but when it is conſiderable enough to carry larger veſſels, it is called by the general name River.

Rivulets have their riſe ſometimes from great rains, or great quantities of thawed ſnow, eſpecially in mountainous places; but they more uſually ariſe from ſprings.

Rivers themſelves all ariſe either from the confluence of ſeveral rivulets, or from lakes.

RIVER, in Phyſics, denotes a ſtream of water running by its own gravity, from the more elevated parts of the earth towards the lower parts, in a natural bed or channel open above.

When the channel is artificial, or cut by art, it is called a canal; of which there are two kinds, viz, that whoſe channel is every where open, without ſluices, called an artificial River, and that whoſe water is kept up and let off by means of ſluices, which is properly a *canal*.

Modern philoſophers endeavour to reduce the motion and flux of Rivers to preciſe laws; and with this view they have applied geometry and mechanics to this ſubject; ſo that the doctrine of Rivers is become a part of the new philoſophy.

The authors who have moſt diſtinguiſhed themſelves in this branch, are the Italians, the French, and the Dutch, but eſpecially the firſt, and among them more eſpecially Gulielmini, and Ximenes.

Rivers, ſays Gulielmini, uſually have their ſources in mountains or elevated grounds; in the deſcent from which it is moſtly that they acquire the velocity, or acceleration, which maintains their future current. In proportion as they advance farther, this velocity diminiſhes, on account of the continual friction of the water againſt the bottom and ſides of the channel; as well as from the various obſtacles they meet with in their progreſs, and from their arriving at length in plains where the deſcent is leſs, and conſequently their inclination to the horizon greater. Thus the Reno, a River in Italy, which he ſays gave occaſion, in ſome meaſure, to his ſpeculations, is found to have near its mouth a declivity of ſcarce 52 ſeconds.

When the acquired velocity is quite ſpent, through the many obſtacles, ſo that the current becomes horizontal, there will then nothing remain to propagate the motion, and continue the ſtream, but the depth, or the perpendicular preſſure of the water, which is always proportional to the depth. And, happily for us, this reſource increaſes, as the occaſion for it increaſes; for in proportion as the water loſes of the velocity acquired by the deſcent, it riſes and increaſes in its depth.

It appears from the laws of motion pertaining to bodies moved on inclined planes, that when water flows freely upon an inclined bed, it acquires a velocity, which is always as the ſquare root of the quantity of deſcent of the bed. But in an horizontal bed, opened by ſluices or otherwiſe, at one or both ends, the water flows out by its gravity alone.

The upper parts of the water of a River, and thoſe at a diſtance from the banks, may continue to flow, from the ſimple cauſe or principle of declivity, how ſmall ſoever it be; for not being detained by any obſtacle, the minuteſt difference of level will have its effect; but the lower parts, which roll along the bottom, will ſcarce be ſenſible of ſo ſmall a declivity; and will only have what motion they receive from the preſſure of the ſuperincumbent waters.

The greateſt velocity of a River is about the middle of its depth and breadth, or the point which is the fartheſt poſſible from the ſurface of the water, and from the bottom and ſides of the bed or channel. Whereas, on the contrary, the leaſt velocity of the water is at the bottom and ſides of the bed, becauſe there the reſiſtance ariſing from friction is the greateſt, which is communicated to the other parts of the ſection of the

River inverſely as the diſtances from the bottom and ſides.

To find whether the water of a River, almoſt horizontal, flows by means of the velocity acquired in its deſcent, or by the preſſure of its depth; ſet up an obſtacle perpendicular to it; then if the water riſe and ſwell immediately againſt the obſtacle, it runs by virtue of its fall; but if it firſt ſtop a little while, in virtue of its preſſure.

Rivers, according to this author, almoſt always make their own beds. If the bottom have originally been a large declivity, the water, hence falling with a great force, will have ſwept away the moſt elevated parts of the ſoil, and carrying them lower down, will gradually render the bottom more nearly horizontal.

The water having made its bed horizontal, becomes ſo itſelf, and conſequently takes with the leſs force againſt the bottom, till at length that force becomes only equal to the reſiſtance of the bottom, which is now arrived at a ſtate of permanency, at leaſt for a conſiderable time; and the longer according to the quality of the ſoil, clay and chalk reſiſting longer than ſand or mud.

On the other hand, the water is continually wearing away the brims of its channel, and this with the more force, as, by the direction of its ſtream, it impinges more directly againſt them. By this means it has a continual tendency to render them parallel to its own courſe. At the ſame time that it has thus rectified its edges, it has widened its own bed, and thence becoming leſs deep, it loſes part of its force and preſſure: this it continues to do till there is an equilibrium between the force of the water and the reſiſtance of its banks, and then they will remain without farther change. And it appears by experience that theſe equilibriums are all real, as we find that Rivers only dig and widen to a certain pitch.

The very reverſe of all theſe things does alſo on ſome occaſions happen. Rivers, whoſe waters are thick and muddy, raiſe their bed, by depoſiting part of the heterogeneous matters contained in them: they alſo contract their banks, by a continual oppoſition of the ſame matter, in bruſhing over them. This matter, being thrown aſide far from the ſtream of water, might even ſerve, by reaſon of the dullneſs of the motion, to form new banks.

If theſe various cauſes of reſiſtance to the motion of flowing waters did not exiſt, viz, the attraction and continual friction of the bottom and ſides, the inequalities in both, the windings and angles that occur in their courſe, and the diminution of their declivity the farther they recede from their ſprings, the velocity of their currents would be accelerated to 10, 15, or even 20 times more than it is at preſent in the ſame Rivers, by which they would become abſolutely unnavigable.

The union of two Rivers into one, makes the whole flow the ſwifter, becauſe, inſtead of the friction of four ſhores, they have only two to overcome, and one bottom inſtead of two; alſo the ſtream, being farther diſtant from the banks, goes on with the leſs interruption, beſides, that a greater quantity of water, moving with a greater velocity, digs deeper in the bed, and of courſe retrenches of its former width. Hence alſo it is, that Rivers, by being united, take up leſs ſpace on the ſurface of the earth, and are more advantageous to low grounds, which drain their ſuperfluous moiſture into them, and have alſo leſs occaſion for dykes to prevent their overflowing.

A very good and ſimple method of meaſuring the velocity of the current of a River, or canal, is the following. Take a cylindrical piece of dry, light wood, and of a length ſomething leſs than the depth of the water in the River; about one end of it let there be ſuſpended as many ſmall weights, as may keep the cylinder in a vertical or upright poſition, with its head juſt above water. To the centre of this end fix a ſmall ſtraight rod, preciſely in the direction of the cylinder's axis; to the end that, when the inſtrument is ſuſpended in the water, the deviations of the rod from a perpendicularity to the ſurface of it, may indicate which end of the cylinder goes foremoſt, by which may be diſcovered the different velocities of the water at different depths; for when the rod inclines forward, according to the direction of the current, it is a proof that the ſurface of the water has the greateſt velocity; but when it reclines backward, it ſhews that the ſwifteſt current is at the bottom; and when it remains perpendicular, it is a ſign that the velocities at the top and bottom are equal.

This inſtrument, being placed in the current of a River or canal, receives all the percuſſions of the water throughout the whole depth, and will have an equal velocity with that of the whole current from the ſurface to the bottom at the place where it is put in, and by that means may be found, both with exactneſs and eaſe, the mean velocity of that part of the River for any determinate diſtance and time.

But to obtain the mean velocity of the whole ſection of the River, the inſtrument muſt be put ſucceſſively both in the middle and towards the ſides, becauſe the velocities at thoſe places are often very different from each other. Having by this means found the ſeveral velocities, from the ſpaces run over in certain times, the arithmetical mean proportional of all theſe trials, which is found by dividing the common ſum of them all by the number of the trials, will be the mean velocity of the River or canal. And if this medium velocity be multiplied by the area of the tranſverſe ſection of the waters at any place, the product will be the quantity running through that place in a ſecond of time.

If it be required to find the velocity of the current only at the ſurface, or at the middle, or at the bottom, a ſphere of wood loaded, or a common bottle corked with a little water in it, of ſuch a weight as will remain ſuſpended in equilibrium with the water at the ſurface or depth which we want to meaſure, will be better for the purpoſe than the cylinder, becauſe it is only affected by the water of that ſole part of the current where it remains ſuſpended.

It follows from what has been ſaid in the former part of this article, that the deeper the waters are in their bed in proportion to its breadth, the more their motion is accelerated; ſo that their velocity increaſes in the inverſe ratio of the breadth of the bed, and alſo of

of the magnitude of the ſection; whence, in order to augment the velocity of water in a River or canal, without augmenting the declivity of the bed, we muſt increaſe the depth of the channel, and diminiſh its breadth. And theſe principles are agreeable to obſervation; as it is well known, that the velocity of flowing waters depends much more on the quantity and depth of the water, and on the compreſſion of the upper parts on the lower, than on the declivity of the bed; and therefore the declivity of a River muſt be made much greater in the beginning than toward the end of its courſe; where it ſhould be almoſt inſenſible. If the depth or volume of water in a River or canal be conſiderable, it will ſuffice, in the part next the mouth, to allow one foot of declivity through 6000, or 8000, or even (according to Dechales, De Fontibus et Fluviis, prop. 49) 10000 feet in horizontal extent; at moſt it need not be above 1 in 6 or 7 thouſand. From hence the quantity of declivity in equal ſpaces muſt ſlowly and gradually increaſe as far as the current is to be made fit for navigation; but in ſuch a manner, as that at this upper end there may not be above one foot of perpendicular declivity in 4000 feet of horizontal extent.

To conclude this article, M. de Buffon obſerves, that people accuſtomed to Rivers can eaſily foretell when there is going to be a ſudden increaſe of water in the bed from floods produced by ſudden falls of rain in the higher countries through which the Rivers paſs. This they perceive by a particular motion in the water, which they expreſs by ſaying, that the River's bottom moves, that is, the water at the bottom of the channel runs off faſter than uſual; and this increaſe of motion at the bottom of a River always announces a ſudden increaſe of water coming down the ſtream. Nor, ſays he, is their opinion ill grounded; becauſe the motion and weight of the waters coming down, though not yet arrived, muſt act upon the waters in the lower parts of the River, and communicate by impulſion part of their motion to them, within a certain diſtance.

On the ſubject of this article, ſee an elaborate treatiſe on Rivers and canals, in the Philoſ. Tranſ. vol. 69, pa. 555 &c, by Mr. Mann, who has availed himſelf of the obſervations of Gulielmini, and moſt other writers.

RIXDOLLAR, a ſilver coin, ſtruck in ſeveral ſtates and free cities in Germany, as alſo in Flanders, Poland, Denmark, Sweden, &c.

There is but little difference between the Rixdollar and the dollar, another ſilver coin ſtruck in Germany, each being nearly equal to the French crown of three livres, or the Spaniſh piece of eight, or 4s. 6d. ſterling.

ROBERVAL (Giles-Personne), an eminent French mathematician, was born in 1602, at Roberval, a pariſh in the dioceſe of Beauvais. He was firſt profeſſor of mathematics at the College of Maitre-Gervais, and afterwards at the College-royal. A ſimilarity of taſte connected him with Gaſſendi and Morin; the latter of whom he ſucceeded in the mathematical chair at the Royal College, without quitting however that of Ramus.

Roberval made experiments on the Torricellian vacuum: he invented two new kinds of balance, one of which was proper for weighing air; and made many other curious experiments. He was one of the firſt members of the ancient Academy of Sciences of 1666; but died in 1675, at 73 years of age. His principal works are,

I. A treatiſe on Mechanics.

II. A work entitled Ariſtarchus Samos.

He had ſeveral memoirs inſerted in the volumes of the Academy of Sciences of 1666, viz,

1. Experiments concerning the Preſſure of the Air.
2. Obſervations on the Compoſition of Motion, and on the Tangents of Curve Lines.
3. The Recognition of Equations.
4. The Geometrical Reſolution of Plane and Cubic Equations.
5. Treatiſe on Indiviſibles.
6. On the Trochoid, or Cycloid.
7. A Letter to Father Merſenne.
8. Two Letters from Torricelli.
9. A new kind of Balance.

ROBERVALLIAN *Lines*, a name given to certain lines, uſed for the transformation of figures: thus called from their inventor Roberval.

Theſe lines bound ſpaces that are infinitely extended in length, which are nevertheleſs equal to other ſpaces that are terminated on all ſides.

The abbot Gallois, in the Memoirs of the Royal Academy, anno 1693, obſerves, that the method of transforming figures, explained at the latter end of Roberval's treatiſe of Indiviſibles, was the ſame with that afterwards publiſhed by James Gregory, in his Geometria Univerſalis, and alſo by Barrow in his Lectiones Geometricæ; and that, by a letter of Torricelli, it appears, that Roberval was the inventor of this manner of transforming figures, by means of certain lines, which Torricelli therefore called Robervallian Lines.

He adds, that it is highly probable, that J. Gregory firſt learned the method in the journey he made to Padua in 1668, the method itſelf having been known in Italy from the year 1646, though the book was not publiſhed till the year 1692.

This account David Gregory has endeavoured to refute, in vindication of his uncle James. His anſwer is inſerted in the Philoſ. Tranſ. of 1694, and the abbot rejoined in the French Memoirs of the Academy of 1703.

ROBINS (Benjamin), an Engliſh mathematician and philoſopher of great genius and eminence, was born at Bath in Somerſetſhire, 1707. His parents were of low condition, and Quakers; and conſequently neither able from their circumſtances, nor willing from their religious profeſſion, to have him much inſtructed in that kind of learning which they are taught to deſpiſe as human. Nevertheleſs, he made an early and ſurpriſing progreſs in various branches of ſcience and literature, particularly in the mathematics; and his friends being deſirous that he might continue his purſuits, and that his merit might not be buried in obſcurity, wiſhed that he could be properly recommended to

to teach that ſcience in London. Accordingly, a ſpecimen of his abilities in this way was ſent up thither, and ſhewn to Dr. Pemberton, the author of the "View of Sir Iſaac Newton's Philoſophy;" who, thence conceiving a good opinion of the writer, for a farther trial of his ſkill ſent him ſome problems, which Robins reſolved very much to his ſatisfaction. He then came to London, where he confirmed the opinion which had been preconceived of his abilities and knowledge.

But though Robins was poſſeſſed of much more ſkill than is uſually required in a common teacher; yet being very young, it was thought proper that he ſhould employ ſome time in peruſing the beſt writers upon the ſublimer parts of the mathematics, before he ſhould undertake publicly the inſtruction of others. In this interval, beſides improving himſelf in the modern languages, he had opportunities of reading in particular the works of Archimedes, Apollonius, Fermat, Huygens, De Witt, Sluſius, Gregory, Barrow, Newton, Taylor, and Cotes. Theſe authors he readily underſtood without any aſſiſtance, of which he gave frequent proofs to his friends: one was, a demonſtration of the laſt propoſition of Newton's treatiſe on Quadratures, which was thought not undeſerving a place in the Philoſophical Tranſactions for 1727.

Not long after, an opportunity offered him of exhibiting to the public a ſpecimen alſo of his knowledge in Natural Philoſophy. The Royal Academy of Sciences at Paris had propoſed, among their prize queſtions in 1724 and 1726, to demonſtrate the laws of motion in bodies impinging on one another. John Bernoulli here condeſcended to be a candidate; and as his diſſertation loſt the reward, he appealed to the learned world by printing it in 1727. In this piece he endeavoured to eſtabliſh Leibnitz's opinion of the force of bodies in motion from the effects of their ſtriking againſt ſpringy materials; as Poleni had before attempted to evince the ſame thing from experiments of bodies falling on ſoft and yielding ſubſtances. But as the inſufficiency of Poleni's arguments had been demonſtrated in the Philoſophical Tranſactions, for 1722; ſo Robins publiſhed in the Preſent State of the Republic of Letters, for May 1728, a Confutation of Bernoulli's performance, which was allowed to be unanſwerable.

Robins now began to take ſcholars; and about this time he quitted the garb and profeſſion of a Quaker; for, having neither enthuſiaſm nor ſuperſtition in his nature, as became a mathematician, he ſoon ſhook off the prejudices of ſuch early habits. But though he profeſſed to teach the mathematics only, he would frequently aſſiſt particular friends in other matters; for he was a man of univerſal knowledge: and the confinement of this way of life not ſuiting his diſpoſition, which was active, he gradually declined it, and went into other courſes, that required more exerciſe. Hence he tried many laborious experiments in gunnery; believing that the reſiſtance of the air had a much greater effect on ſwift projectiles, than was generally ſuppoſed. And hence he was led to conſider thoſe mechanic arts that depend upon mathematical principles, in which he might employ his invention: as, the conſtructing of mills, the building of bridges, draining of fens, rendering of rivers navigable, and making of harbours. Among other arts of this kind, fortification very much engaged his attention; in which he met with opportunities of perfecting himſelf, by a view of the principal ſtrong places of Flanders, in ſome journeys he made abroad with perſons of diſtinction.

On his return home from one of theſe excurſions, he found the learned here amuſed with Dr. Berkeley's treatiſe, printed in 1734, entitled, "The Analyſt;" in which an examination was made into the grounds of the doctrine of Fluxions, and occaſion thence taken to explode that method. Robins was therefore adviſed to clear up this affair, by giving a full and diſtinct account of Newton's doctrines, in ſuch a manner, as to obviate all the objections, without naming them, which had been advanced by Berkeley; and accordingly he publiſhed, in 1735, *A Diſcourſe concerning the Nature and Certainty of Sir Iſaac Newton's Method of Fluxions, and of Prime and Ultimate Ratios.* This is a very clear, neat, and elegant performance: and yet ſome perſons, even among thoſe who had written againſt The Analyſt, taking exception at Robins's manner of defending Newton's doctrine, he afterwards wrote two or three additional diſcourſes.

In 1738, he defended Newton againſt an objection, contained in a note at the end of a Latin piece, called "Matho, ſive Coſmotheoria puerilis," written by Baxter, author of the "Inquiry into the Nature of the Human Soul:" and the year after he printed *Remarks on Euler's Treatiſe of Motion*, on *Smith's Syſtem of Optics*, and on *Jurin's Diſcourſe of Diſtinct and Indiſtinct Viſion*, annexed to Dr. Smith's work.

In the mean time Robins's performances were not confined to mathematical ſubjects: for, in 1739, there came out three pamphlets upon political affairs, which did him great honour. The firſt was entitled, *Obſervations on the preſent Convention with Spain:* the ſecond, *A Narrative of what paſſed in the Common Hall of the Citizens of London, aſſembled for the Election of a Lord Mayor:* the third, *An Addreſs to the Electors and other free Subjects of Great Britain, occaſioned by the late Seceſſion; in which is contained a Particular Account of all our Negotiations with Spain, and their Treatment of us for above ten years paſt.* Theſe were all publiſhed without our author's name; and the firſt and laſt were ſo univerſally eſteemed, that they were generally reputed to have been the production of the great man himſelf, who was at the head of the oppoſition to Sir Robert Walpole. They proved of ſuch conſequence to Mr. Robins, as to occaſion his being employed in a very honourable poſt; for, the patriots at length gaining ground againſt Sir Robert, and a committee of the Houſe of Commons being appointed to examine into his paſt conduct, Robins was choſen their ſecretary. But after the committee had preſented two reports of their proceedings, a ſudden ſtop was put to their farther progreſs, by a compromiſe between the contending parties.

In 1742, being again at leiſure, he publiſhed a ſmall treatiſe, entitled, *New Principles of Gunnery;* containing the reſult of many experiments he had made, by which are diſcovered the force of gunpowder, and the difference in the reſiſting power of the air to ſwift and ſlow

flow motions. To this treatise was prefixed a full and learned account of the progress which modern fortification had made from its first rise; as also of the invention of gunpowder, and of what had already been performed in the theory of gunnery. It seems that the occasion of this publication, was the disappointment of a situation at the Royal Military Academy at Woolwich. On the new modelling and establishing of that Academy, in 1741, our author and the late Mr. Muller were competitors for the place of professor of fortification and gunnery. Mr. Muller held then some post in the Tower of London, under the Board of Ordnance, so that, notwithstanding the great knowledge and abilities of our author, the interest which Mr. Muller had with the Board of Ordnance carried the election in his favour. Upon this disappointment Mr. Robins, indignant at the affront, determined to shew them, and the world, by his military publications, what sort of a man he was that they had rejected.

Upon a discourse containing certain experiments being published in the Philosophical Transactions, with a view to invalidate some of Robins's opinions, he thought proper, in an account he gave of his book in the same Transactions, to take notice of those experiments: and in consequence of this, several dissertations of his on the resistance of the air were read, and the experiments exhibited before the Royal Society, in 1746 and 1747; for which he was presented with the annual gold medal by that Society.

In 1748 came out Anson's Voyage round the World; which, though it bears Walter's name in the title-page, was in reality written by Robins. Of this voyage the public had for some time been in expectation of seeing an account, composed under that commander's own inspection: for which purpose the reverend Richard Walter was employed, as having been chaplain on board the Centurion the greatest part of the expedition. Walter had accordingly almost finished his task, having brought it down to his own departure from Macao for England; when he proposed to print his work by subscription. It was thought proper however that an able judge should first review and correct it, and Robins was appointed; when, upon examination, it was resolved, that the whole should be written entirely by Robins, and that what Walter had done, being mostly taken verbatim from the journals, should serve as materials only. Hence it was that the whole of the introduction, and many dissertations in the body of the work, were composed by Robins, without receiving the least hint from Walter's manuscript; and what he had transcribed from it regarded chiefly the wind and weather, the currents, courses, bearings, distances, offings, soundings, moorings, the qualities of the ground they anchored on, and such particulars as usually fill up a seaman's account. No production of this kind ever met with a more favourable reception, four large impressions having been sold off within a year: it was also translated into most of the European languages; and it still supports its reputation, having been repeatedly reprinted in various sizes. The fifth edition at London in 1749 was revised and corrected by Robins himself; and the 9th edition was printed there in 1761.

Thus becoming famous for his elegant talents in writing, he was requested to compose an apology for the unfortunate affair at Prestonpans in Scotland. This was added as a preface to the Report of the Proceedings and Opinion of the Board of General Officers on their Examination into the Conduct of Lieutenant General Sir John Cope, &c, printed at London in 1749; and this preface was esteemed a master-piece in its kind.

Robins had afterwards, by the favour of lord Anson, opportunities of making farther experiments in Gunnery; which have been published since his death, in the edition of his works by his friend Dr. Wilson. He also not a little contributed to the improvements made in the Royal Observatory at Greenwich, by procuring for it, through the interest of the same noble person, a second mural quadrant, and other instruments; by which it became perhaps the completest of any observatory in the world.

His reputation being now arrived at its full height, he was offered the choice of two very considerable employments. The first was to go to Paris, as one of the commissaries for adjusting the limits in Acadia; the other, to be engineer general to the East India Company, whose forts, being in a most ruinous condition, wanted an able person to put them into a proper state of defence. He accepted the latter, as it was suitable to his genius, and as the Company's terms were both advantageous and honourable. He designed, if he had remained in England, to have written a second part of the Voyage round the World; as appears by a letter from lord Anson to him, dated Bath, Oct. 22, 1749, as follows.

"Dear Sir, when I last saw you in town, I forgot to ask you, whether you intended to publish the second volume of my Voyage before you leave us; which I confess I am very sorry for. If you should have laid aside all thoughts of favouring the world with more of your works, it will be much disappointed, and no one in it more than your very obliged humble servant,

"ANSON."

Robins was also preparing an enlarged edition of his New Principles of Gunnery: but, having provided himself with a complete set of astronomical and other instruments, for making observations and experiments in the Indies, he departed hence at Christmas in 1749; and after a voyage, in which the ship was near being cast away, he arrived at India in July following. There he immediately set about his proper business with the greatest diligence, and formed complete plans for Fort St. David and Madras: but he did not live to put them into execution. For the great difference of the climate from that of England being beyond his constitution to support, he was attacked by a fever in September the same year; and though he recovered out of this, yet about eight months after he fell into a languishing condition, in which he continued till his death, which happened the 29th of July 1751, at only 44 years of age.

By his last will, Mr. Robins left the publishing of his Mathematical Works to his honoured and intimate friend Martin Folkes, Esq. president of the Royal Society, and to Dr. James Wilson; but the former of these gentlemen

gentlemen being incapacitated by a paralytic disorder, for some time before his death, they were afterwards published by the latter, in 2 volumes 8vo, 1761. To this collection, which contains his mathematical and philosophical pieces only, Dr. Wilson has prefixed an account of Mr. Robins, from which this memoir is chiefly extracted. He added also a large appendix at the end of the second volume, containing a great many curious and critical matters in various interesting parts of the mathematics. As to Mr. Robins's own papers in these two volumes, they are as follow: viz, in vol. I,

1. New Principles of Gunnery. First printed in 1742.

2. An Account of that book. Read before the Royal Society, April the 14th and 21st 1743.

3. Of the Resistance of the Air. Read the 12th of June 1746.

4. Of the Resistance of the Air; together with the Method of computing the Motions of Bodies projected in that Medium. Read June 19, 1746.

5. Account of Experiments relating to the Resistance of the Air. Read the 4th of June 1747.

6. Of the Force of Gunpowder, with the Computation of the Velocities thereby communicated to military projectiles. Read the 25th of June 1747.

7. A Comparison of the Experimental Ranges of Cannon and Mortars, with the Theory contained in the preceding papers. Read the 27th of June 1751.

8. Practical Maxims relating to the Effects and Management of Artillery, and the Flight of Shells and Shot.

9. A Proposal for increasing the Strength of the British Navy. Read the 2d of April 1747.

10. A Letter to Martin Folkes, Esq. President of the Royal Society. Read the 7th of January 1748.

11. A Letter to Lord Anson. Read the 26th of October 1749.

12. On Pointing, or Directing of Cannon to strike distant objects.

13. Observations on the Height to which Rockets ascend. Read the 4th of May 1749.

14. An Account of some Experiments on Rockets, by Mr. Ellicott.

15. Of the Nature and Advantage of Rifled Barrel Pieces, by Mr. Robins. Read the 2d of July 1747.

In volume II are,

16. A Discourse concerning the Nature and Certainty of Sir Isaac Newton's Methods of Fluxions, and of Prime and Ultimate Ratios.

17. An Account of the preceding Discourse.

18. A Review of some of the principal Objections, that have been made to the Doctrine of Fluxions and Ultimate Proportions, with some Remarks on the different Methods, that have been taken to obviate them.

19. A Dissertation shewing, that the Account of the Doctrines of Fluxions and of Prime and Ultimate Ratios, delivered in Mr. Robins's Discourse, is agreeable to the real Meaning of their great Inventor.

20. A Demonstration of the Eleventh Proposition of Sir Isaac Newton's Treatise of Quadratures.

21. Remarks on Bernoulli's Discourse upon the Laws of the Communication of Motion.

22. An Examination of a Note concerning the Sun's Parallax, published at the end of Baxter's Matho.

23. Remarks on Euler's Treatise of Motion; Dr. Smith's System of Optics; and Dr. Jurin's Essay on Distinct and Indistinct Vision.

24. Appendix by the Publisher.

It is but justice to say, that Mr. Robins was one of the most accurate and elegant mathematical writers that our language can boast of; and that he made more real improvements in Artillery, the flight and the resistance of projectiles, than all the preceding writers on that subject. His New Principles of Gunnery were translated into several other languages, and commented upon by several eminent writers. The celebrated Euler translated the work into the German language, accompanied with a large and critical commentary; and this work of Euler's was again translated into English in 1714, by Mr. Hugh Brown, with Notes, in one volume 4to.

ROBINS, or ROBYNS (JOHN), an English mathematician, was born in Staffordshire about the close of the 15th century, as he was entered a student at Oxford in 1516, where he was educated for the church. But the bent of his genius lay to the sciences, and he soon made such a progress, says Wood, in "the pleasant studies of mathematics and astrology, that he became the ablest person in his time for those studies, not excepted his friend Record, whose learning was more general. At length, taking the degree of bachelor of divinity in 1531, he was the year following made by king Henry the VIIIth (to whom he was chaplain) one of the canons of his college in Oxon, and in December 1543 canon of Windsor, and in fine chaplain to Queen Mary, who had him in great veneration for his learning. Among several things that he hath written relating to astrology (or astronomy) I find these following:

"*De Culminatione Fixarum Stellarum, &c.*
De Ortu & Occasu Stellarum Fixarum, &c.
Annotationes Astrologicæ, &c. lib. 3.
Annotationes Edwardo VI.
Tractatus de Prognosticatione per Eclipsin.

"All which books, that are in MS, were some time in the choice library of Mr. Thomas Allen of Glocester Hall. After his death, coming into the hands of Sir Kenelm Digby, they were by him given to the Bodleian library, where they yet remain. It is also said, that he the said Robyns hath written a book intitled, *De Portentosis Cometis*, but such a thing I have not yet seen, nor do I know any thing else of the author, only that paying his last debt to nature the 25th of August 1558, he was buried in the chappel of St. George at Windsore."

ROCKET, in Pyrotechny, an artificial firework, usually consisting of a cylindrical case of paper, filled with a composition of certain combustible ingredients; which being tied to a rod, mounts into the air to a considerable height, and there bursts. These are called *Sky Rockets*. Beside which, there are others called *Water Rockets*, from their acting in water.

The

The composition with which Rockets are filled, consists of the three following ingredients, viz, saltpetre, charcoal, and sulphur, all well ground; and in the smaller sizes, gunpowder dust is also added. But the proportions of all the ingredients vary with the weight of the Rocket, as in the following Table.

Compositions for Rockets of Various Sizes.

The General Composition for Rockets is,

Saltpetre	4	lb.
Sulphur	1	lb.
Charcoal	1	lb.

But for large Rockets,

Saltpetre	4	lb.
Sulphur	1	lb.
Mealpowder	1	lb.

For Rockets of a Middle Size,

Saltpetre	3	lb.
Sulphur	2	lb.
Mealpowder	1	lb.
Charcoal	1	lb.

When Rockets are intended to mount upwards, they have a long slender rod fixed to the lower end, to direct their motion.

Theory of the Flight of Rockets.—Mariotte takes the rise of Rockets to be owing to the impulse or resistance of the air against the flame. Desaguliers accounts for it thus.

Conceive the Rocket to have no vent at the choke, and to be set on fire in the conical bore; the consequence would be, either that the Rocket would burst in the weakest place, or that, if all parts were equally strong, and able to sustain the impulse of the flame, the Rocket would burn out immoveable. Now, as the force of the flame is equable, suppose its action downwards, or that upwards, sufficient to lift 40 pounds; as these forces are equal, but their directions contrary, they will destroy each other's action.

Imagine then the Rocket opened at the choke; by this means the action of the flame downwards is taken away, and there remains a force equal to 40 pounds acting upwards, to carry up the Rocket, and the stick or rod it is tied to. Accordingly we find that if the composition of the Rocket be very weak, so as not to give an impulse greater than the weight of the Rocket and stick, it does not rise at all; or if the composition be slow, so that a small part of it only kindles at first, the Rocket will not rise.

The stick serves to keep it perpendicular; for if the Rocket should begin to tumble, moving round a point in the choke, as being the common centre of gravity of Rocket and stick, there would be so much friction against the air, by the stick between the centre and the point, and the point would beat against the air with so much velocity, that the reaction of the medium would restore it to its perpendicularity. When the composition is burnt out, and the impulse upwards has ceased, the common centre of gravity is brought lower towards the middle of the stick; by which means the velocity of the point of the stick is decreased, and that of the point of the Rocket is increased; so that the whole will tumble down, with the Rocket end foremost.

All the while the Rocket burns, the common centre of gravity is shifting and getting downwards, and still the faster and the lower as the stick is lighter; so that it sometimes begins to tumble before it is quite burnt out: but when the stick is too heavy, the common centre of gravity will not get so low, but that the Rocket will rise straight, though not so fast.

From the experiments of Mr. Robins, and other gentlemen, it appears that the Rockets of 2, 3, or 4 inches diameter, rise the highest; and they found them rise to all heights in the air, from 400 to 1254 yards, which is about three quarters of a mile. See Robins's Tracts, vol. 2, pa. 317, and the Philos. Trans. vol. 46, pa. 578.

ROD, or *Pole*, is a long measure, of $16\frac{1}{2}$ feet, or $5\frac{1}{2}$ yards, or the 4th part of a Gunter's chain, for land-measuring.

ROEMER (OLAUS), a noted Danish astronomer and mathematician, was born at Arhusen in Jutland, 1644; and at 18 years of age was sent to the university of Copenhagen. He applied assiduously to the study of the mathematics and astronomy, and became so expert in those sciences, that when Picard was sent by Lewis the XIVth in 1671, to make observations in the north, he was greatly surprised and pleased with him. He engaged him to return with him to France, and had him presented to the king, who honoured him with the dauphin as a pupil in mathematics, and settled a pension upon him. He was joined with Picard and Cassini, in making astronomical observations; and in 1672 he was admitted a member of the academy of sciences.

During the ten years he resided at Paris, he gained great reputation by his discoveries; yet it is said he complained afterwards, that his coadjutors ran away with the honour of many things which belonged to him. Here it was that Roemer, first of any one, found out the velocity with which light moves, by means of the eclipses of Jupiter's satellites. He had observed for many years that, when Jupiter was at his greatest distance from the earth, where he could be observed, the emersions of his first satellite happened constantly 15 or 16 minutes later than the calculation gave them. Hence he concluded that the light reflected by Jupiter took up this time in running over the excess of distance, and consequently that it took up 16 or 18 minutes in running over the diameter of the earth's orbit, and 8 or 9 in coming from the sun to us, provided its velocity was nearly uniform. This discovery had at first many opposers; but it was afterwards confirmed by Dr. Bradley in the most ingenious and beautiful manner.

In 1681 Roemer was recalled back to his own country by Christian the Vth, king of Denmark, who made him professor of astronomy at Copenhagen. The king employed him also in reforming the coin and the architecture, in regulating the weights and measures, and in measuring and laying out the high roads throughout the kingdom; offices which he discharged with the greatest credit and satisfaction. In consequence he was honoured by the king with the appointment of chancellor of the exchequer and other dignities. Finally he became counsellor of state and burgomaster of Copenhagen.

hagen, under Frederic the IVth, the successor of Christian. Roemer was preparing to publish the result of his observations, when he died the 19th of September 1710, at 66 years of age: but this loss was supplied by Horrebow, his disciple, then professor of astronomy at Copenhagen, who published, in 4to, 1753, various observations of Roemer, with his method of observing, under the title of *Basis Astronomiæ*.—He had also printed various astronomical observations and pieces, in several volumes of the Memoirs of the Royal Academy of Sciences at Paris, of the institution of 1666, particularly vol. 1 and 10 of that collection.

ROHAULT (James), a French philosopher, was the son of a rich merchant at Amiens, where he was born in 1620. He cultivated the languages and belles lettres in his own country, and then was sent to Paris to study philosophy. He seems to have been a great lover of truth, at least what he thought so, and to have sought it with much impartiality. He read the ancient and modern philosophers; but Des Cartes was the author who most engaged his notice. Accordingly he became a zealous follower of that great man, and drew up an abridgment and explanation of his philosophy with great clearness and method. In the preface to his *Physics*, for so his work is called, he makes no scruple to say, that "the abilities and accomplishments of this philosopher must oblige the whole world to confess, that France is at least as capable of producing and raising men versed in all arts and branches of knowledge, as ancient Greece." Clerselier, well known for his translation of many pieces of Des Cartes, conceived such an affection for Rohault, on account of his attachment to this philosopher, that he gave him his daughter in marriage against all the remonstrances of his family.

Rohault's Physics were written in French, but have been translated into Latin by Dr. Samuel Clarke, with notes, in which the Cartesian errors are corrected upon the Newtonian system. The fourth and best edition of *Rohault's Physica*, by Clarke, is that of 1718, in 8vo. He wrote also,

Elemens de Mathematiques,
Traité de Mechanique, and
Entretiens sur la Philosophie.

But these dialogues are founded and carried on upon the principles of the Cartesian philosophy, which has now little other merit, than that of having corrected the errors of the Ancients. Rohault died in 1675, and left behind him the character of an amiable, as well as a learned and philosophic man.

His posthumous works were collected and printed in two neat little volumes, first at Paris, and then at the Hague in 1690. The contents of them are, 1. The first 6 books of Euclid. 2. Trigonometry. 3. Practical Geometry. 4. Fortification. 5. Mechanics. 6. Perspective. 7. Spherical Trigonometry. 8. Arithmetic.

ROLLE (Michel), a French mathematician, was born at Ambert, a small town in Auvergne, the 21st of April 1652. His first studies and employments were under notaries and attorneys; occupations but little suited to his genius. He went to Paris in 1675, with the only resource of fine penmanship, and subsisted by giving lessons in writing. But as his inclination for the mathematics had drawn him to that city, he attended the masters in this science, and soon became one himself. Ozanam proposed a question in arithmetic to him, to which Rolle gave so clear and good a solution, that the minister Colbert made him a handsome gratuity, which at last grew into a fixed pension. He then abandoned penmanship, and gave himself up entirely to algebra and other branches of the mathematics. His conduct in life gained him many friends; in which his scientific merit, his peaceable and regular behaviour, with an exact and scrupulous probity of manners, were his only solicitors.

Rolle was chosen a member of the Ancient Academy of Sciences in 1685, and named second geometrical-pensionary on its renewal in 1699; which he enjoyed till his death, which happened the 5th of July 1719, at 67 years of age.

The works published by Rolle, were,

I. A Treatise of Algebra; in 4to, 1690.

II. A method of resolving Indeterminate Questions in Algebra; in 1699. Besides a great many curious pieces inserted in the Memoirs of the Academy of Sciences, as follow:

1. A Rule for the Approximation of Irrational Cubes: an. 1666, vol. 10.
2. A Method of Resolving Equations of all Degrees which are expressed in General Terms: an. 1666, vol. 10.
3. Remarks upon Geometric Lines: 1702 and 1703.
4. On the New System of Infinity: 1703, pa. 312.
5. On the Inverse Method of Tangents: 1705, pa. 25, 171, 222.
6. Method of finding the Foci of Geometric Lines of all kinds: 1706, pa. 284.
7. On Curves, both Geometrical and Mechanical, with their Radii of Curvature: 1707, pa. 370.
8. On the Construction of Equations: 1708, and 1709.
9. On the Extermination of the Unknown Quantities in the Geometrical Analysis: 1709, pa. 419.
10. Rules and Remarks for the Construction of Equations: 1711, pa. 86.
11. On the Application of Diophantine Rules to Geometry: 1712.
12. On a Paradox in Geometric Effections: 1713, pa. 243.
13. On Geometric Constructions: 1713, pa. 261, and 1714, pa. 5.

ROLLING, or *Rotation*, in Mechanics, a kind of circular motion, by which the moveable body turns round its own axis, or centre, and continually applies new parts of its surface to the body it moves upon. Such is that of a wheel, a sphere, a garden roller, or the like.

The motion of Rolling is opposed to that of sliding; in which latter motion the same surface is continually applied to the plane it moves along.

In a wheel, it is only the circumference that properly and simply rolls; the rest of the wheel proceeds in a compound angular kind of motion, and partly rolls,

rolls, partly slides. The want of distinguishing between which two motions, occasioned the difficulty of that celebrated problem of Aristotle's Wheel.

The friction of a body in rolling, is much less than the friction in sliding. And hence arises the great use of wheels, rolls, &c, in machines; as much of the action as possible being laid upon it, to make the resistance the less.

ROMAN *Order*, in Architecture, is the same as the composite. It was invented by the Romans, in the time of Augustus; and it is made up of the Ionic and Corinthian orders, being more ornamental than either.

RONDEL, in Fortification, a round tower, sometimes erected at the foot of a bastion.

ROOD, a square measure, being a quantity of land just equal to the 4th part of an acre, or equal to 40 perches or square poles.

ROOF, in Architecture, the uppermost part of a building; being that which forms the covering of the whole. In this sense, the Roof comprises the timber work, together with its furniture, of slate, or tile, or lead, or whatever else serves for a covering: though the carpenters usually restrain Roof to the timber-work only.

The form of a Roof is various: viz, 1. *Pointed*, when the ridge, or angle formed by the two sides, is an acute angle.—2. *Square*, when the pitch or angle of the ridge is a right angle, called the true pitch.—3. *Flat* or pediment Roof, being only pediment pitch, or the angle very obtuse. There are also various other forms, as hip Roofs, valley Roofs, hopper Roofs, double ridges, platforms, round, &c.—In the true pitch, when the sides form a square or right angle, the girt over both sides of the Roof, is accounted equal to the breadth of the building and the half of the same.

ROOKE (LAWRENCE), an English astronomer and geometrician, was born at Deptford in Kent, 1623, and educated at Eton school. From hence he removed to King's College, Cambridge, in 1639. After taking the degree of master of arts in 1647, he retired into the country. But in the year 1650 he went to Oxford, and settled in Wadham College, that he might have the company of, and receive improvement from Dr. Wilkins, and Mr. Seth Ward the Astronomy Professor; and that he might also accompany Mr. Boyle in his chemical operations.

After the death of Mr. Foster, he was chosen Astronomy Professor in Gresham College, London, in the year 1652. He made some observations upon the comet at Oxford, which appeared in the month of December that year; which were printed by Mr. Seth Ward the year following. And, in 1655, Dr. Wallis publishing his treatise on Conic Sections, he dedicated that work to those two gentlemen.

In 1657, Mr. Rooke was permitted to exchange the astronomy professorship for that of geometry. This step might seem strange, as astronomy still continued to be his favourite study; but it was thought to have been from the convenience of the lodgings, which opened behind the reading hall, and therefore were proper for the reception of those gentlemen after the lectures, who in the year 1660 formed the Royal Society there.

Mr. Rooke having thus successively enjoyed those two places some years before the restoration in 1658, most of those gentlemen who had been accustomed to assemble with him at Oxford, coming to London, joined with other philosophical gentlemen, and usually met at Gresham College to hear Mr. Rooke's lectures, and afterwards withdrew into his apartment; till their meetings were interrupted by the quartering of soldiers in the college that year. And after the Royal Society came to be formed and settled into a regular body, Mr. Rooke was very zealous and serviceable in promoting that great and useful institution; though he did not live till it received its establishment by the Royal charter.

The Marquis of Dorchester, who was not only a patron of learning, but learned himself, used to entertain Mr. Rooke at his seat at Highgate after the restoration, and bring him every Wednesday in his coach to the Royal Society, which then met on that day of the week at Gresham College. But the last time Mr. Rooke was at Highgate, he walked from thence; and it being in the summer, he overheated himself, and taking cold after it, he was thrown into a fever, which cost him his life. He died at his apartments at Gresham College the 27th of June 1662, in the 40th year of his age.

One other very unfortunate circumstance attended his death, which was, that it happened the very night that he had for some years expected to finish his accurate observations on the satellites of Jupiter. When he found his illness prevented him from making that observation, Dr. Pope says, he sent to the Society his request, that some other person, properly qualified, might be appointed for that purpose; so intent was he to the last on making those curious and useful discoveries, in which he had been so long engaged.

Mr. Rooke made a nuncupatory will, leaving what he had to Dr. Ward, then lately made bishop of Exeter: whom he permitted to receive what was due upon bond, if the debtors offered payment willingly, otherwise he would not have the bonds put in suit: "for, said he, as I never was in law, nor had any contention with any man, in my life-time; neither would I be so after my death."

Few persons have left behind them a more agreeable character than Mr. Rooke, from every person that was acquainted with him, or with his qualifications; and in nothing more than for his veracity: for what he asserted positively, might be fully relied on: but if his opinion was asked concerning any thing that was dubious, his usual answer was, "I have no opinion." Mr. Hook has given this copious, though concise character of him: "I never was acquainted with any person who knew more, and spoke less, being indeed eminent for the knowledge and improvement of astronomy." Dr. Wren and Dr. Seth Ward describe him, as a man of profound judgment, a vast comprehension, prodigious memory, and solid experience. His skill in the mathematics was reverenced by all the lovers of those studies, and his perfection in many other sorts of learning deserves no less admiration; but above all, as another writer characterizes him, his extensive know-

ledge had a right influence on the temper of his mind, which had all the humility, goodness, calmness, strength, and sincerity, of a sound and unaffected philosopher. These accounts give us his picture only in miniature; but his successor, Dr. Isaac Barrow, has drawn it in full proportion, in his oration at Gresham College; which is too long to be inserted in this place.

His writings were chiefly;

1. *Observations on the Comet* of Dec. 1652. This was printed by Dr. Seth Ward, in his Lectures on Comets, 4to, 1653.

2. *Directions for Seamen going to the East and West Indies.* Published in the Philosophical Transactions for Jan. 1665.

3. *A Method of Observing the Eclipses of the Moon &c.* In the Philos. Trans. for Feb. 1666.

4. *A Discourse concerning the Observations of the Eclipses of the Satellites of Jupiter.* In the History of the Royal Society, pa. 183.

5. *An Account of an Experiment made with Oil in a long Tube.* Read to the Royal Soc. April 23, 1662 — By this experiment it was found, that the oil sunk when the sun shone out, and rose when he was clouded; the proportions of which are set down in the account.

ROOT, in Arithmetic and Algebra, denotes a quantity which being multiplied by itself produces some higher power; or a quantity considered as the basis or foundation of a higher power, out of which this arises and grows, like as a plant from its Root.

In the involution of powers, from a given Root, the Root is also called the first power; when this is once multiplied by itself, it produces the square or second power; this multiplied by the Root again, makes the cube or 3d power; and so on. And hence the Roots also come to be denominated the square-Root, or cube-Root, or 2d Root, or 3d Root, &c, according as the given power or quantity is considered as the square, or cube, or 2d power, or 3d power, &c. Thus, 2 is the square-Root or 2d Root of 4, and the cube-Root or 3d Root of 8, and the 4th Root of 16, &c.

Hence, the square-Root is the mean proportional between 1 and the square or given power; and the cube-Root is the first of two mean proportionals between 1 and the given cube; and so on.

To Extract the Root of a given number or power. This is the same thing as to find a number or quantity, which being multiplied the proper number of times, will produce the given number or power. So, to find the cube Root of 8, is finding the number 2, which multiplied twice by itself produces the given number 8.

For the usual methods of extracting the Roots of Numbers, see the common treatises on Arithmetic.

A Root, of any power, that consists of two parts, is called a binomial Root; as 12 or 10 + 2. If it consist of three parts, it is a trinomial Root; as 126 or 100 + 20 + 6. And so on.

The extraction of the Roots of algebraic quantities, is also performed after the same manner as that of numbers; as may be seen in any treatise on algebra. See also the article EXTRACTION of Roots.

A general method for all Roots, is also by Newton's binomial theorem. See BINOMIAL *Theorem*.

Finite approximating rules for the extraction of Roots have also been given by several authors, as Raphson, De Lagney, Halley, &c. See the articles APPROXIMATION and EXTRACTION. See also Newton's Universal Arith. the Appendix; Philos. Trans. numb. 210, or Abridg. vol. 1, pa. 81; Maclaurin's Alg. pa. 242; Simpson's Alg. pa. 155; or his Essays, pa. 82, or his Dissertations, pa. 102, or his Select Exerc. pa. 215: where various general theorems for approximating to the Roots of pure powers are given. See also EQUATION and REDUCTION of Equations, APPROXIMATION, and CONVERGING.

But the most commodious and general rule of any, for such approximations, I believe, is that which has been invented by myself, and explained in my Tracts, vol. 1, pa. 49: which theorem is this;

$\dfrac{\overline{n+1}.N + \overline{n-1}.a^n}{\overline{n-1}.N + \overline{n+1}.a^n}a = \sqrt[n]{N}$. That is, having to extract the nth Root of the given number N; take a^n the nearest rational power to that given quantity N, whether greater or less, its Root of the same kind being a; then the required Root, or $\sqrt[n]{N}$, will be as is expressed in this formula above; or the same expressed in a proportion will be thus:

$\overline{n-1}.N + \overline{n+1}.a^n : \overline{n+1}.N + \overline{n-1}.a^n :: a : \sqrt[n]{N}$ the Root sought very nearly. Which rule includes all the particular rational formulas of De Lagney, and Halley, which were separately investigated by them; and yet this general formula is perfectly simple and easy to apply, and more easily kept in mind than any one of the said particular formulas.

Ex. Suppose it be required to double the cube, or to extract the cube Root of the number 2.

Here $N = 2$, $n = 3$, the nearest Root $a = 1$, also $a^3 = 1$; hence, for the cube Root the formula becomes $\dfrac{4N + 2a^3}{2N + 4a^3}a$ or $\dfrac{2N + a^3}{N + 2a^3}a = \sqrt[3]{N}$.

But $N + 2a^3 = 4$, and $2N + a^3 = 5$; therefore as $4 : 5 :: 1 : \dfrac{5}{4} = 1{\cdot}25$ = the Root nearly by a first approximation.

Again, for a second approximation, take $a = \dfrac{5}{4}$,

and consequently $a^3 = \dfrac{125}{64}$;

hence $2N + a^3 = 4 + \dfrac{125}{64} = \dfrac{381}{64}$,

and $N + 2a^3 = 2 + \dfrac{250}{64} = \dfrac{378}{64}$;

therefore as $378 : 381$, or as $126 : 127 :: \dfrac{5}{4} : \dfrac{635}{504} = 1{\cdot}259921$ &c, for the required cube Root of 2, which is true even in the last place of decimals.

ROOT *of an Equation*, denotes the value of the unknown quantity in an equation; which is such a quantity,

quantity, as being substituted instead of that unknown letter, into the equation, shall make all the terms to vanish, or both sides equal to each other. Thus, of the equation $3x + 5 = 14$, the Root or value of x is 3, because substituting 3 for x, makes it become $9 + 5 = 14$. And the Root of the equation $2x^2 = 32$ is 4, because $2 \times 4^2 = 32$. Also the Root of the equation $x^2 = a^2 + c^2$ is $x = \sqrt{a^2 + c^2}$.

For the Nature of Roots, and for extracting the several Roots of equations, see EQUATION.

Every equation has as many Roots, or values of the unknown quantity, as are the dimensions or highest power in it. As a simple equation one Root, a quadratic two, a cubic three, and so on.

Roots are positive or negative, real or imaginary, rational or radical, &c. See EQUATION.

Cubic ROOT. This is threefold, even for a simple cubic. So the cube Root of a^3, is either

$$a, \text{ or } \frac{-1 + \sqrt{-3}}{2}a, \text{ or } \frac{-1 - \sqrt{-3}}{2}a.$$

And even the cube Root of 1 itself is either

$$1, \text{ or } \frac{-1 + \sqrt{-3}}{2}, \text{ or } \frac{-1 - \sqrt{-3}}{2}.$$

Real and Imaginary ROOTS. The odd Roots, as the 3d, 5th, 7th, &c Roots, of all real quantities, whether positive or negative, are real, and are respectively positive or negative. So the cube Root of a^3 is a, and of $-a^3$ is $-a$.

But the even Roots, as the 2d, 4th, 6th, &c, are only real when the quantity is positive; being imaginary or impossible when the quantity is negative. So the square Root of a^2 is a, which is real; but the square Root of $-a^2$, that is, $\sqrt{-a^2}$, is imaginary or impossible; because there is no quantity, neither $+a$ nor $-a$, which by squaring will make the given negative square $-a^2$.

TABLE *of* ROOTS, &c.

THE following Table of Roots, Squares, and Cubes, is very useful in many calculations, and will serve to find square-Roots and cube Roots, as well as square and cubic powers. The Table consists of three columns: in the first column are the series of common numbers, or Roots, 1, 2, 3, 4, 5, 6, &c; in the second column are the squares, and in the third column the cubes of the same. For example, to find the square or the cube of the number or Root 49. Finding this number 49 in the first column; upon the same line with it, stands its square 2401 in the second column, and its cube 117649 in the third column.

Again, to find the square Root of the number 700. Near the beginning of the Table, it appears that the next less and greater tabular squares are 676 and 729, whose Roots are 26 and 27, and therefore the square Root of 700 is between 26 and 27. But a little further on, viz, among the hundreds, it appears that the required Root lies between 26·4 and 26·5, the tabular squares of these being 696·96 and 702·25, cutting off the proper part of the figures for decimals. Take the difference between the less square 696·96 and the given number 700, which gives 3·04, and divide the half of it, viz 1·52, by the less given tabular Root, viz 26·4, and the quotient 575 gives as many more figures of the Root, to be joined to the first three, and thus making the Root equal to 26·4575, which is true in all its places.

Also to find the cube Root of the number 7000; near the beginning of the Table, among the tens, it appears that the cube Root of this number is between 19 and 20; but farther on, among the hundreds, it appears that it lies between 19·1 and 19·2, allowing for the proper number of integers. But if more figures are required; from the given number 7000 take the next less tabular one, or the cube of 19·1, viz 6967871, and there remains 32·129, the 3d part of which, or 10·730, divide by the square of 19·1, viz 364·81, found on the same line, and the quotient 293 is the next three figures of the Root, and therefore the whole cubic Root is 19·1293, which is true in all its figures.—The Table follows.

Table of Square and Cubic Roots.

Root.	Square.	Cube.	Root.	Square.	Cube.	Root.	Square.	Cube.	Root.	Square.	Cube.
1	1	1	64	4096	262144	127	16129	2048383	190	36100	6859000
2	4	8	65	4225	274625	128	16384	2097152	191	36481	6967871
3	9	27	66	4356	287496	129	16641	2146689	192	36864	7077888
4	16	64	67	4489	300763	130	16900	2197000	193	37429	7189057
5	25	125	68	4624	314432	131	17161	2248091	194	37636	7301384
6	36	216	69	4761	328509	132	17424	2299968	195	38025	7414875
7	49	343	70	4900	343000	133	17689	2352637	196	38416	7529536

									1008	1016064	1024192512

The following is another Table of the Square Roots of the first 1000 Numbers to 10 places of decimal figures beside the integers, which needs no farther explanation, as Numbers stand always in the first column, and their Square Roots in the next.

Table of Square ROOTS *to ten Decimal Places.*

No.	Square Root.	No.	Square Root.	No.	Square Root.	No.	Square Root.
1	1·0000000000	64	8·0000000000	127	11·2694276696	190	13·7840487521

ROTA, in Mechanics. See Wheel.

Rota *Aristotelica*, or *Aristotle's Wheel*, denotes a celebrated problem in mechanics, concerning the motion or rotation of a wheel about its axis; so called because first noticed by Aristotle.

The difficulty is this. While a circle makes a revolution on its centre, advancing at the same time in a right line along a plane, it describes, on that plane, a right line which is equal to its circumference. Now if this circle, which may be called the deferent, carry with it another smaller circle, concentric with it, like the nave of a coach wheel; then this little circle, or nave, will describe a line in the time of the revolution, which shall be equal to that of the large wheel or circumference itself; because its centre advances in a right line as fast as that of the wheel does, being in reality the same with it.

The solution given by Aristotle, is no more than a good explication of the difficulty.

Galileo, who next attempted it, has recourse to an infinite number of infinitely little vacuities in the right line described by the two circles; and imagines that the little circle never applies its circumference to those vacuities; but in reality only applies it to a line equal to its own circumference; though it appears to have applied it to a much larger. But all this is nothing to the purpose.

Tacquet will have it, that the little circle, making its rotation more slowly than the great one, does on that account describe a line longer than its own circumference; yet without applying any point of its circumference to more than one point of its base. But this is no more satisfactory than the former.

After the fruitless attempts of so many great men, M. Dortous de Meyran, a French gentleman, had the good fortune to hit upon a solution, which he sent to the Academy of Sciences; where being examined by Mess. de Louville and Soulmon, appointed for that purpose, they made their report that it was satisfactory. The solution is to this effect:

The wheel of a coach is only acted on, or drawn in a right line; its rotation or circular motion arises purely from the resistance of the ground upon which it is applied. Now this resistance is equal to the force which draws the wheel in the right line, inasmuch as it defeats that direction; of consequence the causes of the two motions, the one right and the other circular, are equal. And hence the wheel describes a right line on the ground equal to its circumference.

As for the nave of the wheel, the case is otherwise. It is drawn in a right line by the same force as the wheel; but it only turns round because the wheel does so, and can only turn in the same time with it. Hence it follows, that its circular velocity is less than that of the wheel, in the ratio of the two circumferences; and therefore its circular motion is less than the rectilinear one. Since then it necessarily describes a right line equal to that of the wheel, it can only do it partly by sliding, and partly by revolving, the sliding part being more or less as the nave itself is smaller or larger. See Cycloid.

ROTATION, *Rolling*, in Mechanics. See Rolling.

Rotation, in Geometry, the circumvolution of a surface round an immoveable line, called the *axis of Rotation*. By such Rotation of planes, the figures of certain regular solids are formed or generated. Such as, a cylinder by the Rotation of a rectangle, a cone by the Rotation of a triangle, a sphere or globe by the Rotation of a semicircle, &c.

The method of cubing solids that are generated by such Rotation, is laid down by Mr. Demoivre, in his specimen of the use of the doctrine of fluxions, Philos. Transf. numb. 216; and indeed by most of the writers on Fluxions. In every such solid, all the sections perpendicular to the axis are circles, and therefore the fluxion of the solid, at any section, is equal to that circle multiplied by the fluxion of the axis. So that, if x denote an absciss of that axis, and y an ordinate to it in the revolving plane, which will also be the radius of that circle; then, n being put for 3·1416, the area of the circle is ny^2, and consequently the fluxion of the solid is $ny^2\dot{x}$; the fluent of which will be the content of the solid.

Such solid may also be expressed in terms of the generating plane and its centre of gravity; for the solid is always equal to the product arising from the generating plane multiplied by the path of its centre of gravity, or by the line described by that centre in the Rotation of the plane. And this theorem is general, by whatever kind of motion the plane is moved, in describing a solid.

Rotation, *Revolution*, in Astronomy. See Revolution.

Diurnal Rotation. See Diurnal, and Earth.

ROTONDO, or Rotundo, in Architecture, a popular term for any building that is round both within and withoutside, whether it be a church, hall, a saloon, a vestibule, or the like.

ROUND, Roundness, Rotundity, the property of a circle and sphere or globe &c.

ROWNING (John), an ingenious English mathematician and philosopher, was fellow of Magdalen College, Cambridge, and afterwards Rector of Anderby in Lincolnshire, in the gift of that society. He was a constant attendant at the meetings of the Spalding Society, and was a man of a great philosophical habit and turn of mind, though of a cheerful and companionable disposition. He had a good genius for mechanical contrivances in particular. In 1738 he printed at Cambridge, in 8vo, *A Compendious System of Natural Philosophy*, in 2 vols 8vo; a very ingenious work, which has gone through several editions. He had also two pieces inserted in the Philosophical Transactions, viz, 1. *A Description of a Barometer wherein the Scale of Variation may be increased at pleasure*; vol. 38, pa. 39. And 2. *Direction for making a Machine for finding the Roots of Equations universally, with the Manner of using it*; vol. 60, pa. 240.—Mr. Rowning died at his lodgings in Carey-street near Lincoln's Inn Fields, the latter end of November 1771, at 72 years of age.

Though a very ingenious and pleasant man, he had but an unpromising and forbidding appearance: he was tall, stooping in the shoulders, and of a sallow down-looking countenance.

ROYAL *Oak*, *Robur Carolinum*, in Astronomy, one of the new southern constellations, the stars of which,

which, according to Sharp's catalogue, annexed to the Britannic, are 12.

ROYAL *Society of England*, is an academy or body of persons, supposed to be eminent for their learning, instituted by king Charles the IId, for promoting natural knowledge.

This once illustrious body originated from an assembly of ingenious men, residing in London, who, being inquisitive into natural knowledge, and the new and experimental philosophy, agreed, about the year 1645, to meet weekly on a certain day, to discourse upon such subjects. These meetings, it is said, were suggested by Mr. Theodore Haak, a native of the Palatinate in Germany; and they were held sometimes at Dr. Goddard's lodgings in Wood-street, sometimes at a convenient place in Cheapside, and sometimes in or near Gresham College. This assembly seems to be that mentioned under the title of the *Invisible, or Philosophical College*, by Mr. Boyle, in some letters written in 1646 and 1647. About the years 1648 and 1649, the company which formed these meetings, began to be divided, some of the gentlemen removing to Oxford, as Dr. Wallis, and Dr. Goddard, where, in conjunction with other gentlemen, they held meetings also, and brought the study of natural and experimental philosophy into fashion there; meeting first in Dr. Petty's lodgings, afterwards at Dr. Wilkins's apartments in Wadham College, and, upon his removal, in the lodgings of Mr. Robert Boyle; while those gentlemen who remained in London continued their meetings as before. The greater part of the Oxford society coming to London about the year 1659, they met once or twice a week in Term-time at Gresham College, till they were dispersed by the public distractions of that year, and the place of their meeting was made a quarter for soldiers. Upon the restoration, in 1660, their meetings were revived, and attended by many gentlemen, eminent for their character and learning.

They were at length noticed by the government, and the king granted them a charter, first the 15th of July 1662, then a more ample one the 22d of April 1663, and thirdly the 8th of April 1669; by which they were erected into a corporation, *consisting of a president, council, and fellows, for promoting natural knowledge*, and endued with various privileges and authorities.

Their manner of electing members is by ballotting; and two-thirds of the members present are necessary to carry the election in favour of the candidate. The council consists of 21 members, including the president, vice-president, treasurer, and two secretaries; ten of which go out annually, and ten new members are elected instead of them, all chosen on St. Andrew's day. They had formerly also two curators, whose business it was to perform experiments before the society.

Each member, at his admission, subscribes an engagement, that he will endeavour to promote the good of the society; from which he may be freed at any time, by signifying to the president that he desires to withdraw.

The charges are five guineas paid to the treasurer at admission; and one shilling per week, or 52s. per year, as long as the person continues a member; or, in lieu of the annual subscription, a composition of 25 guineas in one payment.

The ordinary meetings of the society, are once a week, from November till the end of Trinity term the next summer. At first, the meeting was from 5 o'clock till 6 afternoon. Afterwards, their meeting was from 6 till 7 in the evening, to allow more time for dinner, which continued for a long series of years, till the hour of meeting was removed, by the present president, to between 8 and 9 at night, that gentlemen of fashion, as was alleged, might have the opportunity of coming to attend the meetings after dinner.

Their design is to "make faithful records of all the "works of nature or art, which come within their "reach; so that the present, as well as after ages, "may be enabled to put a mark on errors which have "been strengthened by long prescription; to restore "truths that have been long neglected; to push those "already known to more various uses; to make the "way more passable to what remains unrevealed, "&c."

To this purpose they have made a great number of experiments and observations on most of the works of nature; as eclipses, comets, planets, meteors, mines, plants, earthquakes, inundations, springs, damps, fires, tides, currents, the magnet, &c: their motto being *Nullius in Verba*. They have registered experiments, histories, relations, observations, &c, and reduced them into one common stock. They have, from time to time, published some of the most useful of these, under the title of Philosophical Transactions, &c. usually one volume each year, which were, till lately, very respectable, both for the extent or magnitude of them, and for the excellent quality of their contents. The rest, that are not printed, they lay up in their registers.

They have a good library of books, which has been formed, and continually augmenting, by numerous donations. They had also a museum of curiosities in nature, kept in one of the rooms of their own house in Crane Court Fleet-street, where they held their meetings, with the greatest reputation, for many years, keeping registers of the weather, and making other experiments; for all which purposes those apartments were well adapted. But, disposing of these apartments, in order to remove into those allotted them in Somerset Place, where having neither room nor convenience for such purposes, the museum was obliged to be disposed of, and their useful meteorological registers discontinued for many years.

Sir Godfrey Copley, bart. left 5 guineas to be given annually to the person who should write the best paper in the year, under the head of experimental philosophy: this reward, which is now changed to a gold medal, is the highest honour the society can bestow; and it is conferred on St. Andrew's day: but the communications of late years have been thought of so little importance, that the prize medal remains sometimes for years undisposed of.

Indeed this once very respectable society, now consisting of a great proportion of honorary members, who do not usually communicate papers; and many scientific members being discouraged from making their

useful

usual communications, by what is deemed the present arbitrary government of the society; the annual volumes have in consequence become of much less importance, both in respect of their bulk and the quality of their contents.

ROYAL *Society of Scotland*. See SOCIETY.

RUDOLPHINE *Tables*, a set of astronomical tables that were published by the celebrated Kepler, and so called from the emperor Rudolph or Rudolphus.

RULE, *The Carpenters*, a folding rule generally used by carpenters and other artificers; and is otherwise called the sliding-Rule.

This instrument consists of two equal pieces of box-wood, each one foot in length, connected together by a folding joint. One side or face, of the Rule, is divided into inches, and half-quarters, or eighths. On the same face also are several plane scales, divided into 12th parts by diagonal lines; which are used in planning dimensions that are taken in feet and inches. The edge of the Rule is commonly divided decimally, or into 10ths; viz, each foot into 10 equal parts, and each of these into 10 parts again, or 100dth parts of the foot: so that by means of this last scale, dimensions are taken in feet and tenths and hundreds, and multiplied together as common decimal numbers, which is the best way.

On the one part of the other face are four lines, marked A, B, C, D, the two middle ones B and C being on a slider, which runs in a groove made in the stock. The same numbers serve for both these two middle lines, the one line being above the numbers, and the other below them.

These four lines are logarithmic ones, and the three A, B, C, which are all equal to one another, are double lines, as they proceed twice over from 1 to 10. The lowest line D is a single one, proceeding from 4 to 40. It is also called the girt line, from its use in casting up the contents of trees and timber: and upon it are marked WG at 17·15, and AG at 18·95, the wine and ale gauge points, to make this instrument serve the purpose of a gauging rule.

Upon the other part of this face is a table of the value of a load, or 50 cubic feet, of timber, at all prices, from 6 pence to 2s. a foot.

When 1 at the beginning of any line is accounted only 1, then the 1 in the middle is 10, and the 10 at the end 100; and when the 1 at the beginning is accounted 10, then 1 in the middle is 100, and the 10 at the end 1000; and so on. All the smaller divisions being also altered proportionally.

By means of this Rule all the usual operations of arithmetic may be easily and quickly performed, as multiplication, division, involution, evolution, finding mean proportionals, 3d and 4th proportionals, or the Rule of three, &c. For all which, see my Mensuration, part 5, sect. 3, 2d edition.

RULES *of Philosophizing*. See PHILOSOPHIZING.

RULE, in Arithmetic, denotes a certain mode of operation with figures to find sums or numbers unknown, and to facilitate computations.

Each Rule in arithmetic has its particular name, according to the use for which it is intended. The first four, which serve as a foundation of the whole art, are called *addition*, *subtraction*, *multiplication*, and *division*.

From these arise numerous other Rules, which are indeed only applications of these to particular purposes and occasions; as the Rule-of-three, or Golden Rule, or Rule of Proportion; also the Rules of Fellowship, Interest, Exchanges, Position, Progressions, &c, &c. For which, see each article severally.

RULE-*of-Three*, or *Rule of Proportion*, commonly called the *Golden Rule* from its great use, is a Rule that teaches how to find a 4th proportional number to three others that are given.

As, if 3 degrees of the equator contain 208 miles, how many are contained in 360 degrees, or the whole circumference of the earth?

The Rule is this: State, or set the three given terms down in the form of the first three terms of a proportion, stating them proportionally, thus:

```
     deg. mil.   deg.  miles.
as    3 : 208 :: 360 : 24960
            360
          -----
          12480
          624
          -----
        3 )74880
          -----
          24960
```

Then multiply the 2d and 3d terms together, and divide the product by the 1st term, so shall the quotient be the 4th term in proportion, or the answer to the question, which in this example is 24960 or nearly 25 thousand miles, for the circumference of the earth.

This rule is often considered as of two kinds, viz. *Direct*, and *Inverse*.

Rule-of-Three Direct, is that in which more requires more, or less requires less. As in this; if 3 men mow 21 yards of grass in a certain time, how much will 6 men mow in the same time? Here more requires more, that is, 6 men, which are more than 3 men, will also perform more work, in the same time. Or if it were thus; if 6 men mow 42 yards, how much will 3 men mow in the same time? here then less requires less, or 3 men will perform proportionally less work, in the same time. In both these cases then, the Rule, or the proportion, is direct; and the stating must be

thus, as 3 : 21 :: 6 : 42,

or thus, as 6 : 42 :: 3 : 21.

Rule-of-Three Inverse, is when more requires less, or less requires more. As in this; if 3 men mow a certain quantity of grass in 14 hours, in how many hours will 6 men mow the like quantity? Here it is evident that 6 men, being more than 3, will perform the same work in less time, or fewer hours; hence then more requires less, and the Rule or question is inverse, and must be stated by making the number of men change places, thus, as 6 : 14 :: 3 : 7 hours, the time in which 6 men will perform the work; still multiplying the 2d and 3d terms together, and dividing by the 1st.

For various abbreviations, and other particulars relating

lating to these Rules, see any of the common books of arithmetic.

RULE-*of-Five*, or *Compound Rule-of-Three*, is where two Rules-of-three are required to be wrought, or to be combined together, to find out the number sought.

This Rule may be performed, either by working the two statings or proportions separately, making the result or 4th term of the 1st operation to be the 2d term of the last proportion; or else by reducing the two statings into one, by multiplying the two first terms together, and the two third terms together, and using the products as the 1st and 3d terms of the compound stating. As, if the question be this: If 100l. in 2 years yield 9l. interest, how much will 500l. yield in 6 years. Here, the two statings are,

$$\left.\begin{matrix}100\\2\end{matrix}\right\} : 9 :: \left\{\begin{matrix}500\\6\end{matrix}\right.$$

Then, to work the two statings separately,

as 100 : 9 :: 500 : 45l.
and 2 : 45 :: 6 : 135l.

so that 135l. is the interest or answer sought. But to work by one stating, it will be thus,

$$\begin{array}{cccc} 100 & & 500 & \\ 2 & & 6 & \\ \hline 200 : 9 & :: & 3000 : & 135l. \text{ the answer.} \end{array}$$

200) 270.00 (135l.

See the books of arithmetic for more particulars.

Central RULE. See CENTRAL *Rule*.

Parallel RULER. See PARALLEL *Ruler*.

RUMB, or RUM. See RHUMB.

RUMB-*Line*, or *Loxodromic*. See RHUMB-*Line*.

RUSTIC, in Architecture, denotes a manner of building in imitation of simple or rude nature, rather than according to the rules of art.

RUSTIC *Quoins*. See QUOIN.

RUSTIC *Work* is where the stones in the face &c of a building, instead of being smooth, are hatched or picked with the point of an instrument.

Regular RUSTICS, are those in which the stones are chamfered off at the edges, and form angular or square recesses of about an inch deep at their jointings, or beds, and ends.

RUSTIC *Order*, is an order decorated with rustic quoins, or rustic work, &c.

RUTHERFORD (THOMAS, D. D.), an ingenious English philosopher, was the son of the Rev. Thomas Rutherford, rector of Papworth Everard in the county of Cambridge, who had made large collections for the history of that county.

Our author was born the 13th of October 1712. He studied at Cambridge, and became fellow of St. John's college, and regius professor of divinity, in that university; afterwards rector of Shenfield in Essex, and of Barley in Hertfordshire, and archdeacon of Essex. He died the 5th of October 1771, at 59 years of age.

Dr. Rutherford, besides a number of theological writings, published, at Cambridge,

1. *Ordo Institutionum Physicarum*, 1743, in 4to.

2. *A System of Natural Philosophy*, in 2 vols, 4to, 1748. A work which has been much esteemed.

3. He communicated also to the Gentleman's Society at Spalding, a curious correction of Plutarch's description of the instrument used to renew the Vestal fire, as relating to the triangle with which the instrument was formed. It was nothing else, it seems, but a concave speculum, whose principal focus, which collected the rays, is not in the centre of concavity, but at the distance of half a diameter from its surface. But some of the Ancients thought otherwise, as appears from prop. 31 of Euclid's Catoptrics.

The writer of his epitaph says, "He was eminent no less for his piety and integrity, than his extensive learning; and filled every public station in which he was placed with general approbation. In private life, his behaviour was truly amiable. He was esteemed, beloved, and honoured by his family and friends; and his death was sincerely lamented by all who had ever heard of his well deserved character."

S.

S, IN books of Navigation, &c, denotes fouth. So alfo S. E. is fouth-eaft; S. W. fouth-weft; and S. S. E. fouth-fouth-eaft, &c. See COMPASS.

SAGITTA, in Aftronomy, the *Arrow* or *Dart*, a conftellation of the northern hemifphere near the eagle, and one of the 48 old afterifms. The Greeks fay that this conftellation owes its origin to one of the arrows of Hercules, with which he killed the eagle or vulture that gnawed the liver of Prometheus.

The ftars in this conftellation, in the catalogues of Ptolomy, Tycho, and Hevelius, are only 5, but in Flamfteed's they are extended to 18.

SAGITTA, in Geometry, is a term ufed by fome writers for the abfcifs of a curve.

SAGITTA, in Trigonometry &c, is the fame as the verfed fine of an arch; being fo called becaufe it is like a dart or arrow, ftanding on the chord of the arch.

SAGITTARIUS, SAGITTARY, the *Archer*, one of the figns of the zodiac, being the 9th in order, and marked with the character ♐ of a dart or arrow. This conftellation is drawn in the figure of a Centaur, or an animal half man and half horfe, in the act of fhooting an arrow from a bow. This figure the Greeks feign to be Crotus, the fon of Eupheme, the nurfe of the mufes. Among more ancient nations the figure was probably meant for a hunter, to denote the hunting feafon, when the fun enters this fign.

The ftars in this conftellation are, in Ptolomy's catalogue 31, in Tycho's 14, in Hevelius's 22, and in the Britannic catalogue 69.

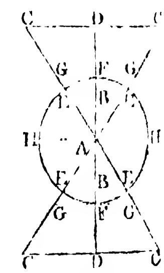
SAILING, in a general fenfe, denotes the movement by which a veffel is wafted along the furface of the water, by the action of the wind upon her fails.

Sailing is alfo ufed for the art or act of navigating; or of determining all the cafes of a fhip's motion, by means of fea-charts &c. Thefe charts are conftructed either on the fuppofition that the earth is a large extended flat furface, whence we obtain thofe that are called plane charts; or on the fuppofition that the earth is a fphere, whence are derived globular charts. Accordingly, Sailing may be diftinguifhed into two general kinds, viz, *plane Sailing*, and *globular Sailing*. Sometimes indeed a third fort is added, viz, *fpheroidical Sailing*, which proceeds upon the fuppofition of the fpheroidical figure of the earth.

Plane SAILING is that which is performed by means of a plane chart; in which cafe the meridians are confidered as parallel lines, the parallels of latitude are at right angles to the meridians, the lengths of the degrees on the meridians, equator, and parallels of latitude, are every where equal.

In Plane Sailing, the principal terms and circumftances made ufe of, are, courfe, diftance, departure, difference of latitude, rhumb, &c; for as to longitude, that has no place in plane Sailing, but belongs properly to globular or fpherical failing. For the explanation of all which terms, fee the refpective articles.

If a fhip fails either due north or fouth, fhe fails on a meridian, her diftance and difference of latitude are the fame, and fhe makes no departure; but where the fhip fails either due eaft or weft, fhe runs on a parallel of latitude, making no difference of latitude, and her departure and diftance are the fame. It may farther be obferved, that the departure and difference of latitude always make the legs of a right-angled triangle, whofe hypotenufe is the diftance the fhip has failed; and the angles are the courfe, its complement, and the right angle; therefore among thefe four things, courfe, diftance, difference of latitude, and departure, any two of them being given, the reft may be found by plane trigonometry.



Thus, in the annexed figure, fuppofe the circle FHFH to reprefent the horizon of the place A, from whence a fhip fails; AC the rhumb fhe fails upon, and C the place arrived at: then HH reprefents the parallel of latitude fhe failed from, and CC the parallel of the latitude arrived in: fo that

AD becomes the difference of latitude.
DC the departure,
AC the diftance failed,
∠DAC is the courfe, and
∠DCA the comp. of the courfe.

And all thefe particulars will be alike reprefented, whether the fhip fails in the NE, or NW, or SE, or SW quarter of the horizon.

From the fame figure, in which
AE or AF or AH reprefents the rad. of the tables,
EB the fine of the courfe,
AB the cofine of the courfe,

we may eafily deduce all the proportions or canons, as they are ufually called by mariners, that can arife in Plane Sailing; becaufe the triangles ADC and ABE and AFG are evidently fimilar. Thefe proportions are exhibited in the following Table, which confifts of 6 cafes, according to the varieties of the two parts that can be given.

Cafe

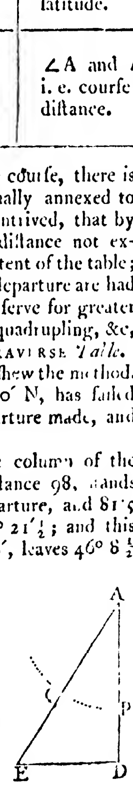
Cafe.	Given.	Required	Solutions.
1	∠A and AC, i. e. courfe and diftance.	AD and DC, i. e. difference of latitude and departure.	AE : AB :: AC : AD, i. e. rad. : f. courfe :: dift. : dif. lat. AE : EB :: AC : DC, i. e. rad. : cof. courfe :: dift. : depart.
2	∠A and AD, i. e. courfe and difference of latitude.	AC and DC, i. e. diftance and departure.	AB : AE :: AD : AC, i. e. cof. cour. : rad. :: dif. lat. : dift. AB : BE :: AD : DC, i. e. cof. cour. : f. cour. :: dif. lat. : dep.
3	∠A and DC, i. e. courfe and departure.	AC and AD, i. e. diftance and difference of latitude.	BE : AE :: DC : AC, i. e. f. cour. : rad. :: depart. : dift. BE : AB :: DC : AD, i. e. f. cour. : cof. cour. :: dep. : dif. lat.
4	AC and AD, i. e. diftance and difference of latitude.	∠A and DC, i. e. courfe and departure.	AC : AD :: AE : AB, i. e. dift. : dif. lat. :: rad. : cof. courfe. AE : EB :: AC : DC, i. e. rad. : f. courfe :: dift. : depart.
5	AC and DC, i. e. diftance and departure.	∠A and AD, i. e. courfe and difference of latitude.	AC : DC :: AE : EB, i. e. dift. : dep. :: rad. : f. courfe. AE : AB :: AC : AD, i. e. rad. : cof. cour. :: dift. : dif. lat.
6	AD and DC, i. e. difference of latitude and departure.	∠A and AC, i. e. courfe and diftance.	AD : DC :: AF : FG, i. e. dif. lat. : dep. :: rad. : tang. courfe. BE : AE :: DC : AC, i. e. f. cour. : rad. :: dep. : dift.

For the ready working of any fingle courfe, there is a table, called a *Traverfe Table*, ufually annexed to treatifes of navigation; which is fo contrived, that by finding the given courfe in it, and a diftance not exceeding 100 or 120 miles, the ufual extent of the table; then the difference of latitude and the departure are had by infpection. And the fame table will ferve for greater diftances, by doubling, or trebling, or quadrupling, &c, or taking proportional parts. See TRAVERSE *Table*.

An ex. to the firft cafe may fuffice to fhew the method. Thus, A fhip from the latitude 47° 30′ N, has failed SW by S 98 miles; required the departure made, and the latitude arrived in.

1. *By the Traverfe Table*. In the column of the courfe, viz 3 points, againft the diftance 98, ftands the number 54·45 miles for the departure, and 81·5 miles for the diff. of lat.; which is 1° 21′½; and this being taken from the given lat. 47° 30′, leaves 46° 8½ for the lat. come to.

2. *By Conftruction*. Draw the meridian AD; and drawing an arc, with the chord of 60, make PQ or angle A equal to 3 points; through Q draw the diftance AQE = 98 miles, and through E the departure ED perp. to AD. Then, by meafuring, the diff. of lat. AD meafures about 81½ miles, and the departure DE about 54½ miles.



3. *By Computation*.

Firft, as radius	- - - - - -	10·00000
to fin. courfe 33° 45′	- - -	9·74474
fo dift. 98	- - - - - - - -	1·99123
to depart. 54·45	- - - -	1·73597
Again, as radius	- - - - -	10·00000
to cof. courfe	- - - - - -	9·91985
fo dift. 98	- - - - - - - -	1·99123
to diff. of lat. 81·48	- - -	1·91108

4. *By Gunter's Scale*. The extent from radius, or 8 points, to 3 points, on the line of fine rhumbs, applied to the line of numbers, will reach from 98 to 54½ the departure. And the extent from 8 points to 5 points, of the rhumbs, reaches from 98 to 81½ on the line of numbers, for the difference of latitude.

And in like manner for other cafes.

Traverfe SAILING, or *Compound Courfes*, is the uniting of feveral cafes of plane failing together into one; as when a fhip fails in a zigzag manner, certain diftances upon feveral different courfes, to find the whole difference of latitude and departure made good on all of them. This is done by working all the cafes feparately, by means of the traverfe table, and conftructing the figure as in this example.

3 F 2. *Ex*. A.

Ex. A ship sailing from a place in latitude 24° 32′ N, has run five different courses and distances, as set down in the 1st and 2d columns of the following traverse table; required her present latitude, with the departure, and the direct course and distance, between the place sailed from, and the place come to.

Traverse Table.

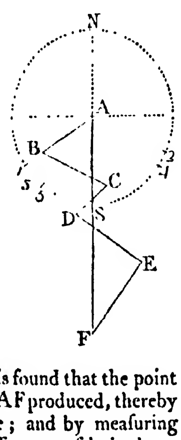
Courses.	Dist.	N	S	E	W
SW b S	45		25·0		37·4
ESE	50		19·1	46·2	
SW	30		21·2		21·2
SE b E	60		33·3	49·9	
SW b S ¼ W	63		50·6		37·5
			149·2	96·1	96·1

Here, by finding, in the general traverse table, the difference of latitude and departure answering to each course and distance, they are set down on the same lines with each course, and in their proper columns of northing, southing, easting, or westing, according to the quarter of the compass the ship sails in, at each course. As here, there is no northing, the differences of latitude are all southward, also two departures are eastward, and three are westward. Then, adding up the numbers in each column, the sum of the eastings appears to be exactly equal to the sum of the westings, consequently the ship is arrived in the same meridian, without making any departure; and the southings, or difference of latitude being 149·2 miles or minutes,

that is - - - - - - - - 2° 29′,
which taken from - - 24 32, the latitude dep. from,

leaves - - - - - - - - - 22 3 N, the latitude come to.

To Construct this Traverse. With the chord of 60 degrees describe the circle N 135 S &c, and quarter it by the two perpendicular diameters; then from S set upon it the several courses, to the points marked 1, 2, 3, 4, 5, through which points draw lines from the centre A, or conceive them to be drawn; lastly, upon the first line lay off the first distance 45 from A to B, also draw BC = 50 and parallel to A 2, and CD = 30 parallel to A 3, and DE = 60 parallel to A 4, and EF = 63, parallel to A 5; then it is found that the point F falls exactly upon the meridian NAF produced, thereby shewing that there is no departure; and by measuring AF, it gives 149 miles for the difference of latitude.

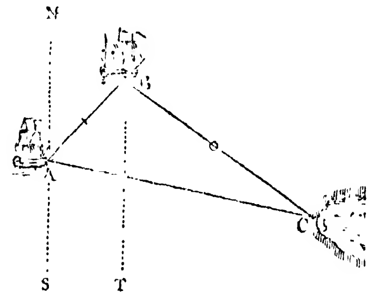


Oblique SAILING, is the resolution of certain cases and problems in Sailing by oblique triangles, or in which oblique triangles are concerned.

In this kind of Sailing, it may be observed, that *to set an object*, means to observe what rhumb or point of the nautical compass is directed to it. And the *bearing* of an object is the rhumb on which it is seen; also the bearing of one place from another, is reckoned by the name of the rhumb passing through those two places.

In every figure relating to any case of plane Sailing, the bearing of a line, not running from the centre of the circle or horizon, is found by drawing a line parallel to it, from the centre, and towards the same quarter.

Ex. A ship sailing at sea, observed a point of land to bear E by S; and then after sailing NE 12 miles, its bearing was found to be SE by E. Required the place of that point, and its distance from the ship at the last observation.



Construction. Draw the meridian line NAS, and, assuming A for the first place of the ship, draw AC the E by S rhumb, and AB the NE one, upon which lay off 12 miles from A to B; then draw the meridian BT parallel to NS, from which set off the SE by E point BC, and the point C will be the place of the land required; then the distance BC measures 26 miles.

By Computation. Here are given the side AB, and the two angles A and B, viz, the $\angle A = 5$ points or 56° 15′, and the $\angle B = 9$ points or 101° 15′; consequently the $\angle C = 2$ points or 22° 30′. Then, by plane trigonometry,

As sin. $\angle C$ 22° 30′ - - - - 9·58284
To sin $\angle B$ 56 15 - - - - 9·91985
So is AB 12 miles - - - - 1·07918

To BC 26·073 miles - - - - 1·41619

SAILING *to Windward*, is working the ship towards that quarter of the compass from whence the wind blows.

For rightly understanding this part of navigation, it will be necessary to explain the terms that occur in it, though most of them may be seen in their proper places in this work.

When the wind is directly, or partly, against a ship's direct course for the place she is bound to, she reaches her port by a kind of zigzag or z like course; which is made by sailing with the wind first on one side of the ship, and then on the other side.

In a ship, when you look towards the head, *Starboard* denotes the right hand side.

Larboard the left hand side.

Forwards, or *afore*, is towards the head.

Aft, or *abaft*, is towards the stern.

The *beam* signifies athwart or across the middle of the ship.

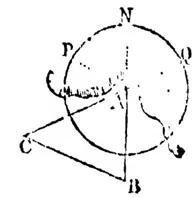
When a ship sails the same way that the wind blows, she is said to sail or run before the wind; and the wind is said to be *right aft*, or *right astern*; and her course is then 16 points, or the farthest possible, from the wind, that is from the point the wind blows from.—When the ship sails with the wind blowing directly across her, she is said to have the *wind on the beam*; and her course is 8 points from the wind.—When the wind blows obliquely across the ship, the wind is said to be *abaft the beam* when it pursues her, or blows more on the hinder part, but *before the beam* when it meets or opposes her course, her course being more than 8 points from the wind in the former case, but less than 8 points in the latter case.—When a ship endeavours to sail towards that point of the compass from which the wind blows, she is said to *sail on a wind*, or to *ply to windward*.—And a vessel sailing as near as she can to the point from which the wind blows, she is said to be *close hauled*. Most ships will lie within about 6 points of the wind; but sloops, and some other vessels, will lie much nearer. To know how near the wind a ship will lie; observe the course she goes on each tack, when she is close hauled; then half the number of points between the two courses, will shew how near the wind the ship will lie.

The *windward*, or *weather side*, is that side of the ship on which the wind blows; and the other side is called the *leeward*, or *lee side*.—*Tacks* and *sheets* are large ropes fastened to the lower corners of the fore and main sails; by which either of these corners is hauled fore or aft.—When a ship sails on a wind, the windward tacks are always hauled forwards, and the leeward sheets aft.—The *starboard tacks are aboard*, when the starboard side is to windward, and the larboard side to leeward. And the *larboard tacks are aboard*, when the larboard side is to windward, and the starboard to leeward.

The most common cases in turning to windward may be constructed by the following precepts. Having drawn a circle with the chord of 60°, for the compass, or the horizon of the place, quarter it by drawing the meridian and parallel of latitude perpendicular to each other, and both through the centre; mark the place of the wind in the circumference; draw the rhumb passing through the place bound to, and lay on it, from the centre, the distance of that place. On each side of the wind lay off, in the circumference, the points or degrees shewing how near the wind the ship can lie; and draw these rhumbs.—Now the first course will be on one of these rhumbs, according to the tack the ship leads with. Draw a line through the place bound to, parallel to the other rhumb, and meeting the first; and thus will shew the course and distance on the other tack.

Ex. The wind being at north, and a ship bound to a port 25 miles directly to windward; beginning with the starboard tacks, what must be the course and distance on each of two tacks to reach the port?

Construction. Having drawn the circle &c, as above described, where A is the port, AP and AQ the two rhumbs, each within 6 points of AN; in NA produced take AB = 25 miles, then B is the place of the ship; draw BC parallel to AP, and meeting QA produced in C; so shall BC and CA be the distances on the two tacks; the former being WNW, and the latter ENE.



Computation.

Here $\angle B = NAP = 6$ points,
and $\angle A = NAQ = 6$ points,
theref. $\angle C = 4$ points.

So that all the angles are given, and the side AB, to find the other two sides AC and BC, which are equal to each other, because their opposite angles A and B are equal. Hence

as sin. C : AB : : sin. A : BC,

i. e. s. 45° : 25 : : s. 67° 30' : $32\frac{2}{3}$ = BC or AC, the distance to be run on each tack.

Sailing *in Currents*, is the method of determining the true course and distance of a ship when her own motion is affected and combined with that of a current.

A *current* or *tide* is a progressive motion of the water, causing all floating bodies to move that way towards which the stream is directed.—The *setting* of a tide, or current, is that point of the compass towards which the waters run; and the *drift* of the current is the rate at which it runs per hour.

The drift and setting of the most remarkable tides and currents, are pretty well known; but for unknown currents, the usual way to find the drift and setting, is thus: Let three or four men take a boat a little way from the ship; and by a rope, fastened to the boat's stem, let down a heavy iron pot, or loaded kettle, into the sea, to the depth of 80 or 100 fathoms, when it can be done: by which means the boat will ride almost as steady as at anchor. Then heave the log, and the number of knots run out in half a minute will give the current's rate, or the miles which it runs per hour; and the bearing of the log shews the setting of the current.

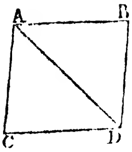
A body moving in a current, may be considered in three cases: viz,

1. Moving with the current, or the same way it sets.
2. Moving against it, or the contrary way it sets.
3. Moving obliquely to the current's motion.

In the 1st case, or when a ship sails with a current, its velocity will be equal to the sum of its proper motion, and the current's drift. But in the 2d case, or when a ship sails against a current, its velocity will be equal to the difference of her own motion and the drift of the current: so that if the current drives stronger than the wind, the ship will drive astern, or lose way. In the 3d case, when the current sets oblique to the course of the ship, her real course, or that made good, will be somewhere between that in which the ship endeavours to go, and the track in which the current tries to drive her; and indeed it will always be along the diagonal of a parallelogram, of which one side represents the ship's course set, and the other adjoining side is the current's drift.

Thus,

Thus, if ABDC be a parallelogram. Now if the wind alone would drive the ſhip from A to B in the ſame time as the current alone would drive her from A to C: then, as the wind neither helps nor hinders the ſhip from coming towards the line CD, the current will bring her there in the ſame time as if the wind did not act. And as the current neither helps nor hinders the ſhip from coming towards the line BD, the wind will bring her there in the ſame time as if the current did not act. Therefore the ſhip muſt, at the end of that time, be found in both thoſe lines, that is, in their meeting D. Conſequently the ſhip muſt have paſſed from A to D in the diagonal AD.



Hence, drawing the rhumbs for the proper courſe of the ſhip and of the current, and ſetting the diſtances off upon them, according to the quantity run by each in the given time; then forming a parallelogram of theſe two, and drawing its diagonal, this will be the real courſe and diſtance made good by the ſhip.

Ex 1. A ſhip ſails E. 5 miles an hour, in a tide ſetting the ſame way 4 miles an hour: required the ſhip's courſe, and the diſtance made good.

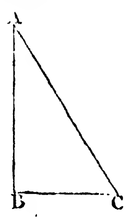
The ſhip's motion is	5m. E.
The current's motion is	4m. E.
Theref. the ſhip's run is	9m. E.

Ex. 2. A ſhip ſails SSW. with a briſk gale, at the rate of 9 miles an hour, in a current ſetting NNE. 2 miles an hour: required the ſhip's courſe, and the diſtance made good.

The ſhip's motion is	SSW. 9m.
The current's motion is	NNE. 2m.
Theref. ſhip's true run is	SSW. 7m.

Ex. 3. A ſhip running ſouth at the rate of 5 miles an hour, in 10 hours croſſes a current, which all that time was ſetting eaſt at the rate of 3 miles an hour: required the ſhip's true courſe and diſtance ſailed.

Here the ſhip is firſt ſuppoſed to be at A, her imaginary courſe is along the line AB, which is drawn ſouth, and equal to 50 miles, the run in 10 hours; then draw BC eaſt, and equal to 30 miles, the run of the current in 10 hours. Then the ſhip is found at C, and her true path is in the line AC = 58·31 her diſtance, and her courſe is the angle at A = 30° 58′ from the ſouth towards the eaſt.



Globular Sailing is the eſtimating the ſhip's motion and run upon principles derived from the globular figure of the earth, viz, her courſe, diſtance, and difference of latitude and longitude.

The principles of this method are explained under the articles Rhumb-*line*, *Mercator's* Chart, and Meridional *Parts*; which ſee.

Globular Sailing, in the extenſive ſenſe here applied to the term, comprehends *Parallel Sailing*, *Middle-latitude Sailing*; and *Mercator's Sailing*; to which may be added *Circular Sailing*, or *Great-circle Sailing*. Of each of which it may be proper here to give a brief account.

Parallel Sailing is the art of finding what diſtance a ſhip ſhould run due eaſt or weſt, in ſailing from the meridian of one place to that of another place, in any parallel of latitude.

The computations in parallel ſailing depend on the following rule:

As radius,
To coſine of the lat. of any parallel;
So are the miles of long. between any two meridians,
To the diſt. of theſe meridians in that parallel.

Alſo, for any two latitudes,
As the coſine of one latitude,
Is to the coſine of another latitude;
So is a given meridional diſt. in the 1ſt parallel,
To the like meridional diſt. in the 2d parallel.

Hence, counting 60 nautical miles to each degree of longitude, or on the equator; then, by the firſt rule the number of miles in each degree on the other parallels, will come out as in the following table.

Table of Meridional Diſtances.

Lat.	Miles.	Lat	Miles.	Lat.	Miles.
1	59·99	31	51·43	61	29·09
2	59·96	32	50·88	62	28·17
3	59·92	33	50·32	63	27·24
4	59·85	34	49·74	64	26·30
5	59·77	35	49·15	65	25·36
6	59·67	36	48·54	66	24·41
7	59·56	37	47·92	67	23·44
8	59·42	38	47·28	68	22·48
9	59·26	39	46·63	69	21·50
10	59·09	40	45·96	70	20·52
11	58·89	41	45·28	71	19·53
12	58·69	42	44·59	72	18·54
13	58·46	43	43·88	73	17·54
14	58·22	44	43·16	74	16·54
15	57·95	45	42·43	75	15·53
16	57·67	46	41·68	76	14·51
17	57·38	47	40·92	77	13·50
18	57·06	48	40·15	78	12·48
19	56·73	49	39·36	79	11·45
20	56·38	50	38·57	80	10·42
21	56·01	51	37·76	81	9·38
22	55·63	52	36·94	82	8·35
23	55·23	53	36·11	83	7·32
24	54·81	54	35·27	84	6·28
25	54·38	55	34·41	85	5·23
26	53·93	56	33·55	86	4·18
27	53·46	57	32·68	87	3·14
28	52·97	58	31·79	88	2·09
29	52·47	59	30·90	89	1·05
30	51·96	60	30·00	90	0·00

See another table of this kind, allowing $69\frac{1}{11}$ English miles to one degree, under the article DEGREE.

To find the meridional distance to any number of minutes between any of the whole degrees in the table, as for instance in the parallel of 48° 26′; take out the tabular distances for the two whole degrees between which the parallel or the odd minutes lie, as for 48° and 49°; subtract the one from the other, and take the proportional part of the remainder for the odd minutes, by multiplying it by those minutes, and dividing by 60; and lastly, subtract this proportional part from the greater tabular number. Thus,

Lat. 48° -	- 40·15	
Lat. 49. -	- 39·36	
As 60′ : 26′ : :	0·79 rem. : 0.34	
	26	
	474	
	158	
60)	20·54	
	0·34	pro. part
Taken from -	40·15	for lat. 48°
Leaves merid. dist.	39·81	for lat. 48° 26′

And, in like manner, by the counter operation, to find what latitude answers to a given meridional distance. As, for ex. in what latitude 46·08 miles answer to a degree of longitude.

From 46·63 for 39°	from 46·63 for 39°
Take 45·96 for 40°	take 46·08 given number.
Then as 0 67 : 60′ : :	0·55 : 49′
	60
	67) 3300
	49′ pro. part.

Therefore the latitude sought is 39° 49′.

Ex. 3 Given the latitude and meridional distance; to find the corresponding difference of longitude. As, if a ship, in latitude 53° 36′, and longitude 10° 18′ east, sail due west 236 miles; required her present longitude.

Here, by the first rule,

As cos. lat.	53° 36′ comp.	0·22664
To radius -	90 00 - -	10·00000
So merid. dist.	236 m. -	2·37291
To diff. long.	397·7 - -	2·59955

Its 60th gives	6°	38′ W. diff. long.
Taken from	10	18 E. long. from
Leaves - -	3	40 E. long. come to.

By the table; the length of a degree on the parallel of 53° 36′ is 35·6.

Then as 35·6 : 60 : : 236 : 397·7, the diff. of long. the same as before.

Middle-latitude SAILING, is a method of resolving the cases of globular Sailing by means of the middle latitude between the latitude departed from, and that come to. This method is not quite accurate, being only an approximation to the truth, and it makes use of the principles of plane Sailing and parallel Sailing conjointly.

The method is founded on the supposition that the departure is reckoned as a meridional distance in that latitude which is a middle parallel between the latitude sailed from, and the latitude come to. And the method is not quite accurate, because the arithmetical mean, or half sum of the cosines of two distant latitudes, is not exactly the cosine of the middle latitude, or half the sum of those latitudes; nor is the departure between two places, on an oblique rhumb, equal to the meridional distance in the middle latitude; as is presumed in this method. Yet when the parallels are near the equator, or near to each other, in any latitude, the error is not considerable.

This method seems to have been invented on account of the easy manner in which the several cases may be resolved by the traverse table, and when a table of meridional parts is wanting. The computations depend on the following rules:

1. Take half the sum, or the arithmetical mean, of the two given latitudes, for the middle latitude. Then,

2. As cosine of middle latitude,
   Is to the radius;
   So is the departure,
   To the diff. of longitude. And,

3. As cosine of middle latitude,
   Is to the tangent of the course;
   So is the difference of latitude,
   To the difference of longitude.

Mercator's SAILING, is the art of resolving the several cases of globular Sailing, by plane trigonometry, with the assistance of a table of meridional parts, or of logarithmic tangents. And the computations are performed by the following rules:

1. As meridional diff. lat.
   To diff. of longitude;
   So is the radius,
   To tangent of the course.

2. As the proper diff lat.
   To the departure;
   So is merid. diff. lat.
   To diff. of longitude.

3. As diff. log. tang. half colatitudes,
   To tang. of 51° 38′ 09″;
   So is a given diff. longitude,
   To tangent of the course.

The manner of working with the meridional parts and logarithmic tangents, will appear from the two following cases.

1. Given the latitudes of two places; to find their meridional difference of latitude.

By the Merid. Parts. When the places are both on the

the ſame ſide of the equator, take the difference of the meridional parts anſwering to each latitude; but when the places are on oppoſite ſides of the equator, take the ſum of the ſame parts, for the meridional difference of latitude ſought.

By the Log. Tangents. In the former caſe, take the difference of the long. tangents of the half colatitudes; but in the latter caſe, take the ſum of the ſame; then the ſaid difference or ſum divided by 12·63, will give the meridional difference of latitude ſought.

2. Given the latitude of one place, and the meridional difference of latitude between that and another place; to find the latitude of this latter place.

By the Merid. Parts. When the places have like names, take the ſum of the merid. parts of the given lat. and the given diff.; but take the difference between the ſame when they have unlike names; then the reſult, being found in the table of meridional parts, will give the latitude ſought.

By the Log. Tangents. Multiply the given meridional diff. of lat. by 12·63; then in the former caſe ſubtract the product from the log. tangent of the given half colatitude, but in the latter caſe add them; then ſeek the degrees and minutes anſwering to the reſult among the log. tangents, and theſe degrees, &c. doubled will be the colatitude ſought.

Circular SAILING, or *Great-circle* SAILING, is the art of finding what places a ſhip muſt go through, and what courſes to ſteer, that her track may be in the arc of a great circle on the globe, or nearly ſo, paſſing through the place ſailed from and the place bound to.

This method of Sailing has been propoſed, becauſe the ſhorteſt diſtance between two places on the ſphere, is an arc of a great circle intercepted between them, and not the ſpiral rhumb paſſing through them, unleſs when that rhumb coincides with a great circle, which can only be on a meridian, or on the equator.

As the ſolutions of the caſes in Mercator's Sailing are performed by plane triangles, in this method of Sailing they are reſolved by means of ſpherical triangles. A great variety of caſes might be here propoſed, but thoſe that are the moſt uſeful, and moſt commonly occur, pertain to the following problem.

Problem I. Given the latitudes and longitudes of two places on the earth; to find their neareſt diſtance on the ſurface, together with the angles of poſition from either place to the other.

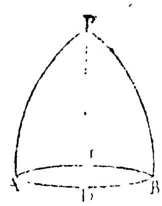
This problem comprehends 6 caſes.

Caſe 1. When the two places lie under the ſame meridian; then their difference of latitude will give their diſtance, and the poſition of one from the other will be directly north and ſouth.

Caſe 2. When the two places lie under the equator; their diſtance is equal to their difference of longitude, and the angle of poſition is a right angle, or the courſe from one to the other is due eaſt or weſt.

Caſe 3. When both places are in the ſame parallel of latitude. Ex. gr. The places both in 37° north, but the longitude of the one 25° weſt, and of the other 76° 23′ weſt.

Let P denote the north pole, and A and B the two places on the ſame parallel BDA, alſo BIA their diſtance aſunder, or the arc of a great circle paſſing through them. Then is the angle A or B that of poſition, and the angle BPA = 51° 23′ the difference of longitude, and the ſide PA or PB = 53° the colatitude.

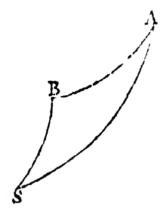


Draw PI perp. to AB, or biſecting the angle at P. Then in the triangle API, right-angled at I, are given the hypotenuſe AP = 53°, and the angle API = 25° 41′ 30″; to find the angle of poſition A or B = 73° 51′; and the half diſtance AI = 20° 15′½; this doubled gives 40° 31′ for the whole diſtance AB, or 2431 nautical miles, which is 31 miles leſs than the diſtance along ADB, or by parallel Sailing.

Caſe 4. When one place has latitude, and the other has none, or is under the equator. For example, ſuppoſe the Iſland of St. Thomas, lat. 0°, and long. 1° 0′ eaſt; and Port St. Julian, in lat. 48° 51′ ſouth, and long. 65° 10′ weſt.

Port St. Julian, lat.	48° 51′ S.	- long.	65° 10′ W.
Iſle St. Thomas -	0 00	- - - -	1 00 E.
Julian's colat.	41 09	Diff. long.	66 10

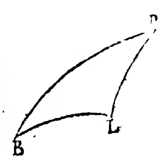
Hence, if S denote the ſouth pole, A the Iſle St. Thomas at the equator, and B St. Julian; then in the triangle are given SA a quadrant or 90°, BS = 41° 9′ the colat. of St. Julian, and the ∠S = 66° 10′ the dif. of longitude; to find AB = 74° 35′ = 4475 miles, which is leſs by 57 miles than the diſtance found by Mercator's Sailing; alſo the angle of poſition at A = 51°22′, and the angle of poſition B = 108° 24′.



Caſe 5. When the two given places are both on the ſame ſide of the equator; for example the Lizard, and the iſland of Bermudas.

The Lizard, lat.	49° 57′ N.	- long.	5° 21′ W.
Bermudas,	32 35 N.	-	63 32 W.
			58 11

Here, if P be the north pole, L the Lizard, and B Bermudas; there are given,
PL = 40° 03′ colat. of the Lizard,
PB = 57 25 colat. of Bermudas,
∠P = 58 11 diff. of longitude;
to find BL = 45° 44 = 2744 miles the diſtance, and
∠ of poſition B = 49° 27′, alſo
∠ of poſition L = 90° 31′.



Caſe 6. When the given places lie on different ſides of the equator; as ſuppoſe St. Helena and Bermudas. Here

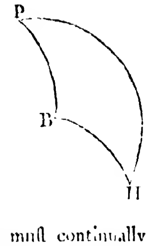
PB

PB = 57° 25′ polar dist. Bermudas,

PH = 105 55 polar dist. St. Helena,

∠P = 57 43 diff. long.

To find BH = 73° 26′ = 4406 miles, the distance, also the angle of position H = 48° 0′, and the angle of position B = 121° 59′.



From the solutions of the foregoing cases it appears, that to sail on the arc of a great circle, the ship must continually alter her course; but as this is a difficulty too great to be admitted into the practice of navigation, it has been thought sufficiently exact to effect this business by a kind of approximation, that is, by a method which nearly approaches to the sailing on a great circle: namely, upon this principle, that in small arcs, the difference between the arc and its chord or tangent is so small, that they may be taken for one another in any nautical operations: and accordingly it is supposed that the great circles on the earth are made up of short right lines, each of which is a segment of a rhumb line On this supposition the solution of the following problem is deduced.

Problem II. Having given the latitudes and longitudes of the places sailed from and bound to; to find the successive latitudes on the arc of a great circle in those places where the alteration in longitude shall be a given quantity; together with the courses and distances between those places.

1. Find the angle of position at each place, and their distance, by one of the preceding cases.

2. Find the greatest latitude the great circle runs through, i. e. find the perpendicular from the pole to that circle; and also find the several angles at the pole, made by the given alterations of longitude between this perpendicular and the successive meridians come to.

3. With this perpendicular and the polar angles severally, find as many corresponding latitudes, by saying, as radius : tang. greatest lat. : : cos. 1st polar angle : tang. 1st lat. : : cos. 2d polar angle : tang. of 2d lat. &c.

4. Having now the several latitudes passed through, and the difference of longitude between each, then by Mercator's Sailing find the courses and distances between those latitudes. And these are the several courses and distances the ship must run, to keep nearly on the arc of a great circle.

The smaller the alterations in longitude are taken, the nearer will this method approach to the truth; but it is sufficient to compute to every 5 degrees of difference of longitude; as the length of an arc of 5 degrees differs from its chord, or tangent, only by 0·002.

The track of a ship, when thus directed nearly in the arc of a great circle, may be delineated on the Mercator's chart, by marking on it, by help of the latitudes and longitudes, the successive places where the ship is to alter her course; then those places or points, being joined by right lines, will shew the path along which the ship is to sail, under the proposed circumstances.

On the subject of these articles, see Robertson's Elements of Navigation, vol. 2.

Spheroidical SAILING, is computing the cases of navigation on the supposition or principles of the spheroidical figure of the earth. See Robertson's Navigation, vol. 2, b. 8. sect. 8.

SAILING, *in a more confined sense*, is the art of conducting a ship from place to place, by the working or handling of her sails and rudder.

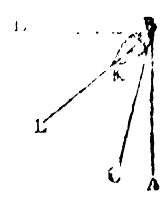
To bring Sailing to certain rules, M. Renau computes the force of the water, against the ship's rudder, stem, and side; and the force of the wind against her sails. In order to this, he first considers all fluid bodies, as the air, water, &c, as composed of little particles, which when they act upon, or move against any surface, do all move parallel to one another, or strike against the surface after the same manner. Secondly, that the motion of any body, with regard to the surface it strikes, must be either perpendicular, parallel, or oblique.

From these principles he computes, that the force of the air or water, striking perpendicularly upon a sail or rudder, is to the force of the same striking obliquely, in the duplicate ratio of radius to the sine of the angle of incidence: and consequently that all oblique forces of the wind against the sails, or of the water against the rudder, will be to one another in the duplicate ratio of the sines of the angles of incidence.

Such are the conclusions from theory; but it is very different in real practice, or experiments, as appears from the tables of experiments inserted at the article RESISTANCE.

Farther, when the different degrees of velocity are considered, it is also found that the forces are as the squares of the velocities of the moving air or water nearly; that is, a wind that blows twice as swift, as another, will have 4 times the force upon the sail; and when 3 times as swift, 9 times the force, &c. And it being also indifferent, whether we consider the motion of a solid in a fluid at rest, or of the fluid against the solid at rest; the reciprocal impressions being always the same; if a solid be moved with different velocities in the same fluid matter, as water, the different resistances which it will receive from that water, will be in the same proportion as the squares of the velocities of the moving body.

He then applies these principles to the motions of a ship, both forwards and sideways, through the water, when the wind, with certain velocities, strikes the sails in various positions. After this, the author proceeds to demonstrate, that the best position or situation of a ship, so as she may make the least lee-way, or side motion, but go to windward as much as possible, is this: that, let the sail have what situation it will, the ship be always in a line bisecting the complement of the wind's angle of incidence upon the sail. That is, supposing the sail in the position BC, and the wind blowing from A to B, and consequently the angle of the wind's incidence on the sail is ABC, the complement of which is CBE: then must the ship be put in the position BK, or move in the line BL, bisecting the ∠ CBE.



He shews farther, that the angle which the sail ought to make with the wind, i. e. the angle ABC, ought to be but 24 degrees; that being the most advantageous situation to go to windward the most possible.

To this might be added many curious particulars from Borelli de Vi Percussionis, concerning the different directions given to a vessel by the rudder, when sailing with a wind, or floating without sails in a current: in the former case, the head of the ship always coming to the rudder, and in the latter always flying off from it; as also from Euler, Bouguer, and Juan, who have all written learnedly on this subject.

SALIANT, in Fortification, is said of an angle that projects its point outwards; in opposition to a re-entering angle, which has its point turned inwards. Instances of both kinds of these we have in tenailles and star-works.

SALON, or Saloon, in Architecture, a grand, lofty, spacious sort of hall, vaulted at top, and usually comprehending two stories, with two ranges of windows. It is sometimes built square, sometimes round or oval, sometimes octagonal, as at Marly, and sometimes in other forms.

SAP, or Sapp, in Building, as to sap a wall, &c, is to dig out the ground from beneath it, so as to bring it down all at once for want of support.

Sap, in the Military Art, denotes a work carried on under cover of gabions and fascines on the flank, and mantlets or stuffed gabions on the front, to gain the descent of a ditch, or the like.

It is performed by digging a deep trench, descending by steps from top to bottom, under a corridor, carrying it as far as the bottom of the ditch, when that is dry; or as far as the surface of the water, when wet.

SAROS, in Chronology, a period of 223 lunar months. The etymology of the word is said to be Chaldean, signifying restitution, or return of eclipses; that is, conjunctions of the sun and moon in nearly the same place of the ecliptic. The Saros was a cycle like to that of Meto.

SARRASIN, or Sarrazin, in Fortification, a kind of port-cullis, otherwise called a herse, which is hung with ropes over the gate of a town or fortress, to be let fall in case of a surprise.

SATELLITES, in Astronomy, are certain secondary planets, moving round the other planets, as the moon does round the earth. They are so called because always found attending them, from rising to setting, and making the tour about the sun together with them.

The words moon and Satellite are sometimes used indifferently: thus we say, either Jupiter's moons, or Jupiter's Satellites; but usually we distinguish, restraining the term moon to the earth's attendant, and applying the term Satellite to the little moons more recently discovered about Jupiter, Saturn, and the Georgian planet, by the assistance of the telescope, which is necessary to render them visible.

The Satellites move round their primary planets, as their centres, by the same laws as those primary ones do round their centre the sun; viz, in such manner that, in the Satellites of the same planet, the squares of the periodic times are proportional to the cubes of their distances from the primary planet. For the physical cause of their motions, see Gravity. See also Planets.

We know not of any Satellites beside those above mentioned; what other discoveries may be made by farther improvements in telescopes, time only can bring to light.

Satellites *of Jupiter*. There are are four little moons, or secondary planets now known performing their evolutions about Jupiter, as that planet does about the Sun.

Simon Marius, mathematician of the elector of Brandenburg, about the end of November 1609, observed three little stars moving round Jupiter's body, and proceeding along with him; and in January 1610, he found a 4th. In January 1610 Galileo also observed the same in Italy, and in the same year published his observations. These Satellites were also observed in the same month of January 1710, by Thomas Harriot, the celebrated author of a work upon algebra, and who made constant observations of these Satellites, from that time till the 26th of February 1612; as appears by his curious astronomical papers, lately discovered by Dr. Zach, at the seat of the earl of Egremont, at Petworth in Sussex.

One Antony Maria Schyrlæus di Reita, a capuchin of Cologne, imagined that, besides the four known Satellites of Jupiter, he had discovered five more, on December 29, 1642. But the observation being communicated to Gassendus, who had observed Jupiter on the same day, he soon perceived that the monk had mistaken five fixed stars, in the effusion of the water of Aquarius, marked in Tycho's catalogue 24, 25, 26, 27, 28, for Satellites of Jupiter.

When Jupiter comes into a line between any of his Satellites and the sun, the Satellite disappears, being then *eclipsed*, or involved in his shadow.—When the Satellite goes behind the body of Jupiter, with respect to an observer on the earth, it is then said to be *occulted*, being hid from our sight by his body, whether in his shadow or not.—And when the Satellite comes into a position between Jupiter and the Sun, it casts a shadow upon the face of that planet, which we see as an obscure round spot.—And lastly, when the Satellite comes into a line between Jupiter and us, it is said to *transit* the disc of the planet, upon which it appears as a round black spot.

The periods or revolutions of Jupiter's Satellites, are found out from their conjunctions with that planet; after the same manner, as those of the primary planets are discovered from their oppositions to the sun. And their distances from the body of Jupiter, are measured by a micrometer, and estimated in semidiameters of that planet, and thence in miles.

By the latest and most exact observations, the periodical times and distances of these Satellites, and the angles under which their orbits are seen from the earth, at its mean distance from Jupiter, are as below:

Satellites of Jupiter.					
Satellites.	Periodic Times.	Distances in		Angles of Orbit.
		Semidiameters.	Miles.	
1	$1^d\ 18^h\ 27'\ 34''$	$5\frac{2}{3}$	266,000	$3'\ 55''$
2	3 13 13 42	$9\frac{1}{30}$	423,000	6 14
3	7 3 42 36	$14\frac{5}{13}$	676,000	9 58
4	16 16 32 0	$25\frac{1}{18}$	1,189,000	17 30

The eclipses of the Satellites, especially of those of Jupiter, are of very great use in astronomy. First, in determining pretty exactly the distance of Jupiter from the earth. A second advantage still more considerable, which is drawn from these eclipses, is the proof which they give of the progressive motion of light. It is demonstrated by these eclipses, that light does not come to us in an instant, as the Cartesians pretended, although its motion is extremely rapid. For if the motion of light were infinite, or came to us in an instant, it is evident that we should see the commencement of an eclipse of a Satellite at the same moment, at whatever distance we might be from it; but, on the contrary, if light move progressively, then it is as evident, that the farther we are from a planet,* the later we shall be in seeing the moment of its eclipse, because the light will take up a longer time in arriving at us; and so it is found in fact to happen, the eclipses of these Satellites appearing always later and later than the true computed times, as the earth removes farther and farther from the planet. When Jupiter and the earth are at their nearest distance, being in conjunction both on the same side of the sun, then the eclipses are seen to happen the soonest; and when the sun is directly between Jupiter and the earth, they are at their greatest distance asunder, the distance being more than before by the whole diameter of the earth's annual orbit, or by double the earth's distance from the sun, then the eclipses are seen to happen the latest of any, and later than before by about a quarter of an hour. Hence therefore it follows, that light takes up a quarter of an hour in travelling across the orbit of the earth, or near 8 minutes in passing from the sun to the earth; which gives us about 12 millions of miles per minute, or 200,000 miles per second, for the velocity of light. A discovery that was first made by M. Roemer.

The third and greatest advantage derived from the eclipses of the Satellites, is the knowledge of the longitudes of places on the earth. Suppose two observers of an eclipse, the one, for example, at London, the other at the Canaries; it is certain that the eclipse will appear at the same moment to both observers; but as they are situated under different meridians, they count different hours, being perhaps 9 o'clock to the one, when it is only 8 to the other; by which observations of the true time of the eclipse, on communication, they find the difference of their longitudes to be one hour in time, which answers to 15 degrees of longitude.

Satellites *of Saturn*, are 7 little secondary planets revolving about him.

One of them, which till lately was reckoned the 4th in order from Saturn, was discovered by Huygens, the 25th of March 1655, by means of a telescope 12 feet long; and the 1st, 2d, 3d, and 5th, at different times, by Cassini; viz, the 5th in October 1671, by a telescope of 17 feet; the 3d in December 1672, by a telescope of Campani's, 35 feet long; and the first and second in March 1684, by help of Campani's glasses, of 100 and 136 feet. Finally, the 6th and 7th Satellites have lately been discovered by Dr. Herschel, with his 40 feet reflecting telescope, viz, the 6th on the 19th of August 1787, and the 7th on the 17th of September 1788. These two he has called the 6th and 7th Satellites, though they are nearer to the planet Saturn than any of the former five, that the names or numbers of these might not be mistaken or confounded, with regard to former observations of them.

Moreover, the great distance between the 4th and 5th Satellite, gave occasion to Huygens to suspect that there might be some intermediate one, or else that the 5th might have some other Satellite moving round it, as its centre. Dr Halley, in the Philos. Trans. (numb. 145, or Abr. vol. 1. pa. 371) gives a correction of the theory of the motions of the 4th or Huygenian Satellite. Its true period he makes $15^d\ 22^h\ 41'\ 6''$.

The periodical revolutions, and distances of these Satellites from the body of Saturn, expressed in semidiameters of that planet, and in miles, are as follow.

Satellites of Saturn.				
Satellites.	Periods.	Distances in		Diam. of Orbit.
		Semidiameters.	Miles.	
1	$1^d\ 21^h\ 18'\ 27''$	$4\frac{3}{5}$	170,000	$1'\ 27''$
2	2 17 41 22	$5\frac{1}{2}$	217,000	1 52
3	4 12 25 12	8	303,000	2 36
4	15 22 41 13	18	704,000	6 18
5	79 7 48 0	54	2,050,000	17 4
6	1 8 53 9	$3\frac{5}{6}$	135,000	1 14
7	0 22 40 46	$2\frac{5}{8}$	107,000	0 57

The four first describe ellipses like to those of the ring, and are in the same plane. Their inclination to the ecliptic is from 30 to 31 degrees. The 5th describes an orbit inclined from 17 to 18 degrees with the orbit of Saturn; his plane lying between the ecliptic and those of the other Satellites, &c. Dr. Herschel observes that the 5th Satellite turns once round its axis exactly in the time in which it revolves about the planet Saturn; in which respect it resembles our moon, which does the same thing. And he makes the angle of its distance from Saturn, at his mean distance, $17'\ 2''$. Philos. Trans. 1792, pa. 22. See a long account of observations of these Satellites, with tables of their mean motions, by Dr. Herschel, Philos. Trans. 1790, pa. 427 &c.

Satellites *of the Georgian Planet*, or *Herschel*, are two little moons that revolve about him, like those of Jupiter

Jupiter and Saturn. These Satellites were discovered by Dr. Herſchel, in the month of January 1787, who gave an account of them in the Philoſ. Tranſ. of that year, pa. 125 &c; and a ſtill farther account of them in the vol. for 1788, pa. 364 &c; from which it appears that their ſynodical periods, and angular diſtances from their primary, are as follow:

Satellite.	Periods.				Diſt.	
1	8^d	17^h	$1'$	$19''$	$0'$	$33''$
2	13	11	5	$1\frac{1}{2}$	0	$44\frac{2}{5}$

The orbits of theſe Satellites are nearly perpendicular to the ecliptic; and in magnitude they are probably not leſs than thoſe of Jupiter.

SATELLITE *of Venus*. Caſſini thought he ſaw one, and Mr. Short and other aſtronomers have ſuſpected the ſame thing. (Hiſt. de l'Acad. 1741, Philoſ. Tranſ. numb. 459). But the many fruitleſs ſearches that have been ſince made to diſcover it, leave room to ſuſpect that it has been only an optical illuſion, formed by the glaſſes of teleſcopes; as appears to be the opinion of F. Hell, at the end of his Ephemeris for 1766, and Boſcovich, in his 5th Optical Diſſertation.

Neither has it been diſcovered that either of the other planets Mars and Mercury have any Satellites revolving about them.

SATURDAY, the 7th or laſt day of the week, ſo called, as ſome have ſuppoſed, from the idol Seater, worſhipped on this day by the ancient Saxons, and thought to be the ſame as the Saturn of the Latins. In aſtronomy, every day of the week is denoted by ſome one of the planets, and this day is marked with the planet ♄ Saturn. Saturday anſwers to the Jewiſh ſabbath.

SATURN, one of the primary planets, being the 6th in order of diſtance from the ſun, and the outermoſt of all, except the Georgian planet, or Herſchel, lately diſcovered; and is marked with the character ♄, denoting an old man ſupporting himſelf with a ſtaff, repreſenting the ancient god Saturn.

Saturn ſhines with but a feeble light, partly on account of his great diſtance, and partly from its dull red colour. This planet is perhaps one of the moſt engaging objects that aſtronomy offers to our view; it is ſurrounded with a double ring, one without the other, and beyond theſe by 7 Satellites, all in the plane of the rings; the rings and planets being all dark and denſe bodies, like Saturn himſelf, theſe bodies caſting their ſhadows mutually one upon another; though the reflected light of the rings is uſually brighter than that of the planet itſelf.

Saturn has alſo certain obſcure zones, or belts, appearing at times acroſs his diſc, like thoſe of Jupiter, which are changeable, and are probably obſcurations in his atmoſphere. Dr Herſchel, Philoſ. Tranſ. 1790, ſhews that Saturn has a denſe atmoſphere; that he revolves about an axis, which is perpendicular to the plane of the rings; that his figure is, like the other planets, the oblate ſpheroid, being flatted at the poles, the polar diameter being to the equatorial one as 10 to 11; that his ring has a motion of rotation in its own plane, its axis of motion being the ſame as that of Saturn himſelf, and its periodical time equal to $10^h\ 32'\ 15''\cdot4$. See alſo RING, and SATELLITE.

Concerning the diſcovery of the ring and figure of Saturn; we find that Galileo firſt perceived that his figure is not round: but Huygens ſhewed, in his Syſtema Saturniana 1659, that this was owing to the poſitions of his ring; for his ſpheroidical form could only be ſeen by Herſchel's teleſcope; though indeed Caſſini, in an obſervation made June 19, 1692, ſaw the oval figure of Saturn's ſhadow upon his ring.

Mr. Bugge determines (Philoſ. Tranſ. 1787, pa. 42) the heliocentric longitude of Saturn's deſcending node to be $9^s\ 21°\ 5'\ 8''\frac{1}{2}$; and that the planet was in that node Auguſt 21, 1784, at $18^h\ 20'\ 10''$, time at Copenhagen.

The annual period of Saturn about the ſun, is 10759 days 7 hours, or almoſt 30 years; and his diameter is about 67000 miles, or near $8\frac{1}{2}$ times the diameter of the earth; alſo his diſtance is about $9\frac{1}{2}$ times that of the earth. Hence ſome have concluded that his light and heat are entirely unfit for rational inhabitants. But that their light is not ſo weak as we imagine, is evident from their brightneſs in the night time. Beſides, allowing the ſun's light to be 45000 times as ſtrong, with reſpect to us, as the light of the moon when full, the ſun will afford 500 times as much light to Saturn as the full moon does to us, and 1600 times as much to Jupiter. So that theſe two planets, even without any moon, would be much more enlightened than we at firſt imagine; and by having ſo many, they may be very comfortable places of reſidence. Their heat, ſo far as it depends on the force of the ſun's rays, is certainly much leſs than ours; to which no doubt the bodies of their inhabitants are as well adapted as ours are to the ſeaſons we enjoy. And if it be conſidered that Jupiter never has any winter, even at his poles, which probably is alſo the caſe with Saturn, the cold cannot be ſo intenſe on theſe two planets as is generally imagined. To this may be added, that there may be ſomething in the nature of their mould warmer than in that of our earth; and we find that all our heat does not depend on the rays of the ſun; for if it did, we ſhould always have the ſame months equally hot or cold at their annual return, which is very far from being the caſe.

See the articles PLANET, PERIOD, RING, SATELLITE.

SAUCISSE, in Artillery, a long train of powder incloſed in a roll or pipe of pitched cloth, and ſometimes of leather, about 2 inches in diameter; ſerving to ſet fire to mines or caiſſons. It is uſually placed in a wooden pipe, called an auget, to prevent its growing damp.

SAUCISSON, in Fortification, a kind of faggot, made of thick branches of trees, or of the trunks of ſhrubs, bound together; for the purpoſe of covering the men, and to ſerve as epaulements; and alſo to repair breaches, ſtop paſſages, make traverſes over a wet ditch, &c.

The Sauciſſon differs from the faſcine, which is only made of ſmall branches; and by its being bound at both ends, and in the middle.

SAVILLE (Sir HENRY), a very learned Engliſhman,

man, the second son of Henry Saville, Esq. was born at Bradley, near Halifax, in Yorkshire, November the 30th, 1549. He was entered of Merton-college, Oxford, in 1561, where he took the degrees in arts, and was chosen fellow. When he proceeded master of arts in 1570, he read for that degree on the Almagest of Ptolomy, which procured him the reputation of a man eminently skilled in mathematics and the Greek language; in the former of which he voluntarily read a public lecture in the university for some time.

In 1578 he travelled into France and other countries; where, diligently improving himself in all useful learning, in languages, and the knowledge of the world, he became a most accomplished gentleman. At his return, he was made tutor in the Greek tongue to queen Elizabeth, who had a great esteem and liking for him.

In 1585 he was made warden of Merton-college, which he governed six-and-thirty years with great honour, and improved it by all the means in his power.—In 1596 he was chosen provost of Eton-college; which he filled with many learned men.—James the First, upon his accession to the crown of England, expressed a great regard for him, and would have preferred him either in church or state; but Saville declined it, and only accepted the ceremony of knighthood from the king at Windsor in 1604. His only son Henry dying about that time, he thenceforth devoted his fortune to the promoting of learning. Among other things, in 1619, he founded, in the university of Oxford, two lectures, or professorships, one in geometry, the other in astronomy; which he endowed with a salary of 160l. a year each, besides a legacy of 600l. to purchase more lands for the same use. He also furnished a library with mathematical books near the mathematical school, for the use of his professors; and gave 100l. to the mathematical chest of his own appointing: adding afterwards a legacy of 40l. a year to the same chest, to the university, and to his professors jointly. He likewise gave 120l. towards the new-building of the schools, beside several rare manuscripts and printed books to the Bodleian library; and a good quantity of Greek types to the printing-press at Oxford.

After a life thus spent in the encouragement and promotion of science and literature in general, he died at Eton-college the 19th of February 1622, in the 73d year of his age, and was buried in the chapel there. On this occasion, the university of Oxford paid him the greatest honours, by having a public speech and verses made in his praise, which were published soon after in 4to, under the title of *Ultima Linea Savilii*.

As to the character of Saville, the highest encomiums are bestowed on him by all the learned of his time: by Casaubon, Mercerus, Meibomius, Joseph Scaliger, and especially the learned bishop Montague; who, in his *Diatribæ* upon Selden's History of Tythes, styles him, "that magazine of learning, whose memory shall be honourable amongst not only the learned, but the righteous for ever."

Several noble instances of his munificence to the republic of letters have already been mentioned: in the account of his publications many more, and even greater, will appear. These are,

1. *Four Books of the Histories of Cornelius Tacitus, and the Life of Agricola*; with Notes upon them, in folio, dedicated to Queen Elizabeth, 1581.

2. *A View of certain Military Matters*, or Commentaries concerning Roman Warfare, 1598.

3. *Rerum Anglicarum Scriptores post Bedam*, &c. 1596. This is a collection of the best writers of our English history; to which he added chronological tables at the end, from Julius Cæsar to William the Conqueror.

4. *The Works of St. Chrysostom*, in Greek, in 8 vols. folio, 1613. This is a very fine edition, and composed with great cost and labour. In the preface he says, "that having himself visited, about 12 years before, all the public and private libraries in Britain, and copied out thence whatever he thought useful to this design, he then sent some learned men into France, Germany, Italy, and the East, to transcribe such parts as he had not already, and to collate the others with the best manuscripts." At the same time, he makes his acknowledgments to several eminent men for their assistance; as Thuanus, Velserus, Schottus, Casaubon, Ducæus, Gruter, Hoeschelius, &c. In the 8th volume are inserted Sir Henry Saville's own notes, with those of other learned men. The whole charge of this edition, including the several sums paid to learned men, at home and abroad, employed in finding out, transcribing, and collating the best manuscripts, is said to have amounted to no less than 8000l. Several editions of this work were afterwards published at Paris.

5. In 1618 he published a Latin work, written by Thomas Bradwardin, abp. of Canterbury, against Pelagius, intitled, *De Causa Dei contra Pelagium, et de virtute causarum*; to which he prefixed the life of Bradwardin.

6. In 1621 he published a collection of his own Mathematical Lectures on Euclid's Elements; in 4to.

7. *Oratio coram Elizabetha Regina Oxoniæ habita*, anno 1592. Printed at Oxford in 1658, in 4to.

8. He translated into Latin king James's *Apology for the Oath of Allegiance*. He also left several manuscripts behind him, written by order of king James; all which are in the Bodleian library. He wrote notes likewise upon the margin of many books in his library, particularly Eusebius's *Ecclesiastical History*; which were afterwards used by Valesius, in his edition of that work in 1659.—Four of his letters to Camden are published by Smith, among *Camden's Letters*, 1691, 4to.

Sir Henry Saville had a younger brother, *Thomas* SAVILLE, who was admitted probationer fellow of Merton college, Oxford, in 1580. He afterwards travelled abroad into several countries. Upon his return he was chosen fellow of Eton-college; but he died at London in 1593. Thomas Saville was also a man of great learning, and an intimate friend of Camden; among whose letters, just mentioned, there are 15 of Mr. Saville's to him.

SAUNDERSON (Dr. NICHOLAS), an illustrious professor of mathematics in the university of Cambridge, and a fellow of the Royal Society, was born at Thurlston in Yorkshire in 1682. When he was but twelve months old, he lost not only his eye sight, but his very eye-balls, by the small-pox; so that he could retain no more ideas of vision than if he had been born blind. At an early age, however, being of very promising

mifing parts, he was fent to the free-fchool at Penniſton, and there laid the foundation of that knowledge of the Greek and Latin languages, which he afterwards improved ſo far, by his own application to the claſſic authors, as to hear the works of Euclid, Archimedes, and Diophantus read in their original Greek.

Having acquired a grammatical education, his father, who was in the exciſe, inſtructed him in the common rules of arithmetic. And here it was that his excellent mathematical genius firſt appeared: for he very ſoon became able to work the common queſtions, to make very long calculations by the ſtrength of his memory, and to form new rules to himſelf for the better reſolving of ſuch queſtions as are often propoſed to learners as trials of ſkill.

At the age of 18, our author was introduced to the acquaintance of Richard Weſt, of Underbank, Eſq. a lover of mathematics, who, obſerving Mr. Saunderſon's uncommon capacity, took the pains to inſtruct him in the principles of algebra and geometry, and gave him every encouragement in his power to the proſecution of theſe ſtudies. Soon after this he became acquainted alſo with Dr. Nettleton, who took the ſame pains with him. And it was to theſe two gentlemen that Mr. Saunderſon owed his firſt inſtitution in the mathematical ſciences: they furniſhed him with books, and often read and expounded them to him. But he ſoon ſurpaſſed his maſters, and became fitter to teach, than to learn any thing from them.

His father, otherwiſe burdened with a numerous family, finding a difficulty in ſupporting him, his friends began to think of providing both for his education and maintenance. His own inclination led him ſtrongly to Cambridge, and it was at length determined he ſhould try his fortune there, not as a ſcholar, but as a maſter: or, if this deſign ſhould not ſucceed, they promiſed themſelves ſucceſs in opening a ſchool for him at London. Accordingly he went to Cambridge in 1707, being then 25 years of age, and his fame in a ſhort time filled the univerſity. Newton's Principia, Optics, and Univerſal Arithmetic, were the foundations of his lectures, and afforded him a noble field for the diſplaying of his genius; and great numbers came to hear a blind man give lectures on optics, diſcourſe on the nature of light and colours, explain the theory of viſion, the effect of glaſſes, the phenomenon of the rainbow, and other objects of ſight.

As he inſtructed youth in the principles of the Newtonian philoſophy, he ſoon became acquainted with its incomparable author, though he had ſeveral years before left the univerſity; and frequently converſed with him on the moſt difficult parts of his works: he alſo held a friendly communication with the other eminent mathematicians of the age, as Halley, Cotes, Demoivre, &c.

Mr. Whiſton was all this time in the mathematical profeſſor's chair, and read lectures in the manner propoſed by Mr. Saunderſon on his ſettling at Cambridge; ſo that an attempt of this kind looked like an encroachment on the privilege of his office; but, as a good-natured man, and an encourager of learning, he readily conſented to the application of friends made in behalf of ſo uncommon a perſon.

Upon the removal of Mr. Whiſton from his profeſſorſhip, Mr. Saunderſon's merit was thought ſo much ſuperior to that of any other competitor, that an extraordinary ſtep was taken in his favour, to qualify him with a degree, which the ſtatute requires: in conſequence he was choſen in 1711, Mr. Whiſton's ſucceſſor in the Lucaſian profeſſorſhip of mathematics, Sir Iſaac Newton intereſting himſelf greatly in his favour. His firſt performance, after he was ſeated in the chair, was an inaugural ſpeech made in very elegant latin, and a ſtyle truly Ciceronian; for he was well verſed in the writings of Tully, who was his favourite in proſe, as Virgil and Horace were in verſe. From this time he applied himſelf cloſely to the reading of lectures, and gave up his whole time to his pupils. He continued to reſide among the gentlemen of Chriſt-college till the year 1723, when he took a houſe in Cambridge, and ſoon after married a daughter of Mr. Dickens, rector of Boxworth in Cambridgeſhire, by whom he had a ſon and a daughter.

In the year 1728, when king George viſited the univerſity, he expreſſed a deſire of ſeeing ſo remarkable a perſon; and accordingly our profeſſor attended the king in the ſenate, and by his favour was there created doctor of laws.

Dr. Saunderſon was naturally of a ſtrong healthy conſtitution; but being too ſedentary, and conſtantly confining himſelf to the houſe, he became a valetudinarian: and in the ſpring of the year 1739 he complained of a numbneſs in his limbs, which ended in a mortification in his foot, of which he died the 19th of April that year, in the 57th year of his age.

There was ſcarcely any part of the mathematics on which Dr. Saunderſon had not compoſed ſomething for the uſe of his pupils. But he diſcovered no intention of publiſhing any thing till, by the perſuaſion of his friends, he prepared his Elements of Algebra for the preſs, which after his death were publiſhed by ſubſcription in 2 vols 4to, 1740.

He left many other writings, though none perhaps prepared for the preſs. Among theſe were ſome valuable comments on Newton's Principia, which not only explain the more difficult parts, but often improve upon the doctrines. Theſe are publiſhed in Latin at the end of his poſthumous Treatiſe on Fluxions, a valuable work, publiſhed in 8vo, 1756.—His manuſcript lectures too, on moſt parts of natural philoſophy, which I have ſeen, might make a conſiderable volume, and prove an acceptable preſent to the public if printed.

Dr. Saunderſon, as to his character, was a man of much wit and vivacity in converſation, and eſteemed an excellent companion. He was endued with a great regard to truth; and was ſuch an enemy to diſguiſe, that he thought it his duty to ſpeak his thoughts at all times with unreſtrained freedom. Hence his ſentiments on men and opinions, his friendſhip or diſregard, were expreſſed without reſerve; a ſincerity which raiſed him many enemies.

A blind man, moving in the ſphere of a mathematician, ſeems a phenomenon difficult to be accounted for, and has excited the admiration of every age in which it has appeared. Tully mentions it as a thing ſcarce credible in his own maſter in philoſophy, Diodotus; that he exerciſed himſelf in it with more aſſiduity

duity after he became blind; and, what he thought next to impossible to be done without sight, that he professed geometry, describing his diagrams so exactly to his scholars, that they could draw every line in its proper direction. St. Jerome relates a still more remarkable instance in Didymus of Alexandria, who, though blind from his infancy, and therefore ignorant of the very letters, not only learned logic, but geometry also to very great perfection, which seems most of all to require sight. But, if we consider that the ideas of extended quantity, which are the chief objects of mathematics, may as well be acquired by the sense of feeling as that of sight, that a fixed and steady attention is the principal qualification for this study, and that the blind are by necessity more abstracted than others (for which reason it is said that Democritus put out his eyes, that he might think more intensely), we shall perhaps find reason to suppose that there is no branch of science so much adapted to their circumstances.

At first, Dr. Saunderson acquired most of his ideas by the sense of feeling; and this, as is commonly the case with the blind, he enjoyed in great perfection. Yet he could not, as some are said to have done, distinguish colours by that sense; for, after having made repeated trials, he used to say, it was pretending to impossibilities. But he could with great nicety and exactness observe the smallest degree of roughness or defect of polish in a surface. Thus, in a set of Roman medals, he distinguished the genuine from the false, though they had been counterfeited with such exactness as to deceive a connoisseur who had judged by the eye. By the sense of feeling also, he distinguished the least variation; and he has been seen in a garden, when observations have been making on the sun, to take notice of every cloud that interrupted the observation almost as justly as they who could see it. He could also tell when any thing was held near his face, or when he passed by a tree at no great distance, merely by the different impulse of the air on his face.

His ear was also equally exact. He could readily distinguish the 5th part of a note. By the quickness of this sense he could judge of the size of a room, and of his distance from the wall. And if ever he walked over a pavement, in courts or piazzas which reflected a sound, and was afterwards conducted thither again, he could tell in what part of the walk he stood, merely by the note it sounded.

Dr. Saunderson had a peculiar method of performing arithmetical calculations, by an ingenious machine and method which has been called his Palpable Arithmetic, and is particularly described in a piece prefixed to the first volume of his Algebra. That he was able to make long and intricate calculations, both arithmetical and algebraical, is a thing as certain as it is wonderful. He had contrived for his own use, a commodious notation for any large numbers, which he could express on his abacus, or calculating table, and with which he could readily perform any arithmetical operations, by the sense of feeling only, for which reason it was called his Palpable Arithmetic.

His calculating table was a smooth thin board, a little more than a foot square, raised upon a small frame so as to lie hollow; which board was divided into a great number of little squares, by lines intersecting one another perpendicularly, and parallel to the sides of the table, and the parallel ones only one-tenth of an inch from each other; so that every square inch of the table was thus divided into 100 little squares. At every point of intersection the board was perforated by small holes, capable of receiving a pin; for it was by the help of pins, stuck up to the head through these holes, that he expressed his numbers. He used two sorts of pins, a larger and a smaller sort; at least their heads were different, and might easily be distinguished by feeling. Of these pins he had a large quantity in two boxes, with their points cut off, which always stood ready before him when he calculated. The writer of that account describes particularly the whole process of using the machine, and concludes, "He could place and displace his pins with incredible nimbleness and facility, much to the pleasure and surprize of all the beholders. He could even break off in the middle of a calculation, and resume it when he pleased, and could presently know the condition of it, by only drawing his fingers gently over the table."

SAURIN (JOSEPH), an ingenious French mathematician, was born in 1659, at Courtaison, in the principality of Orange. His father, minister at Grenoble, was a man of a very studious disposition, and was the first preceptor or instructor to our author; who made a rapid progress in his studies, and at a very early age was admitted a minister at Eure in Dauphiny. But preaching an offensive sermon, he was obliged to quit France in 1683. On this occasion he retired to Geneva; from whence he went into the State of Berne, and was appointed to a living at Yverdun. He was no sooner established in this his post, than certain theologians raised a storm against him. Saurin, disgusted with the controversy, and still more with the Swiss, where his talents were buried, passed into Holland, and from thence into France, where he put himself under the protection of the celebrated Bossu, to whom he made his abjuration in 1690, as it is suspected, that he might find protection, and have an opportunity of cultivating the sciences at Paris. And he was not disappointed: he met with many flattering encouragements; was even much noticed by the king, had a pension from the court, and was admitted of the Academy of Sciences in 1707, in the quality of geometrician. This science was now his chief study and delight; with many writings upon which he enriched the volumes of the Journal des Savans, and the Memoirs of the Academy of Sciences These were the only works of this kind that he published: he was author of several other pieces of a controversial nature, against the celebrated Rousseau, and other antagonists, over whom with the assistance of government he was enabled to triumph. The latter part of his life was spent in more peace, and in cultivating the mathematical sciences; and he died the 29th of December 1737, of a lethargic fever, at 78 years of age.

The character of Saurin was lively and impetuous, endued with a considerable degree of that noble independence and loftiness of manner, which is apt to be mistaken for haughtiness or insolence; in consequence of which, his memory was attacked after his death, as his reputation had been during his life; and it was even said

ſaid he had been guilty of crimes, by his own confeſſion, that ought to have been puniſhed with death.

Saurin's mathematical and philoſophical papers, printed in the Memoirs of the Academy of Sciences, which are pretty numerous, are to be found in the volumes for the years following; viz, 1709, 1710, 1713, 1716, 1718, 1720, 1722, 1723, 1725, 1727.

SAUVEUR (Joseph), an eminent French mathematician, was born at La Fleche the 24th of March 1653. He was abſolutely dumb till he was ſeven years of age; and then the organs of ſpeech did not diſengage ſo effectually, but that he was ever after obliged to ſpeak very ſlowly and with difficulty. He very early diſcovered a great turn for mechanics, and was always inventing and conſtructing ſomething or other in that way.

He was ſent to the college of the Jeſuits to learn polite literature, but made very little progreſs in poetry and eloquence. Virgil and Cicero had no charms for him; but he read with greedineſs books of arithmetic and geometry. However, he was prevailed on to go to Paris in 1670, and, being intended for the church, there he applied himſelf for a time to the ſtudy of philoſophy and theology: but ſtill ſucceeded no better. In ſhort, mathematics was the only ſtudy he had any paſſion or reliſh for, and this he cultivated with extraordinary ſucceſs; for during his courſe of philoſophy, he learned the firſt ſix books of Euclid in the ſpace of a month, without the help of a maſter.

As he had an impediment in his voice, though otherwiſe endued with extraordinary abilities, he was adviſed by M. Boſſuet, to give up all deſigns upon the church, and to apply himſelf to the ſtudy of phyſic: but this being utterly againſt the inclination of his uncle, from whom he drew his principal reſources, Sauveur determined to devote himſelf to his favourite ſtudy, and to perfect himſelf in it, ſo as to teach it for his ſupport; and in effect he ſoon became the faſhionable preceptor in mathematics, ſo that at 23 years of age he had prince Eugene for his ſcholar.—He had not yet read the geometry of Des Cartes; but a foreigner of the firſt quality deſiring to be taught it, he made himſelf maſter of it in an inconceivably ſmall ſpace of time.—Baſſet being a faſhionable game at that time, the marquis of Dangeau aſked him for ſome calculations relating to it, which gave ſuch ſatisfaction, that Sauveur had the honour to explain them to the king and queen.

In 1681 he was ſent with M. Mariotte to Chantilli, to make ſome experiments upon the waters there, which he did with much applauſe. The frequent viſits he made to this place inſpired him with the deſign of writing a treatiſe on fortification; and, in order to join practice with theory, he went to the ſiege of Mons in 1691, where he continued all the while in the trenches. With the ſame view alſo he viſited all the towns of Flanders; and on his return he became the mathematician in ordinary at the court, with a penſion for life.—In 1680 he had been choſen to teach mathematics to the pages of the Dauphineſs. In 1686 he was appointed mathematical profeſſor in the Royal College. And in 1696 admitted a member of the Academy of Sciences, where he was in high eſteem with the members of that ſociety.—He became alſo particularly acquainted with the prince of Condé, from whom he received many marks of favour and affection. Finally, M. Vauban having been made marſhal of France, in 1703, he propoſed Sauveur to the king as his ſucceſſor in the office of examiner of the engineers; to which the king agreed, and honoured him with a penſion, which our author enjoyed till his death, which happened the 9th of July 1716, in the 64th year of his age.

Sauveur, in his character, was of a kind obliging diſpoſition, of a ſweet, uniform, and unaffected temper; and although his fame was pretty generally ſpread abroad, it did not alter his humble deportment, and the ſimplicity of his manners. He uſed to ſay, that what one man could accompliſh in mathematics, another might do alſo, if he choſe it.

He was twice married. The firſt time he took a very ſingular precaution; for he would not meet the lady till he had been with a notary to have the conditions, he intended to inſiſt on, reduced into a written form; for fear the ſight of her ſhould not leave him enough maſter of himſelf. This was acting very wiſely, and like a true mathematician; who always proceeds by rule and line, and makes his calculations when his head is cool.—He had children by both his wives; and by the latter a ſon who, like himſelf, was dumb for the firſt ſeven years of his life.

An extraordinary part of Sauveur's character is, that though he had neither a muſical voice nor ear, yet he ſtudied no ſcience more than muſic, of which he compoſed an entire new ſyſtem. And though he was obliged to borrow other people's voice and ears, yet he amply repaid them with ſuch demonſtrations as were unknown to former muſicians. He alſo introduced a new diction in muſic, more appropriate and extenſive. He invented a new doctrine of ſounds. And he was the firſt that diſcovered, by theory and experiment, the velocity of muſical ſtrings, and the ſpaces they deſcribe in their vibrations, under all circumſtances of tenſion and dimenſions. It was he alſo who firſt invented for this purpoſe the monochord and the echometer. In ſhort, he purſued his reſearches even to the muſic of the ancient Greeks and Romans, to the Arabs, and to the very Turks and Perſians themſelves; ſo jealous was he, leſt any thing ſhould eſcape him in the ſcience of ſounds.

Sauveur's writings, which conſiſt of pieces rather than of ſet works, are all inſerted in the volumes of the Memoirs of the Academy of Sciences, from the year 1700 to the year 1716, on various geometrical, mathematical, philoſophical, and muſical ſubjects.

SCALE, a mathematical inſtrument, conſiſting of certain lines drawn on wood, metal, or other matter, divided into various parts, either equal or unequal. It is of great uſe in laying down diſtances in proportion, or in meaſuring diſtances already laid down.

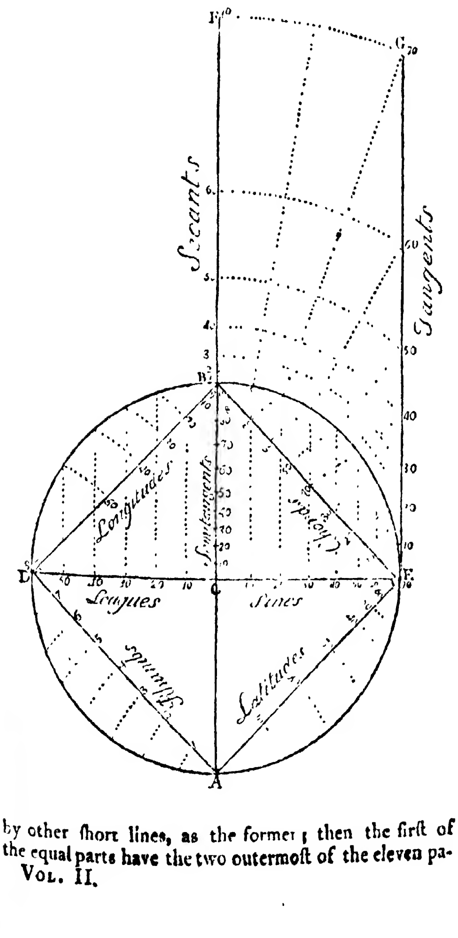
There are Scales of various kinds, accommodated to the ſeveral uſes: the principal are the *plane Scale*, the *diagonal Scale*, *Gunter's Scale*, and the *ſliding Scale*.

Plane or Plain Scale, a mathematical inſtrument of very extenſive uſe and application; which is commonly made of 2 feet in length; and the lines uſually drawn upon it are the following, viz,

1. Lines

1	Lines of Equal parts, and marked		E. P.
2	- - -	Chords - - -	Cho.
3	- - -	Rhumbs - - -	Ru.
4	- - -	Sines - - -	Sin.
5	- - -	Tangents - -	Tan.
6	- - -	Secants - -	Sec.
7	- - -	Semitangents - -	S. T.
8	- - -	Longitude - -	Long.
9	- - -	Latitude - -	Lat.

1. The lines of equal parts are of two kinds, viz, ſimply divided, and diagonally divided. The firſt of theſe are formed by drawing three lines parallel to one another, and dividing them into any equal parts by ſhort lines drawn acroſs them, and in like manner ſubdividing the firſt diviſion or part into 10 other equal ſmall parts; by which numbers or dimenſions of two figures may be taken off. Upon ſome rulers, ſeveral of theſe ſcales of equal parts are ranged parallel to each other, with figures ſet to them to ſhew into how many equal parts they divide the inch; as 20, 25, 30, 35, 40, 45, &c. The 2d or diagonal diviſions are formed by drawing eleven long parallel and equidiſtant lines, which are divided into equal parts, and croſſed



by other ſhort lines, as the former; then the firſt of the equal parts have the two outermoſt of the eleven parallels divided into 10 equal parts, and the points of diviſion being connected by lines drawn diagonally, the whole ſcale is thus divided into dimenſions or numbers of three places of figures.

The other lines upon the ſcales are ſuch as are commonly uſed in trigonometry, navigation, aſtronomy, dialling, projection of the ſphere, &c, &c; and their conſtructions are moſtly taken from the diviſions of a circle, as follow:

Deſcribe a circle with any convenient radius, and quarter it by drawing the diameters AB and DE at right angles to each other; continue the diameter AB out towards F, and draw the tangent line EG parallel to it; alſo draw the chords AD, DB, BE, EA. Then,

2. For the line of chords, divide a quadrant BE into 90 equal parts; on E as a centre, with the compaſſes transfer theſe diviſions to the chord line EB, which mark with the correſponding numbers, and it will become a line of chords, to be transferred to the ruler.

3. For the line of rhumbs, divide the quadrant AD into 8 equal parts; then with the centre A transfer the diviſions to the chord AD, for the line of rhumbs.

4. For the line of ſines, through each of the diviſions of the arc BE, draw right lines parallel to the radius BC, which will divide the radius CE into the ſines, or verſed ſines, numbering it from C to E for the ſines, and from E to C for the verſed ſines.

5. For the line of tangents, lay a ruler on C, and the ſeveral diviſions of the arc BE, and it will interſect the line EG, which will become a line of tangents, and numbered from E to G with 10, 20, 30, 40, &c.

6. For the line of ſecants, transfer the diſtances between the centre C and the diviſions on the line of tangents to the line BF, from the centre C, and theſe will give the diviſions of the line of ſecants, which muſt be numbered from B towards F, with 10, 20, 30, &c.

7. For the line of ſemitangents, lay a ruler on D and the ſeveral diviſions of the arc EB, which will interſect the radius CB in the diviſions of the ſemitangents, which are to be marked with the correſponding figures of the arc EB.

The chief uſes of the ſines, tangents, ſecants, and ſemitangents, are to find the poles and centres of the ſeveral circles repreſented in the projections of the ſphere.

8. For the line of longitude, divide the radius CD into 60 equal parts; through each of theſe, parallels to the radius BC will interſect the arc BD in as many points: from D as a centre the diviſions of the arc BD being transferred to the chord BD, will give the diviſions of the line of longitude.

If this line be laid upon the ſcale cloſe to the line of chords, both inverted, ſo that 60° in the ſcale of longitude be againſt 0° in the chords, &c; and any degree of latitude be counted on the chords, there will ſtand oppoſite to it, in the line of longitude, the miles contained in one degree of longitude, in that latitude; the meaſure of 1 degree under the equator being 60 geographical miles.

9. For the line of latitude, lay a ruler on B, and the several divisions on the sines on CE, and it will intersect the arc AE in as many points; on A as a centre transfer the intersections of the arc AE to the chord AE, for the line of latitude.

See also Robertson's Description and use of Mathematical Instruments.

Decimal, or *Gunter's*, or *Plotting*, or *Proportional*, or *Reducing* SCALE. See the several articles.

SCALE, in Architecture and Geography, a line divided into equal parts, placed at the bottom of a map or draught, to serve as a common measure to all the parts of the building, or all the distances and places of the map.

In maps of large tracts, as kingdoms and provinces, &c, the Scale usually consists of miles; whence it is denominated a Scale of miles.—In more particular maps, as those of manors, &c, the Scale is usually of chains &c.—The Scales used in draughts of buildings mostly consist of modules, feet, inches, palms, fathoms, or the like.

To find the distance between two towns &c, in a map, the interval is taken in the compasses, and set off in the scale; and the number of divisions it includes gives the distance. The same method serves to find the height of a story, or other part in a design.

Front SCALE, in Perspective, is a right line in the draught, parallel to the horizontal line; divided into equal parts, representing feet, inches, &c.

Flying SCALE, is a right line in the draught, tending to the point of view, and divided into unequal parts, representing feet, inches, &c.

Differential SCALE, is used for the scale of relation subtracted from unity. See SERIES.

SCALE *of Relation*, in Algebra, an expression denoting the relation of the terms of recurring series to each other. See SERIES.

Hour SCALE. See HOUR.

SCALE, in Music, is a denomination given to the arrangement of the six syllables, invented by Guido Aratino, *ut re mi fa sol la*; called also gammut. It is called Scale, or ladder, because it represents a kind of ladder, by means of which the voice rises to acute, or sinks to grave; each of the six syllables being as it were one step of the ladder.

SCALE is also used for a series of sounds rising or falling towards acuteness or gravity, from any given pitch of tune, to the greatest distance that is fit or practicable, through such intermediate degrees as to make the succession most agreeable and perfect, and in which we have all the harmonical intervals most commodiously divided.

The scale is otherwise called an *universal system*, as including all the particular systems belonging to music. See SYSTEM.

There were three different Scales in use among the Ancients, which had their denominations from the three several sorts of music, viz, the *diatonic*, *chromatic*, and *inharmonic*. Which see.

SCALENE, or SCALENOUS *triangle*, is a triangle whose sides and angles are all unequal.—A cylinder or cone, whose axis is oblique or inclined to its base, is also said to be scalenous: though more frequently it is called oblique.

SCALIGER (JOSEPH JUSTUS), a celebrated French chronologer and critic, was the son of Julius Cæsar Scaliger, and born at Agen in France, in 1540. He studied in the college of Bourdeaux; after which his father took him under his own care, and employed him in transcribing his poems; by which means he obtained such a taste for poetry, that before he was 17 years old, he wrote a tragedy upon the subject of Oedipus, in which he introduced all the poetical ornaments of style and sentiment.

His father dying in 1558, he went to Paris the year following, with a design to apply himself to the Greek tongue. For this purpose he for two months attended the lectures of Turnebus; but finding that in the usual course he should be a long time in gaining his point, he shut himself up in his closet, and by constant application for two years gained a perfect knowledge of the Greek language. After which he applied himself to the Hebrew, which he learned by himself with great facility. And in like manner he ran through many other languages, till he could speak it is said no less than 13 ancient and modern ones. He made no less progress in the sciences; and his writings procured him the reputation of one of the greatest men of that or any other age. He embraced the reformed religion at 22 years of age. In 1563, he attached himself to Lewis Casteignier de la Roch Pazay, whom he attended in several journies. And, in 1593, the curators of the university of Leyden invited him to an honorary professorship in that university, where he lived 16 years, and where he died of a dropsy in 1609, at 69 years of age.

Scaliger was a man of great temperance; was never married; and was so close a student, that he often spent whole days in his study without eating: and though his circumstances were always very narrow, he constantly refused the presents that were offered him.

He was author of many ingenious works on various subjects. His elaborate work, *De Emendatione Temporum*; his exquisite animadversions on Eusebius; with his *Canon Isagogicus Chronologiæ*; and his accurate comment upon Manilius's *Astronomicon*, sufficiently evince his knowledge in the astronomy, and other branches of learning, among the Ancients, and who, according to the opinion of the celebrated Vieta, was far superior to any of that age. And he had no less a character given him by the learned Casaubon.—He wrote *Cyclometrica et Diatriba de Equinoctiorum Anticipatione*. He wrote also notes upon Seneca, Varro, and Ausonius's Poems. But that which above all things renders the name of Scaliger memorable to posterity, is the invention of the Julian period, which consists of 7980 years, being the continued product of the three cycles, of the sun 28, the moon 19, and Roman indiction 15. This period had its beginning fixed to the 764th year before the creation, and is not yet completed, and comprehends all other cycles, periods, and epochas, with the times of all memorable actions and histories.—The collections intitled *Scaligeriana*, were collected from his conversations by one of his friends; and being ranged in alphabetical order, were published by Isaac Vossius.

SCANTLING, a measure, size, or standard, by which the dimensions &c of things are to be determined.

The

The term is particularly applied to the dimensions of any piece of timber, with regard to its breadth and thickness.

SCAPEMENT, in Clock-work, a general term for the manner of communicating the impulse of the wheels to the pendulum. The ordinary Scapements consist of the swing-wheel and pallets only; but modern improvements have added other levers or detents, chiefly for the purposes of diminishing friction, or for detaching the pendulum from the pressure of the wheels during part of the time of its vibration. Notwithstanding the very great importance of the Scapement to the performance of clocks, no material improvement was made in it from the first application of the pendulum to clocks to the days of Mr. George Graham; nothing more was attempted before his time, than to apply the impulse of the swing-wheel in such manner as was attended with the least friction, and would give the greatest motion to the pendulum. Dr. Halley discovered, by some experiments made at the Royal Observatory at Greenwich, that by adding more weight to the pendulum, it was made to vibrate larger arcs, and the clock went faster; by diminishing the weight of the pendulum, the vibrations became shorter, and the clock went slower; the result of these experiments being diametrically opposite to what ought to be expected from the theory of the pendulum, probably first roused the attention of Mr. Graham, and led him to such farther trials as convinced him, that this seeming paradox was occasioned by the retrograde motion, which was given to the swing-wheel by every construction of Scapement that was at that time in use; and his great sagacity soon produced a remedy for this defect, by constructing a Scapement which prevented all recoil of the wheels, and restored to the clock pendulum, wholly in theory, and nearly in practice, all its natural properties in its detached simple state; this Scapement was named by its celebrated inventor the *dead beat*, and its great superiority was so universally acknowledged, that it was soon introduced into general use, and still continues in universal esteem. The importance of the Scapement to the accurate going of clocks, was by this improvement rendered so unquestionable, that artists of the first rate all over Europe, were forward in producing each his particular construction, as may be seen in the works of Thiout l'ainé, M. J. A. Lepaute, M. le Roy, M. Ferdinand Bertoud, and Mr. Cummings' Elements of Clock and Watchwork, in which we have a minute description of several new and ingenious constructions of Scapements, with an investigation of the principles on which their claim to merit is founded; and a comparative view of the advantages or defects of the several constructions. Besides the Scapements described in the above works, many curious constructions have been produced by eminent artists, who have not published any account of them, nor of the motives which have induced each to prefer his favourite construction: Mr. Harrison, Mr. Hindley of York, Mr. Ellicot, Mr. Mudge, Mr. Arnold, Mr. Whitehurst, and many other ingenious artists of this country, have made Scapements of new and peculiar constructions, of which we are unable, for the above reason, to give any farther account than that those of Mr. Harrison and Mr. Hindley had scarce any friction, with a certain mode and quantity of recoil; those of all the other gentlemen, we believe, have been on the principle of the dead beat, with such other improvements as they severally judged most conducive to a good performance.

Count Bruhl has just published (in 1794) a small pamphlet, "On the Investigation of Astronomical Circles," to which he has annexed, "a Description of the Scapement in Mr. Mudge's first Timekeeper, drawn up in August 1771." Before entering upon the Description, the Count premises a few observations, in one of which he recognizes a hint concerning the nature of Mr. Mudge's Scapement, thrown out by this artist in a small tract printed by him in the year 1763, which is this. "The force derived from the mainspring should be made as equal as possible, by making the mainspring wind up another smaller spring at a less distance from the balance, at short intervals of time. *I think it would not be impracticable to make it wind up at every vibration, a small spring similar to the pendulum spring, that should immediately act on the balance, by which the whole force acting on the balance would be reduced to the greatest simplicity, with this advantage, that the force would increase in proportion to the arch.*" From this hint, Count Bruhl is surprised that no other artists have taken up Mr. Mudge's invention. He then gives the Description of that invention as follows: "Mr. Mudge's Timekeeper has five wheels, with numbers high enough to admit pinions of twelve, and yet to go eight days. The Scapement consists of a wheel almost like that of a common crown wheel, and acts on pallets, each of which has a separate axis lying in the same line. To each pallet a spring is fixed in the shape of a pendulum spring; these springs are wound up alternately by the action of the last wheel upon the pallets, which is performed in the following manner:—Whenever one of the pallets (for instance the upper one) is set in motion by a tooth of the wheel sliding upon it, and then resting against a hook, or, rather a bearing at its end, the balance is entirely detached from it, being then employed in carrying the other pallet the contrary way. When the balance returns from that vibration (partly by the force of the pendulum spring, and partly by that of one of the two small springs which it had bent by the motion of that pallet which it had carried along with itself) it lays hold of the upper pallet and carries it round in the same manner as it did before the lower one, and, of course, in the same direction which the upper pallet had received from the power of the mainspring at the time that it was quite unconnected with the balance. The communication of motion from the balance to the pallets, and vice versa, is effected by two pins fixed to a crank, which in following the balance, hit each its proper pallet alternately. By what has been said, it is evident that whatever inequality there may be in the power derived from the mainspring (provided the latter be sufficient to wind up those little pallet springs) it can never interfere with the regularity of the balance's motion, but at the instant of unlocking the pallets, which is so instantaneous an operation, and the resistance so exceedingly small, that it cannot possibly amount to any sensible error. The removal of this great obstacle was certainly never so effectually done by any other contrivance

vance, and deserves the highest commendation, as a probable means to perfect a portable machine that will measure time correctly. But this is not the only, nor indeed the principal advantage which this timekeeper will possess over any other; for, as it is impossible to reduce friction to so small a quantity as not to affect the motion of a balance, the consequence of which is, that it describes sometimes greater and sometimes smaller arcs, it became necessary to think of some method by which the balance might be brought to describe those different arcs in the same time. If a balance could be made to vibrate without friction or resistance from the medium in which it moves, the mere expanding and contracting of the pendulum spring, would probably produce the so much wished-for effect, as its force is supposed to be proportional to the arcs described; but as there is no machine void of friction, and as from that cause, the velocity of every balance decreases more rapidly than the spaces gone through decrease, this inequality could only be removed by a force acting on the balance, which assuming different ratios in its different stages, could counterbalance that inequality. This very material and important remedy, Mr. Mudge has effected by the construction of his Scapement; for his pallet springs having a force capable of being increased almost at pleasure, at the commencement of every vibration, the proportion in their different degrees of tension may be altered till it answers the intended purpose. This shews how effectually Mr. Mudge's Scapement removes the two greatest difficulties that have hitherto baffled the attempts of every other artist, namely, the inequalities of the power derived from the main spring, and the irregularities arising from friction, and the variable resistance of the medium in which the balance moves. Although at the time I am writing this account of his invention, the machine is not yet finished; I am not the less confident that whenever it is, it will be found to be one of the most useful of any which has as yet appeared."

SCARP, in Fortification, the interior slope of the ditch of a place; that is, the slope of that side of a ditch which is next to the place, or on the outside of the rampart at its foot, facing the champaign or open country. The slope on the outer side of the ditch is called the *counterscarp*.

SCENOGRAPHY, in Perspective, the perspective representation of a body on a plane; or a description and view of it in all its parts and dimensions, such as it appears to the eye in any oblique view.

This differs essentially from the ichnography and the orthography. The ichnography of a building, &c, represents the plan or ground work of the building, or section parallel to it; and the orthography the elevation, or front, or one side, also in its natural dimensions; but the Scenography exhibits the whole of the building that appears to the eye, front, sides, height, and all, not in their real dimensions or extent, but raised on the geometrical plan in perspective.

In architecture and fortification, Scenography is the manner of delineating the several parts of a building or fortress, as they are represented in perspective.

To exhibit the SCENOGRAPHY *of any body*. 1. Lay down the basis, ground-plot, or plan, of the body, in the perspective ichnography, that is, draw the perspective appearance of the plan or basement, by the proper rules of perspective. 2. Upon the several points of the said perspective plan, raise the perspective heights, and connect the tops of them by the proper slope or oblique lines. So will the Scenography of the body be completed, when a proper shade is added. See PERSPECTIVE.

SCHEINER (CHRISTOPHER), a considerable German mathematician and astronomer, was born at Mundelheim in Schwaben in 1575. He entered into the society of the Jesuits at 20 years of age; and afterwards taught the Hebrew tongue and the mathematics at Ingolstadt, Friburg, Brisac, and Rome. At length he became confessor to the archduke Charles, and rector of the college of the Jesuits at Neisse in Silesia, where he died in 1650, at 75 years of age.

Scheiner was chiefly remarkable for being one of the first who observed the spots in the sun with the telescope, though not the very first; for his observations of those spots were first made, at Ingolstadt, in the latter part of the year 1611, whereas Galileo and Harriot both observed them in the latter part of the year before, or 1610. Scheiner continued his observations on the solar phenomena for many years afterwards at Rome, with great assiduity and accuracy, constantly making drawings of them on paper, describing their places, figures, magnitude, revolutions and periods, so that Riccioli delivered it as his opinion that there was little reason to hope for any better observations of those spots. Des Cartes and Hevelius also say, that in their judgment, nothing can be expected of that kind more satisfactory. These observations were published in one volume folio, 1630, under the title of *Rosa Ursina*, &c; almost every page of which is adorned with an image of the sun with the spots. He wrote also several smaller pieces relating to mathematics and philosophy, the principal of which are,

2. *Oculus, sive Fundamentum Opticum, &c;* which was reprinted at London, in 1652, in 4to.

3. *Sol Ecclipticus, Disquisitiones Mathematicæ.*

4. *De Controversiis et Novitatibus Astronomicis.*

SCHEME, a draught or representation of any geometrical or astronomical figure, or problem, by lines sensible to the eye; or of the celestial bodies in their proper places for any moment; otherwise called a diagram.

SCHEME *Arches*. See ARCH.

SCHOLIUM, a note, remark, or annotation, occasionally made on some passage, proposition, or the like.

The term is much used in geometry, and other parts of the mathematics; where, after demonstrating a proposition, it is used to point out how it might be done some other way; or to give some advice or precaution, in order to prevent mistakes; or to add some particular use or application of it.

Wolfius has given abundance of curious and useful arts and methods, and a good part of the modern philosophy, with the description of mathematical instruments, &c; all by way of Scholia to the respective propositions in his Elementa Mathefeos.

SCHONER (JOHN), a noted German philosopher and mathematician, was born at Carolostadt in the year 1477, and died in 1547, at 70 years of age.—His early propensity to those sciences may be deemed a just prognostication of the great progress which

which he afterwards made in them. So that from his uncommon acquirements, he was chosen mathematical professor at Nuremburg when he was but a young man. He wrote a great many works, and was particularly fa[illegible] for his astronomical tables, which he published aft[illegible] manner of those of Regiomontanus, and to wh[illegible]e gave the title of *Resolutæ*, on account of their clearness. But notwithstanding his great knowledge, he was, after the fashion of the times, much addicted to judicial astrology, which he took great pains to improve. The list of his writings is chiefly as follows:

1. Three Books of Judicial Astrology.
2. The Astronomical Tables named *Resolutæ*.
3. *De Usu Globi Stelliferi; De Compositione Globi Cœlestis; De Usu Globi Terrestris, et de Compositione ejusdem.*
4. *Æquatorium Astronomicum.*
5. *Libellus de Distantiis Locorum per Instrumentum et Numeros Investigandis.*
6. *De Compositione Torqueti.*
7. *In Constructionem et Usum Rectanguli sive Radii Astronomici Annotationes.*
8. *Horarii Cylindri Canones.*
9. *Planisphærium, seu Meteoroscopium.*
10. *Organum Uranicum.*
11. *Instrumentum Impedimentorum Lunæ.*

All printed at Nuremburg, in folio, 1551.

Of these, the large treatise of dialling rendered him more known in the learned world than all his other works besides; in which he discovers a surprising genius and fund of learning of that kind.

SCHOOL, a place where the languages, humanities, or arts and sciences, &c, are taught.

School is also used for a whole faculty, university, or sect; as Plato's school, the school of Epicurus, the school of Paris, &c.—The school of Tiberias was famous among the ancient Jews; and it is to this we owe the Massora, and Massoretes.

School *Philosophy*, &c. the same with *scholastic*.

SCIAGRAPHY, or Sciography, the profile or vertical section of a building; used to shew the inside of it.

Sciagraphy, in Astronomy &c, is a term used by some authors for the art of finding the hour of the day or night, by the shadow of the sun, moon, stars, &c. See Dial.

SCIENCE, a clear and certain knowledge of any thing, founded on demonstration, or on self evident principles.—In this sense, *doubting* is opposed to science; and *opinion* is the middle between the two.

Science is more particularly used for a formed system of any branch of knowledge, comprehending the doctrine, reason, and theory of the thing, without any immediate application of it to any uses or offices of life. And in this sense, the word is used in opposition to *art*.

Science may be divided into these three sorts: First, the knowledge of things, their constitutions, properties, and operations, whether material or immaterial. And this, in a little more enlarged sense of the word, may be called physics, or natural philosophy. Secondly, the skill of rightly applying our own powers and actions for the attainment of good and useful things, as *Ethics*. Thirdly, the doctrine of signs; as words, logic, &c.

SCIENTIFIC, or Scientifical, something relating to the pure and sublimer sciences; or that abounds in science, or knowledge.

A work, or method, &c, is said to be scientifical, when it is founded on the pure reason of things, or conducted wholly on the principles of them. In which sense the word stands opposed to narrative, arbitrary, opinionative, positive, tentative, &c.

SCIOPTIC, or Scioptric *Ball*, a sphere or globe of wood, with a circular hole or perforation, where a lens is placed. It is so fitted that, like the eye of an animal, it may be turned round every way, to be used in making experiments of the darkened room.

SCIOPTRICS. See Camera Obscura.

SCIOTHERICUM *Telescopium*, is an horizontal dial, adapted with a telescope for observing the true time both by day and night, to regulate and adjust pendulum clocks, watches, and other time-keepers. It was invented by Mr. Molyneux, who published a book with this title, which contains an accurate description of this instrument, with all its uses and applications.

SCLEROTICA, one of the common membranes of the eye, on its hinder part. It is a large, thick, firm, hard, opaque membrane, extended from the external circumference of the cornea to the optic nerve, and forms much the greater part of the external globe of the eye. The Sclerotica and the cornea compose the case in which all the internal coats of the eye and its humours are contained.

SCONCES, small forts, built for the defence of some pass, river, or other place. Some Sconces are made regular, of four, five, or six bastions; others are of smaller dimensions, fit for passes, or rivers; and others for the field.

SCORE, in Music, denotes partition, or the original draught of the whole composition, in which the several parts, viz the treble, second treble, bass, &c. are distinctly scored, and marked.

SCORPIO, the *Scorpion*, the 8th sign of the zodiac, denoted by the character ♏, being a rude design of the animal of that name.

The Greeks, who would be supposed the inventors of astronomy, and who have, with that intent, fathered some story or other of their own upon every one of the constellations, give a very singular account of the origin of this one. They tell us that this is the creature which killed Orion. The story goes, that the famous hunter of that name boasted to Diana and Latona, that he would destroy every animal that was upon the earth; the earth, they say, enraged at this, sent forth the poisonous reptile the Scorpion, which insignificant creature stung him, that he died. Jupiter, they say, raised the Scorpion to the heavens, giving him this place among the constellations; and that afterwards Diana requested of him to do the same honour to Orion, which he at last consented to, but placed him in such a situation, that when the Scorpion rises, he sets.

But the Egyptians, or whatever early nation it was that framed the zodiac, probably placed this poisonous reptile in that part of the heavens to denote that when the sun arrived at it, fevers and sicknesses, the maladies of autumn, would begin to rage. This they represented by an animal whose sting was of power to occasion some

of

of them; and it was thus they formed all the constellations.

The ancients allotted one of the twelve principal among their deities to be the guardian for each of the 12 signs of the zodiac. The Scorpion, as their history of it made it a fierce and fatal animal that had killed the great Orion, fell naturally to the protection of the god of war; Mars is therefore its tutelary deity; and to this single circumstance is owing all that jargon of the astrologers, who tell us that there is a great analogy between the planet Mars and the constellation Scorpio. To this also is owing the doctrine of the alchymists, that iron, which they call Mars, is also under the dominion of the same constellation, and that the transmutation of that metal into gold can only be performed when the sun is in this sign.

The stars in Scorpio, in Ptolomy's catalogue, are 24; in that of Tycho 10, in that of Hevelius 20, but in that of Flamsteed and Sharp 44.

Scorpion is also the name of an ancient military engine, used chiefly in the defence of walls, &c.

Marcellinus describes the Scorpion, as consisting of two beams bound together by ropes. From the middle of the two, rose a third beam, so disposed, as to be pulled up and let down at pleasure; and on the top of this were fastened iron hooks, where a sling was hung, either of iron or hemp; and under the third beam lay a piece of hair-cloth full of chaff, tied with cords. It had its name Scorpio, because when the long beam or tiller was erected, it had a sharp top in manner of a sting.

To use the engine, a round stone was put into the sling, and four persons on each side, loosening the beams bound by the ropes, drew back the erect beam to the hook; then the engineer, standing on an eminence, gave a stroke with a hammer on the chord to which the beam was fastened with its hook, which set it at liberty; so that hitting against the soft hair-cloth, it struck out the stone with a great force.

SCOTIA, in Architecture, a semicircular cavity or channel between the tores, in the bases of columns; and sometimes under the larmier or drip, in the cornice of the Doric order. The workmen often call it the Casement, and it is also otherwise called the Trochilus.

SCREW, or Scrue, one of the six mechanical powers; chiefly used in pressing or squeezing bodies close, though sometimes also in raising weights.

The Screw is a spiral thread or groove cut round a cylinder, and everywhere making the same angle with the length of it. So that, if the surface of the cylinder, with this spiral thread upon it, were unfolded and stretched into a plane, the spiral thread would form a straight inclined plane, whose length would be to its height, as the circumference of the cylinder is to the distance between two threads of the Screw; as is evident by considering, that in making one round, the spiral rises along the cylinder the distance between the two threads.

Hence the threads of a Screw may be traced upon the smooth surface of a cylinder thus: Cut a sheet of paper into the form of a right-angled triangle, having its base to its height in the above proportion, viz, as the circumference of the cylinder of the Screw is to the intended distance between two threads; then wrap this paper triangle about the cylinder, and the hypothenuse of it will trace out the line of the spiral thread.

When the spiral thread is upon the outside of a cylinder, the Screw is said to be a *male* one. But if the thread be cut along the inner surface of a hollow cylinder, or a round perforation, it is said to be *female*. And this latter is also sometimes called the *box* or *nut*.

When motion is to be given to something, the male and female Screw are necessarily conjoined; that is, whenever the screw is to be used as a simple engine, or mechanical power. But when joined with an axis in peritrochio, there is no occasion for a female; but in that case it becomes part of a compound engine.

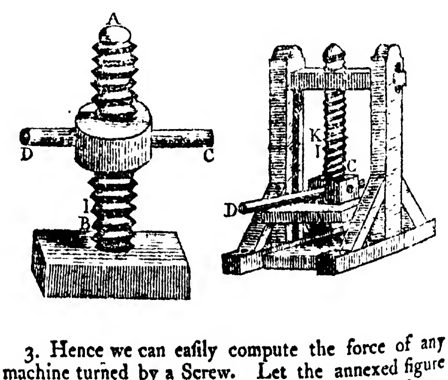
The Screw cannot properly be called a simple machine, because it is never used without the application of a lever, or winch, to assist in turning it.

Of the Force and Power of the Screw.

1. The force of a power applied to turn a Screw round, is to the force with which it presses upwards or downwards, setting aside the friction, as the distance between two threads is to the circumference where the power is applied.

For, the Screw being only an inclined plane, or half wedge, whose height is the distance between two threads, and its base the said circumference; and the force in the horizontal direction being to that in the vertical one as the lines perpendicular to them, viz, as the height of the plane, or distance of the two threads, is to the base of the plane, or circumference at the place where the power is applied; therefore the power is to the pressure, as the distance of two threads, is to that circumference.

2. Hence, when the Screw is put in motion; then the power is to the weight which would keep it in equilibrio, as the velocity of the latter is to that of the former. And hence their two momenta are equal, which are produced by multiplying each weight or power by its own velocity. Two different forms of Screw presses, are as below.



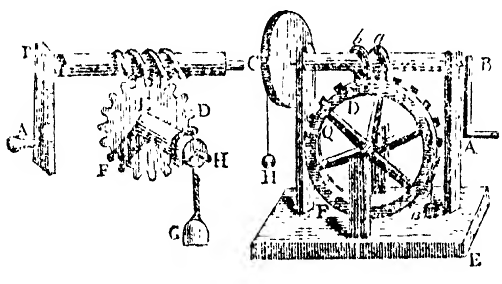
3. Hence we can easily compute the force of any machine turned by a Screw. Let the annexed figure represent a press driven by a Screw, whose threads are each a quarter of an inch asunder; and let the Screw be turned by a handle of 4 feet long from C to D; then if the natural force of a man, by which he can lift, or pull,

pull, or draw, be 150 pounds; and it be required to determine with what force the Screw will preſs on the board, when the man turns the handle at C and D with his whole force. The diameter CD of the power being 4 feet, or 48 inches, its circumference is 48 × 3·1416 or 150^{4} nearly; and the diſtance of the threads being $\frac{1}{4}$ of an inch; therefore the power is to the preſſure, as $\frac{1}{4}$ to $150\frac{4}{5}$ or as 1 to $603\frac{1}{5}$: but the power is equal to 150lb; therefore as 1 : $603\frac{1}{5}$ :: 150 : 90,480; and conſequently the preſſure at the bottom of the Screw, is equal to a weight of 90,480 pounds, independent of friction.

But the power has to overcome, not only the weight, or other reſiſtance, but alſo the friction of the Screw, which in this machine is very great, in ſome caſes equal to the weight itſelf, ſince it is ſometimes ſufficient to ſuſtain the weight, when the power is taken off.

Mr. Hunter has deſcribed a new method of applying the Screw with advantage in particular caſes, in the Philoſ Tranſ. vol. 71, pa. 58 &c.

The Endleſs SCREW, or *Perpetual* SCREW, is one which works in, and turns, a dented wheel DF, without a concave or female Screw; being ſo called becauſe it may be turned for ever, without coming to an end. From the following ſchemes it is evident, that while the Screw turns once round, the wheel only advances the diſtance of one tooth.



1. If the power applied to the lever, or handle, of an endleſs Screw AB, be to the weight, in a ratio compounded of the periphery of the axis of the wheel EH, to the periphery deſcribed by the power in turning the handle, and of the revolutions of the wheel DF to the revolutions of the Screw CB, the power will balance the weight. Hence,

2. As the motion of the wheel is very ſlow, a ſmall power may raiſe a very great weight, by means of an endleſs Screw. And therefore the chief uſe of ſuch a Screw is, either where a great weight is to be raiſed through a little ſpace; or where only a ſlow gentle motion is wanted. For which reaſon it is very uſeful in clocks and watches.

3. Having given the number of teeth, the diſtance of the power from the centre of the Screw B, the radius of the axis HE, and the power; to find the weight it will raiſe. Multiply the diſtance of the power from the centre of the Screw AB, by the number of the teeth, and the product will be the ſpace paſſed through by the power, while the weight paſſes through a ſpace equal to the periphery of the axis: then ſay, as the radius of the axis is to the ſpace of the power juſt found, ſo is the power to a 4th proportional, which will be the weight the power is able to ſuſtain. Thus, if AB = 3, the radius of the axis HE = 1, the power 150 pounds, and the number of teeth of the wheel DF 48; then the weight will be found = 21,600 = 3 × 150 × 48. Whence it appears that the endleſs Screw exceeds all others in increaſing the force of a power.

4. A machine for ſhewing the power of the Screw may be contrived in the following manner. Let the wheel C (laſt fig.) have a Screw *ab* on its axis, working in the teeth of the wheel D, which ſuppoſe to be 48 in number. It is plain that for every revolution of the wheel C, and Screw *ab*, by the winch A, the wheel D will be moved one tooth by the Screw; and therefore in 48 revolutions of the winch, the wheel D will be turned once round. Then if the circumference of a circle, deſcribed by the handle of the winch, be equal to the circumference of a groove *e* round the wheel D, the velocity of the handle will be 48 times as great as the velocity of any given point in the groove. Conſequently when a line G goes round the groove *e*, and has a weight of 48lb hung to it below the pedeſtal EF, a power equal to one pound at the handle will balance and ſupport the weight.

Archimedes's SCREW, is a ſpiral pump, being a machine for raiſing water, firſt invented by Archimedes.

Its ſtructure and uſe will be underſtood by the following deſcription of it.

ABCD (Pl. xxiii, fig. 6) is a wheel, which is turned round, according to the order of thoſe letters, by the fall of water EF, which need not be more than 3 feet. The axis G of the wheel is raiſed ſo as to make an angle of about 44° with the horizon; and on the top of that axle is a wheel H, which turns ſuch another wheel I of the ſame number of teeth; the axle K of this laſt wheel being parallel to the axle G of the two former wheels. The axle G is cut into a double threaded Screw, as in the annexed figure (fig. 7), exactly reſembling the Screw on the axis of the fly of a common jack, which muſt be what is called a right-handed Screw, if the firſt wheel turns in the direction ABCD; but a left-handed Screw, if the ſtream turns the wheel the contrary way; and the Screw on the axle G muſt be cut in a contrary way to that on the axle K, becauſe theſe axles turn in contrary directions. Theſe Screws muſt be covered cloſe over with boards, like theſe of a cylindrical caſk; and then they will be ſpiral tubes. Or they may be made of tubes or pipes of lead, and wrapt round the axles in ſhallow grooves cut in it, like the figure 8. The lower end of the axle G turns conſtantly in the ſtream that turns the wheel, and the lower ends of the ſpiral tubes are open into the water. So that, as the wheel and axle are turned round, the water riſes in the ſpiral tubes, and runs out at L through the holes M, N, as they come about below the axle. Theſe holes, of which there may be any number, as 4 or 6, are in a broad cloſe ring on the top of the axle, into which ring the water is delivered from the upper open ends of the Screw tubes, and falls into the open box N. The lower end of the axle K turns on a gudgeon in the water in N; and the ſpiral tubes in that axle take up the water from N, and deliver it into another ſuch box under the top of K; on which there may be ſuch another wheel

wheel as T, to turn a third axle by such a wheel upon it. And in this manner may water be raised to any proposed height, when there is a stream sufficient for that purpose to act on the broad float boards of the first wheel. Archimedes's Screw, or a still simpler form of it, is also represented in fig. 9.

SCROLLS, or Scrowls, or *Volutes*, a term in Architecture. See Volutes.

SCRUE. See Screw.

SCRUPLE, the least of the weights used by the ancients. Among the Romans it was the 24th part of an ounce, or the third part of a drachm.

Scruple is still a small weight among us, equal to 20 grains, or the 3d part of a drachm. Among goldsmiths the scruple is 24 grains.

Scruple, in Chronology, a small portion of time much used by the Chaldeans, Jews, Arabs, and other eastern people, in computations of time. It is the 1080th part of an hour, and by the Hebrews called *helakin*.

Scruples, in Astronomy. As

Scruples *Eclipsed*, denote that part of the moon's diameter which enters the shadow, expressed in the same measure in which the apparent diameter of the moon is expressed See Digit.

Scruples *of Half Duration*, an arch of the moon's orbit, which the moon's centre describes from the beginning of an eclipse to its middle.

Scruples *of Immersion*, or *Incidence*, an arch of the moon's orbit, which her centre describes from the beginning of the eclipse, to the time when the centre falls into the shadow. See Immersion.

Scruples *of Emersion*, an arch of the moon's orbit, which her centre describes in the time from the first emersion of the moon's limb, to the end of the eclipse.

SCYTALA, in Mechanics, a term which some writers use for a kind of radius, or spoke, standing out from the axis of a machine, as a lever or handle, to turn it round, and work it by.

SEA, in Geography, is frequently used for that vast tract of water encompassing the whole earth, more properly called ocean. But

Sea is more properly used for a particular part or division of the ocean, denominated from the countries it washes, or from other circumstances. Thus we say, the Irish sea, the Mediterranean sea, the Baltic sea, the Red sea, &c.

Sea among sailors is variously applied, to a single wave, or to the agitation produced by a multitude of waves in a tempest, or to their particular progress and direction. Thus they say, a heavy sea broke over our quarter, or we shipped a heavy sea; there is a great sea in the offing; the sea sets to the southward. Hence a ship is said to head the sea, when her course is opposed to the setting or direction of the surges. A *Long Sea* implies a steady and uniform motion of long and extensive waves. On the contrary, a *Short Sea* is when they run irregularly, broken, and interrupted, so as frequently to burst over a vessel's side or quarter.

Properties and Affections of the Sea.

1. *General Motion of the Sea.* M. Dassie of Paris, in a work long since published, has been at great pains to prove that the Sea has a general motion, independent of winds and tides, and of more consequence in navigation than is usually supposed. He affirms that this motion is from east to west, inclining toward the north when the sun is on the north side of the equinoctial, but toward the south when he is on the south side of it. Philos. Trans. No. 135.

2. *Bason or Bottom of the* Sea, or *Fundus Maris*, a term used to express the bed or bottom of the sea in general. Mr. Boyle has published a treatise on this subject, in which he has given an account of its irregularities and various depths founded on the observations communicated to him by mariners.

Count Marsigli has, since his time, given a much fuller account of this part of the globe. The materials which compose the bottom of the Sea, may reasonably be supposed, in some degree, to influence the taste of its waters; and this author has made many experiments to prove that fossil coal, and other bituminous substances, which are found in plenty at the bottom of the Sea, may communicate in great part its bitterness to it.

It is a general rule among sailors, and is found to hold true in many instances, that the more the shores of any place are steep and high, forming perpendicular cliffs, the deeper the Sea is below; and that on the contrary, level shores denote shallow Seas. Thus the deepest part of the Mediterranean is generally allowed to be under the height of Malta. And the observation of the strata of earth and other fossils, on and near the shores, may serve to form a good judgment as to the materials to be found in its bottom. For the veins of salt and of bitumen doubtless run on the same, and in the same order, as we see them at land; and the strata of rocks that serve to support the earth of hills and elevated places on shore, serve also, in the same continued chain, to support the immense quantity of water in the bason of the Sea.

The coral fisheries have given occasion to observe that there are many, and those very large caverns or hollows in the bottom of the Sea, especially where it is rocky; and that the like caverns are sometimes found in the perpendicular rocks which form the steep sides of those fisheries. These caverns are often of great depth, as well as extent, and have sometimes wide mouths, and sometimes only narrow entrances into large and spacious hollows.

The bottom of the Sea is covered with a variety of matters, such as could not be imagined by any but those who have examined into it, especially in deep water, where the surface only is disturbed by tides and storms, the lower part, and consequently its bed at the bottom, remaining for ages perhaps undisturbed. The soundings, when the plummet first touches the ground on approaching the shores, give some idea of this. The bottom of the plummet is hollowed, and in that hollow there is placed a lump of tallow; which being the part that first touches the ground, the soft nature of the fat receives into it some part of those substances which it meets with at the bottom: this matter, thus brought up, is sometimes pure sand, sometimes a kind of sand made of the fragment of shells, beaten to a sort of powder, sometimes it is made of a like powder of the several sorts of corals, and sometimes it is composed of

of fragments of rocks; but beside these appearances, which are natural enough, and are what might well be expected, it brings up substances which are of the most beautiful colours. Marsigli Hist. Phys. de la Mer.

Dr. Donati, in an Italian work, containing an essay towards a natural history of the Adriatic Sea, printed at Venice in 1750, has related many curious observations on this subject, and which confirm the observations of Marsigli: having carefully examined the soil and productions of the various countries that surround the Adriatic Sea, and compared them with those which he took up from the bottom of the Sea, he found that there is very little difference between the former and the latter. At the bottom of the water there are mountains, plains, vallies, and caverns, similar to those upon land. The soil consists of different strata placed one upon another, and mostly parallel and correspondent to those of the rocks, islands, and neighbouring continents. They contain stones of different sorts, minerals, metals, various putrefied bodies, pumice stones, and lavas formed by volcanos.

One of the objects which most excited his attention, was a crust, which he discovered under the water, composed of crustaceous and testaceous bodies, and beds of polypes of different kinds, confusedly blended with earth, sand, and gravel; the different marine bodies which form this crust, are found at the depth of a foot or more, entirely petrified and reduced into marble; these he supposes are naturally placed under the Sea when it covers them, and not by means of volcanos and earthquakes, as some have conjectured. On this account he imagines that the bottom of the Sea is constantly rising higher and higher, with which other obvious causes of increase concur; and from this rising of the bottom of the Sea, that of its level or surface naturally results; in proof of which this writer recites a great number of facts. Philos. Trans. vol. 49, pa. 585.

3. *Luminousness of the* SEA. This is a phenomenon that has been noticed by many nautical and philosophical writers. Mr. Boyle ascribes it to some cosmical law or custom of the terrestrial globe, or at least of the planetary vortex.

Father Bourzes, in his voyage to the Indies, in 1704, took particular notice of this phenomenon, and very minutely describes it, without assigning the true cause.

The Abbé Nollet was long of opinion, that the light of the Sea proceeded from electricity; and others have had recourse to the same principle, and shewn that the luminous points in the surface of the Sea are produced merely by friction.

There are however two other hypotheses, which have more generally divided between them the solution of this phenomenon; the one of these ascribes it to the shining of luminous insects or animalcules, and the other to the light proceeding from the putrefaction of animal substances. The Abbé Nollet, who at first considered this luminousness as an electrical phenomenon, having had an opportunity of observing the circumstances of it, when he was at Venice in 1749, relinquished his former opinion, and concluded that it was occasioned either by the luminous aspect, or by some liquor or effluvia of an insect which he particularly describes, though he does not altogether exclude other causes, and especially the spawn or fry of fish.

The same hypothesis had also occurred to M. Vianelli; and both he and Grizellini, a physician in Venice, have given drawings of the insects from which they imagined this light to proceed.

A similar conjecture is proposed by a correspondent of Dr. Franklin, in a letter read at the Royal Society in 1756; the writer of which apprehends, that this appearance may be caused by a great number of little animals, floating on the surface of the Sea. And Mr. Forster, in his account of a voyage round the world with captain Cook, in the years 1772, 3, 4, and 5, describes this phenomenon as a kind of blaze of the Sea; and, having attentively examined some of the shining water, expresses his conviction that the appearance was occasioned by innumerable minute animals of a round shape, moving through the water in all directions, which show separately as so many luminous sparks when taken up on the hand: he imagines that these small gelatinous luminous specks may be the young fry of certain species of some medusæ, or blubber. And M. Dagelat and M. Rigaud observed several times, and in different parts of the ocean, such luminous appearances by vast masses of different animalcules; and a few days after the Sea was covered, near the coasts, with whole banks of small fish in innumerable multitudes, which they supposed had proceeded from the shining animalcules.

But M. le Roi, after giving much attention to this phenomenon, concludes that it is not occasioned by any shining insects, especially as, after carefully examining with a microscope some of the luminous points, he found them to have no appearance of an animal; and he also found that the mixture of a little spirit of wine with water just drawn from the Sea, would give the appearance of a great number of little sparks, which would continue visible longer than those in the ocean: the same effect was produced by all the acids, and various other liquors. M. le Roi is far from asserting that there are no luminous insects in the Sea; for he allows that several gentlemen have found them; but he is satisfied that the Sea is luminous chiefly on some other account, though he does not so much as offer a conjecture with respect to the true cause.

Other authors, equally dissatisfied with the hypothesis of luminous insects, for explaining the phenomenon which is the subject of this article, have ascribed it to some substance of the phosphoric kind, arising from putrefaction. The observations of F. Bourzes, above referred to, render it very probable, that the luminousness of the Sea arises from slimy and other putrescent matter, with which it abounds, though he does not mention the tendency to putrefaction, as a circumstance of any consequence to the appearance. But the experiments of Mr. Canton, which have the advantage of being easily made, seem to leave no room to doubt that the luminousness of the Sea is chiefly owing to putrefaction. And his experiments confirm an observation of Sir John Pringle's, that the quantity of salt contained in Sea water hastens putrefaction; but since that precise quantity of salt which promotes putre-

faction the most, is less than that which is found in Sea-water, it is probable, Mr. Canton observes, that if the Sea were less salt, it would be more luminous. See Philos. Trans. vol. 59, pa. 446, and Franklin's Exper. and Observ. pa. 274.

Of the Depth of the Sea, its Surface, &c.

What proportion the superficies of the Sea bears to that of the land, is not accurately known, though it is said to be somewhat more than two to one. This proportion of the surface of the Sea to the land, has been found by experiment thus: taking the printed paper map or covering of a terrestrial globe, with a pair of scissors clip out the parts that are land, and those that are water; then weighing these parcels separately in a pair of fine scales, the land is found to be near $\frac{1}{4}$, and the water rather more than $\frac{3}{4}$ of the whole.

With regard to the profundity or depth of the Sea, Varenius affirms, that it is in some places unfathomable, and in others very various, being in certain places from $\frac{1}{20}$th of a mile to $4\frac{1}{2}$ miles in depth, in other places deeper, but much less in bays than in oceans. In general, the depths of the Sea bear a great analogy to the height of mountains on the land, so far as is hitherto discovered.

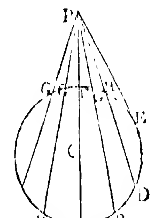
There are two special reasons why the Sea does not increase by means of rivers, &c, running every where into it. The first is, because waters return from the Sea by subterranean cavities and aqueducts, through various parts of the earth. Secondly, because the quantity of vapours raised from the Sea, and falling in rain upon the land, only cause a circulation of the water, but no increase of it. It has been found by experiment and calculation, that in a summer's day, there may be raised in vapours from the surface of the Mediterranean Sea, 528 millions of tuns of water; and yet this Sea receiveth not, from all its nine great rivers, above 183 millions of tuns per day, which is but about a third part of what is exhausted in vapours; and this defect in the supply by the rivers, may serve to account for the continual influx of a current by the mouth or straits at Gibraltar. Indeed it is rather probable, that the waters of the Sea suffer a continual slow decrease as to their quantity, by sinking always deeper into the earth, by filtering through the fissures in the strata and component parts.

SEASONS, certain portions or quarters of the year, distinguished by the signs which the sun then enters. Upon them depend the different temperatures of the air, different works in tillage, &c.

The year is divided into four Seasons, spring, summer, autumn, winter, which take their beginnings when the sun enters the first point of the signs Aries, Cancer, Libra, Capricorn.

The Seasons are very well illustrated by fig. 1, plate viii; where the candle at I represents the sun in the centre, about which the earth moves in the ecliptic ABCD, which cuts the equinoctial *abcd* in the two equinoxes E and G. When the earth is in these two points, it is evident that the sun equally illuminates both the poles, and makes the days and nights equal all over the earth. But while the earth moves from G by C to ♑, the upper or north pole becomes more and more enlightened, the days become longer, and the nights shorter; so that when the earth is at ♑, or the sun at ♋, our days are at the longest, as at midsummer. While the earth moves from ♑ by D to E, our days continually decrease, by the north pole gradually declining from the sun, till at E or autumn they become equal to the nights, or 12 hours long. Again, while the earth moves from E by A to F, the north pole becomes always more and more involved in darkness, and the days grow always shorter, till at F or ♋, when it is midwinter to the inhabitants of the northern hemisphere. Lastly, while the earth moves from ♋ by B to G, the north parts come more and more out of darkness, and the days grow continually longer, till at G the two poles are equally enlightened, and the days equal to the nights again. And so on continually year after year.

SECANT, in Geometry, a line that cuts another, whether right or curved; Thus the line PA or PB, &c, is a Secant of the circle ABD, because cutting it in the point F, or G, &c. Properties of such Secants to the circle are as follow:



1. Of several Secants PA, PB, PD, &c, drawn from the same point P, that which passes through the centre C is the greatest; and from thence they decrease more and more as they recede farther from the centre; viz. PB less than PA, and PD less than PB, and so on, till they arrive at the tangent at E, which is the limit of all the Secants.

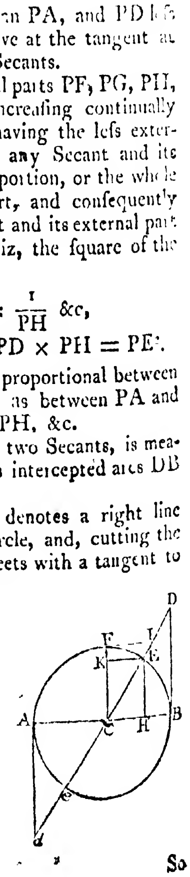
2. Of these Secants, the external parts PF, PG, PH, &c, are in the reverse order, increasing continually from F to E, the greater Secant having the less external part, and in such sort, that any Secant and its external part are in reciprocal proportion, or the whole is reciprocally as its external part, and consequently that the rectangle of every Secant and its external part is equal to a constant quantity, viz, the square of the tangent. That is,

$$PA : \frac{1}{PF} :: PB : \frac{1}{PG} :: PD : \frac{1}{PH} \text{ \&c,}$$
$$\text{or } PA \times PF = PB \times PG = PD \times PH = PE^2.$$

3. The tangent PE is a mean proportional between any Secant and its external part; as between PA and PF, or PB and PG, or PD and PH, &c.

4. The angle DPB, formed by two Secants, is measured by half the difference of its intercepted arcs DB and GH.

SECANT, in Trigonometry, denotes a right line drawn from the centre of a circle, and, cutting the circumference, proceeds till it meets with a tangent to the same circle.



Thus, the line CD, drawn from the centre C, till it meets the tangent BD, is called a Secant; and particularly the Secant of the arc BE, to which BD is a tangent. In like manner, by producing DC to meet the tangent A*d* in *d*, then C*d*, equal to CD, is the Secant of the arch AE which is the supplement of the arch BE.

So that an arch and its ſupplement have their Secants equal, only the latter one is negative to the former, being drawn the contrary way. And thus the Secants in the 2d and 3d quadrant are negative, while thoſe in the 1ſt and 4th quadrants are poſitive.

The Secant CI of the arc EF, which is the complement of the former arch BE, is called the *coſecant* of BE, or the Secant of its complement. The coſecants in the 1ſt and 2d quadrants are affirmative, but in the 3d and 4th negative.

The Secant of an arc is reciprocally as the coſine, and the coſecant reciprocally as the ſine; or the rectangle of the Secant and coſine, and the rectangle of the coſecant and ſine, are each equal to the ſquare of the radius.

For CD : CE : : CB : CH, or $ſ : r : : r : c$,
and CI : CE : : CF : CK, or $\sigma : r : : r : s$;

and conſequently $r^2 = cſ = s\sigma$; where r denotes the radius, s the ſine, c the coſine, $ſ$ the Secant, and σ the coſecant.

An arc a, to the radius r, being given, the Secant $ſ$, and coſecant σ, and their logarithms, or the logarithmic Secant and coſecant, may be expreſſed in infinite ſeries, as follows, viz,

$$ſ = r + \frac{a^2}{2r} + \frac{5a^4}{24r^3} + \frac{61a^6}{720r^5} + \frac{277a^8}{8064r^7} \text{ \&c.}$$

$$\sigma = \frac{r^2}{a} + \frac{a}{6} + \frac{7a^3}{360r^2} + \frac{31a^5}{15120r^4} + \frac{127a^7}{604800r^6} \text{ \&c.}$$

$$log.\, ſ = m \times \left(\frac{a^2}{2} + \frac{a^4}{12} + \frac{a^6}{45} + \frac{17a^8}{2520} \text{ \&c.}\right)$$

$$log.\, \sigma = -log.\, a + m \times \left(\frac{a^2}{6} + \frac{a^4}{180} + \frac{a^6}{2835} + \frac{a^8}{37800} \text{\&c.}\right)$$

where m is the modulus of the ſyſtem of logarithms.

Secants, *Figure of*. See Figure *of Secants*.

Secants, *Line of*. See Sector, and Scale.

SECOND, in Geometry, or Aſtronomy, &c, the 60th part of a prime or minute: either in the diviſion of circles, or in the meaſure of time. A degree, or an hour, are each divided into 60 minutes, marked thus ′; a minute is ſubdivided into 60 Seconds, marked thus ″; a Second into 60 thirds, marked thus ‴; &c.

We ſometimes ſay a *Second minute*, a *third minute*, &c, but more uſually only *Second*, *third*, &c.

The Seconds pendulum, or pendulum that vibrates Seconds, in the latitude of London, is $39\frac{1}{8}$ inches long.

SECONDARY *Circles of the Ecliptic*, are circles of longitude of the ſtars; or circles which, paſſing through the poles of the ecliptic, are at right angles to the ecliptic.

By means of theſe Secondary circles, all points in the heavens are referred to the ecliptic; that is, any ſtar, planet, or other phenomenon, is underſtood to be in that point of the ecliptic, which is cut by the Secondary circle that paſſes through ſuch ſtar, &c.

If two ſtars be thus referred to the ſame point of the ecliptic, they are ſaid to be in conjunction; if in oppoſite points, they are in oppoſition; if they are referred to two points at a quadrant's diſtance, they are ſaid to be in a quartile aſpect, if the points differ a 6th part of the ecliptic, they are in ſextile aſpect, &c.

In general, all circles that interſect one of the ſix greater circles of the ſphere at right angles, may be called Secondary circles. As the azimuth or vertical circles in reſpect of the horizon, &c; the meridian in reſpect of the equator, &c.

Secondary *Planets*, or *Satellites*, are thoſe moving round other planets as the centres of their motion, and along with them round the ſun.

SECTION, in Geometry, denotes a ſide or ſurface appearing of a body, or figure, cut by another; or the place where lines, planes, &c, cut each other.

The common Section of two planes is always a right line; being the line ſuppoſed to be drawn by one plane in its cutting or entering the other. If a ſphere be cut in any manner by a plane, the figure of the Section will be a circle; alſo the common interſection of the ſurfaces of two ſpheres, is the circumference of a circle; and the two common Sections of the ſurfaces of a right cone and a ſphere, are the circumferences of circles if the axis of the cone paſs through the centre of the ſphere, otherwiſe not; moreover, of the two common Sections of a ſphere and a cone, whether right or oblique, if the one be a circle the other will be a circle alſo, otherwiſe not. See my Tracts, tract 7, prop. 7, 8, 9.

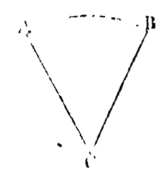
The Sections of a cone by a plane, are five; viz, a triangle, circle, ellipſe, hyperbola, and parabola. See each of theſe terms, as alſo Conic Section.

Sections of Buildings and Bodies, &c, are either vertical, or horizontal, &c. The

Vertical Section, or ſimply the Section, of a building, denotes its profile, or a delineation of its heights and depths raiſed on the plan; as if the fabric had been cut aſunder by a vertical plane, to diſcover the inſide. And

Horizontal Section is the ichnography or ground plan, or a Section parallel to the horizon.

SECTOR, of a Circle, is a portion of the circle comprehended between two radii and their included arc. Thus, the mixt triangle ABC, contained between the two radii AC and BC, and the arc AB, is a Sector of the circle.



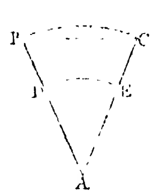
The Sector of a circle, as ABC, is equal to a triangle, whoſe baſe is the arc AB, and its altitude the radius AC or BC. And therefore the radius being drawn into the arc, half the product gives the area.

Similar Sectors, are thoſe which have equal angles included between their radii. Theſe are to each other as the ſquares of their bounding arcs, or as their whole circles.

Sector alſo denotes a mathematical inſtrument, which is of great uſe in geometry, trigonometry, ſurveying, &c, in meaſuring and laying down and finding proportional quantities of the ſame kind: as between lines and lines, ſurfaces and ſurfaces, &c: whence the French call it the *compaſs of proportion*.

The great advantage of the Sector above the common scales, &c, is, that it is contrived so as to suit all radii, and all scales. By the lines of chords, sines, &c, on the Sector, we have lines of chords, sines, &c, to any radius between the length and breadth of the Sector when open.

The Sector is founded on the 4th proposition of the 6th book of Euclid; where it is demonstrated, that similar triangles have their like sides proportional. An idea of the theory of its construction may be conceived thus. Let the lines AB, AC represent the legs of the Sector; and AD, AE, two equal sections from the centre: then if the points BC and DE be connected, the lines BC and DE will be parallel; therefore the triangles ABC, ADE will be similar, and consequently the sides AB, BC, AD, DE proportional, that is, as AB : BC : : AD : DE; so that if AD be the half, 3d, or 4th part of AB, then DE will be a half, 3d, or 4th part of BC: and the same holds of all the rest. Hence, if DE be the chord, sine or tangent, of any arc, or of any number of degrees, to the radius AD, then BC will be the same to the radius AB.



The Sector, it is supposed, was the invention of Guido Baldo or Ubaldo, about the year 1568. The first printed account of it was in 1584, by Gaspar Mordente at Antwerp, who indeed says that his brother Fabricius Mordente invented it, in the year 1554. It was next treated of by Daniel Speckle, at Strasburgh, in 1589; after that by Dr. Thomas Hood, at London, in 1598: and afterwards by many other writers on practical geometry, in all the nations of Europe.

Description of the SECTOR. This instrument consists of two rules or legs, the longer the better, made of box, or ivory, or brass, &c, representing the radii, moveable round an axis or joint, the middle of which represents the centre; from whence several scales are drawn on the faces. See the fig. 1, plate xxvi.

The scales usually set upon Sectors, may be distinguished into single and double. The single scales are such as are set upon plane scales: the double scales are those which proceed from the centre; each of these being laid twice on the same face of the instrument, viz. once on each leg. From these scales, dimensions or distances are to be taken, when the legs of the instrument are set in an angular position.

The scales set upon the best Sectors are

Single	1	A line of Inches, each divided into 8 and 10 parts,	
	2	Decimals, containing 100 parts.	
	3	Chords	marked Cho.
	4	Sines	Sin.
	5	Tangents	Tang.
	6	Rhumbs.	Rhum.
	7	Latitude	Lat.
	8	Hours.	Hou.
	9	Longitude	Lon.
	10	Inclin. Merid.	In. mer.
	11	the logarithms of Numbers	Num.
	12	Sines	Sin.
	13	Versed Sines	V. Sin.
	14	Tangents	Tan.

Double	1	a line of Lines, or equal parts	marked Lin.
	2	Chords	Cho.
	3	Sines	Sin.
	4	Tangents to 45°	Tan.
	5	Secants	Sec.
	6	Tangents to above 45°	Tan.
	7	Polygons	Pol.

The manner in which these scales are disposed on the Sector, is best seen in the figure.

The scales of lines, chords, sines, tangents, rhumbs, latitudes, hours, longitude, incl. merid. may be used, with the instrument either shut or open, each of these scales being contained on one of the legs only. The scales of inches, decimals, log. numbers, log. sines, log. versed sines, and log. tangents, are to be used with the Sector quite open, with the two rulers or legs, stretched out in the same direction, part of each scale lying on both legs.

The double scales of lines, chords, sines, and lower tangents, or tangents under 45°, are all of the same radius or length; they begin at the centre of the instrument, and are terminated near the other extremity of each leg; viz, the lines at the division 10, the chords at 60, the sines at 90, and the tangents at 45; the remainder of the tangents, or those above 45°, are on other scales beginning at $\frac{1}{4}$ of the length of the former, counted from the centre, where they are marked with 45, and run to about 76 degrees.

The secants also begin at the same distance from the centre, where they are marked with 10, and are from thence continued to as many degrees as the length of the Sector will allow, which is about 75°.

The angles made by the double scales of lines, of chords, of sines, and of tangents to 45 degrees, are always equal. And the angles made by the scales of upper tangents, and of secants, are also equal.

The scales of polygons are set near the inner edge of the legs; and where these scales begin, they are marked with 4, and from thence are figured backwards, or towards the centre, to 12.

From this disposition of the double scales, it is plain, that those angles that are equal to each other while the legs of the Sector were close, will still continue to be equal, although the Sector be opened to any distance.

The scale of inches is laid close to the edge of the Sector, and sometimes on the edge; it contains as many inches as the instrument will receive when opened; each inch being usually divided into 8, and also into 10 equal parts. The decimal scale lies next to this: it is of the length of the Sector when opened, and is divided into 10 equal parts, or primary divisions, and each of these into 10 other equal parts; so that the whole is divided into 100 equal parts: and by this decimal scale, all the other scales, that are taken from tables, may be laid down. The scales of chords, rhumbs, sines, tangents, hours, &c, are such as are described under Plane Scale.

The scale of logarithmic or artificial numbers, called Gunter's scale, or Gunter's line, is a scale expressing the logarithms of common numbers, taken in their natural order.

The construction of the double scale will be evident by inspecting the instrument. As to the scale of polygons,

gons, it uſually comprehends the ſides of the polygons from 6 to 12 ſides incluſive: the diviſions are laid down by taking the lengths of the chords of the angles at the centre of each polygon, and laying them down from the centre of the inſtrument. When the polygons of 4 and 5 ſides are alſo introduced, this line is conſtructed from a ſcale of chords, where the length of 90° is equal to that of 60° of the double ſcale of chords on the Sector.

In deſcribing the uſe of the Sector, the terms *lateral diſtance* and *tranſverſe diſtance* often occur. By the former is meant the diſtance taken with the compaſſes on one of the ſcales only, beginning at the centre of the Sector; and by the latter, the diſtance taken between any two correſponding diviſions of the ſcales of the ſame name, the legs of the Sector being in an angular poſition.

Uſes of the SECTOR.

Of the Line of Lines. This is uſeful, to divide a given line into any number of equal parts, or in any proportion, or to make ſcales of equal parts, or to find 3d and 4th proportionals, or mean proportionals, or to increaſe or decreaſe a given line in any proportion. Ex. 1. To divide a given line into any number of equal parts, as ſuppoſe 9: make the length of the given line a tranſverſe diſtance to 9 and 9, the number of parts propoſed; then will the tranſverſe diſtance of 1 and 1 be one of the equal parts, or the 9th part of the whole; and the tranſverſe diſtance of 2 and 2 will be 2 of the equal parts, or $\frac{2}{9}$ of the whole line; and ſo on. 2. Again, to divide a given line into any number of parts that ſhall be in any aſſigned proportion, as ſuppoſe three parts, in the proportion of 2, 3, and 4. Make the given line a tranſverſe diſtance to 9, the ſum of the propoſed numbers 2, 3, 4; then the tranſverſe diſtances of theſe numbers ſeverally will be the parts required.

Of the Scale of Chords. 1. To open the Sector to any angle, as ſuppoſe 50 degrees: Take the diſtance from the joint to 50 on the chords, the number of degrees propoſed; then open the Sector till the tranſverſe diſtance from 60 to 60, on each leg, be equal to the ſaid lateral diſtance of 50; ſo ſhall the ſcale of chords make the propoſed angle of 50 degrees.—By the converſe of this operation, may be known the angle the Sector is opened to; viz, taking the tranſverſe diſtance of 60, and applying it laterally from the joint.

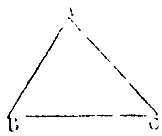
2. To protract or lay down an angle of any given number of degrees. At any opening of the Sector, take the tranſverſe diſtance of 60°, with which extent deſcribe an arc; then take the tranſverſe diſtance of the number of degrees propoſed, and apply it to that arc; and through the extremities of this diſtance on the arc draw two lines from the centre, and they will form the angle as propoſed. When the angle exceeds 60°, lay it off at twice or thrice.—By the converſe operation any angle may be meaſured; viz, With any radius deſcribe an arc from the angular point; ſet that radius tranſverſely from 60 to 60; then take the diſtance of the intercepted arc and apply it tranſverſely to the chords, which will ſhew the degrees in the given angle.

Of the Line of Polygons. 1. In a given circle to inſcribe a regular polygon, for example an octagon. Open the legs of the Sector till the tranſverſe diſtance from 6 to 6 be equal to the radius of the circle; then will the tranſverſe diſtance of 8 and 8 be the ſide of the inſcribed octagon. 2. Upon a line given to deſcribe a regular polygon. Make the given line a tranſverſe diſt. to 5 and 5; and at that opening of the Sector take the tranſverſe diſtance of 6 and 6; with which as a radius, from the extremities of the given line deſcribe arcs to interſect each other, which interſection will be the centre of a circle in which the propoſed polygon may be inſcribed; then from that centre deſcribe the ſaid circle through the extremities of the given line, and apply this line continually round the circumference, for the ſeveral angular points of the polygon.—3. On a given right line as a baſe, to deſcribe an iſoſceles triangle, having the angles at the baſe double the angle at the vertex. Open the Sector till the length of the given line fall tranſverſely on 10 and 10 on each leg; then take the tranſverſe diſtance to 6 and 6, and it will be the length of each of the equal ſides of the triangle.

Of the Sines, Tangents, and Secants. By the ſeveral lines diſpoſed on the ſector, we have ſcales of ſeveral radii. So that, 1. Having a length or radius given, not exceeding the length of the Sector when opened, we can find the chord, ſine, &c, to the ſame: for ex. ſuppoſe the chord, ſine, or tangent of 20 degrees to a radius of 3 inches be required. Make 3 inches the opening or tranſverſe diſtance to 60 and 60 on the chords; then will the ſame extent reach from 45 to 45 on the tangents, and from 90 to 90 on the ſines; ſo that to whatever radius the line of chords is ſet, to the ſame are all the others ſet alſo. In this diſpoſition therefore, if the tranſverſe diſtance between 20 and 20 on the chords be taken with the compaſſes, it will give the chord of 20 degrees; and if the tranſverſe of 20 and 20 be in like manner taken on the ſines, it will be the ſine of 20 degrees; and laſtly, if the tranſverſe diſtance of 20 and 20 be taken on the tangents, it will be the tangent of 20 degrees, to the ſame radius.—2. If the chord or tangent of 70 degrees were required. For the chord, the tranſverſe diſtance of half the arc, viz 35, muſt be taken, as before; which diſtance taken twice gives the chord of 70 degrees. To find the tangent of 70 degrees, to the ſame radius, the ſcale of upper tangents muſt be uſed, the under one only reaching to 45: making therefore 3 inches the tranſverſe diſtance to 45 and 45 at the beginning of that ſcale, the extent between 70 and 70 degrees on the ſame, will be the tangent of 70 degrees to 3 inches radius.—3. To find the ſecant of an arc; make the given radius the tranſverſe diſtance between 0 and 0 on the ſecants; then will the tranſverſe diſtance of 20 and 20, or 70 and 70, give the ſecant of 20 or 70 degrees.—4. If the radius, and any line repreſenting a ſine, tangent, or ſecant, be given, the degrees correſponding to that line may be found by ſetting the Sector to the given radius, according as a ſine, tangent, or ſecant is concerned; then taking the given line between the compaſſes, and applying the two feet tranſverſely to the proper ſcale, and ſliding the feet along till they both reſt on like diviſions on both legs; then the diviſions will ſhew the degrees and parts correſponding to the given line.

Uſe of the Sector in Trigonometry, or in working any other proportions.

By means of the double ſcales, which are the parts more peculiar to the Sector, all proportions are worked by the property of ſimilar triangles, making the ſides proportional to the baſes, that is, on the Sector, the lateral diſtances proportional to the tranſverſe ones; thus, taking the diſtance of the firſt term, and applying it to the 2d, then the diſtance of the 3d term, properly applied, will give the 4th term: obſerving that the ſides of triangles are taken off the line of numbers laterally, and the angles are taken tranſverſely, off the ſines or tangents or ſecants, according to the nature of the proportion. For example, in a plane triangle ABC, given two ſides and an angle oppoſite to one of them, to find the reſt; viz, given AB = 56, AC = 64, and ∠B = 46° 30′, to find BC and the angles A and C. In this caſe, the ſides are proportional to the ſines of their oppoſite angles; hence theſe proportions,



as AC (64) : ſin. ∠B (46° 30′) : : AB (56) : ſin. ∠C, and as ſin. B : AC : : ſin. A : BC.

Therefore, to work theſe proportions by the Sector, take the lateral diſtance of 64 = AC from the lines, and open the Sector to make this a tranſverſe diſtance of 46° 30′ = ∠B, on the ſines; then take the lateral diſtance of 56 = AB on the lines, and apply it tranſverſely on the ſines, which will give 39° 24′ = ∠C. Hence, the ſum of the angles B and C, which is 85° 54′, taken from 180°, leaves 94° 6′ = ∠A. Then, to work the 2d proportion, the Sector being ſet at the ſame opening as before, take the tranſverſe diſtance of 94° 6′ = ∠A, on the ſines, or, which is the ſame thing, the tranſverſe diſtance of its ſupplement 85° 54′; then this applied laterally to the lines, gives 88 = the ſide BC ſought.

For the complete hiſtory of the Sector, with its more ample and particular conſtruction and uſes, ſee Robertſon's *Treatiſe of ſuch Mathematical Inſtruments, as are uſually put into a Portable Caſe*, the Introduction.

Sector *of a Sphere*, is the ſolid generated by the revolution of the Sector of a circle about one of its radii; the other radius deſcribing the ſurface of a cone, and the circular arc a circular portion of the ſurface of the ſphere of the ſame radius. So that the ſpherical Sector conſiſts of a right cone, and of a ſegment of the ſphere having the ſame common baſe with the cone. And hence the ſolid content of it will be found by multiplying the baſe of ſpherical ſurface by the radius of the ſphere, and taking a 3d part of the product.

Sector *of an ellipſe*, or *of an hyperbola*, &c, is a part reſembling the circular Sector, being contained by three lines, two of which are radii, or lines drawn from the centre of the figure to the curve, and the intercepted arc or part of that curve.

Aſtronomical Sector, an inſtrument invented by Mr. George Graham, for finding the difference in right aſcenſion and declination between two objects, whoſe diſtance is too great to be obſerved through a fixed teleſcope, by means of a micrometer. This inſtrument (fig. 1, pl. 26,) conſiſts of a braſs plate, called the Sector, formed like a T, having the ſhank CD, as a radius, about 2½ feet long, and 2 inches broad at the end D, and an inch and a half at C; and the croſs-piece AB, as an arch, about 6 inches long, and one and a half broad; upon which, with a radius of 30 inches, is deſcribed an arch of 10 degrees, each degree being divided in as many parts as are convenient. Round a ſmall cylinder C, containing the centre of this arch, and fixed in the ſhank, moves a plate of braſs, to which is fixed a teleſcope CE, having its line of collimation parallel to the plane of the Sector, and paſſing over the centre C of the arch AB, and the index of a Vernier's dividing plate, whoſe length, being equal to 16 quarters of a degree, is divided into 15 equal parts, fixed to the eye end of the teleſcope, and made to ſlide along the arch; which motion is performed by a long ſcrew, G, at the back of the arch, communicating with the Vernier through a ſlit cut in the braſs, parallel to the divided arch. Round the centre F of a circular braſs plate *abc*, of 5 inches diameter, moves a braſs croſs KLMN, having the oppoſite ends O and P of one bar turned up perpendicularly about 3 inches, to ſerve as ſupporters to the Sector, and ſcrewed to the back of its radius; ſo that the plane of the Sector is parallel to the plane of the circular plate, and can revolve round the centre of that plate in this parallel poſition. A ſquare iron axis HIF, 18 inches long, is ſcrewed flat to the back of the circular plate along one of its diameters, ſo that the axis is parallel to the plane of the Sector. The whole inſtrument is ſupported on a proper pedeſtal, ſo that the ſaid axis ſhall be parallel to the earth's axis, and proper contrivances are annexed to fix it in any poſition. The inſtrument, thus ſupported, can revolve round its axis HI, parallel to the earth's axis, with a motion like that of the ſtars, the plane of the Sector being always parallel to the plane of ſome hour circle, and conſequently every point of the teleſcope deſcribing a parallel of declination; and if the Sector be turned round the joint F of the circular plate, its graduated arch may be brought parallel to an hour-circle; and conſequently any two ſtars, whoſe difference of declination does not exceed the degrees in that arch, will paſs over it.

To obſerve their paſſage, direct the teleſcope to the preceding ſtar, and fix the plane of the Sector a little to the weſtward of it; move the teleſcope by the ſcrew G, and obſerve at the tranſit of each over the croſs wires the time ſhewn by the clock, and alſo the diviſion upon the arch AB, ſhewn by the index; then is the difference of the arches the difference of the declination; and that of the times ſhews the difference of the right aſcenſion of thoſe ſtars. For a more particular deſcription of this inſtrument, ſee Smith's Optics, book iii, chap. 9.

SECULAR *Year*, the ſame with Jubilee.

SECUNDANS, an infinite ſeries of numbers, beginning from nothing, and proceeding according to the ſquares of numbers in arithmetical progreſſion, as 0, 1, 4, 9, 16, 25, 36, 49, 64, &c.

SEEING, the act of perceiving objects by the organ of ſight; or the ſenſe we have of external objects by means of the eye.

For the apparatus, or diſpoſition of the parts neceſſary to Seeing, ſee EYE. And for the manner in which Seeing is performed, and the laws of it, ſee VISION.

Our beſt anatomiſts differ greatly as to the cauſe why we do not ſee double with the two eyes? Galen, and others after him, aſcribe it to a coalition, or decuſſation, of the optic nerve, behind the os ſphenoides. But whether they decuſſate or coaleſce, or only barely touch one another, is not well agreed upon.

The Bartholines and Veſalius ſay expreſsly, they are united by a perfect confuſion of their ſubſtance; Dr. Gibſon allows them to be united by the cloſeſt conjunction, but not by a confuſion of their fibres.

Alhazen, an Arabian philoſopher of the 12th century, accounts for ſingle viſion by two eyes, by ſuppoſing that when two correſponding parts of the retina are affected, the mind perceives but one image.

Des Cartes and others account for the effect another way; viz, by ſuppoſing that the fibrillæ conſtituting the medullary part of thoſe nerves, being ſpread in the retina of each eye, have each of them correſponding parts in the brain, ſo that when any of thoſe fibrillæ are ſtruck by any part of an image, the correſponding parts of the brain are affected by it. Somewhat like which is the opinion of Dr. Briggs, who takes the optic nerves of each eye to conſiſt of homologous fibres, having their riſe in the thalamus nervorum opticorum, and being thence continued to both the retinæ, which are compoſed of them; and farther, that thoſe fibrillæ have the ſame paralleliſm, tenſion, &c, in both eyes; conſequently when an image is painted on the ſame correſponding ſympathizing parts of each retina, the ſame effects are produced, the ſame notice carried to the thalamus, and ſo imparted to the ſoul. Hence it is, that double viſion enſues upon an interruption of the paralleliſm of the eyes; as when one eye is depreſſed by the finger, or their ſymphony is interrupted by diſeaſe: but Dr. Briggs maintains, that it is but in few ſubjects there is any decuſſation; and in none any conjunction more than mere contact; though his notion is by no means conſonant to facts, and it is attended with many improbable circumſtances.

It was the opinion of Sir Iſaac Newton, and of many others, that objects appear ſingle, becauſe the two optic nerves unite before they reach the brain. But Dr. Porterfield ſhews, from the obſervation of ſeveral anatomiſts, that the optic nerves do not mix or confound their ſubſtance, being only united by a cloſe coheſion; and objects have appeared ſingle, where the optic nerves were found to be disjoined. To account for this phenomenon, this ingenious writer ſuppoſes, that, by an original law in our natures, we imagine an object to be ſituated ſomewhere in a right line drawn from the picture of it upon the retina, through the centre of the pupil; conſequently the ſame object appearing to both eyes to be in the ſame place, we cannot diſtinguiſh it into two. In anſwer to an objection to this hypotheſis, from objects appearing double when one eye is diſtorted, he ſays, the mind miſtakes the poſition of the eye, imagining, that it had moved in a manner correſponding to the other, in which caſe the concluſion would have been juſt: in this he ſeems to have recourſe to the power of habit, though he diſclaims that hypotheſis. This principle however has been thought ſufficient to account for this appearance.

Originally, every object making two pictures, one in each eye, is imagined to be double; but, by degrees, we find that when two correſponding parts of the retina are impreſſed, the object is but one; but if thoſe correſponding parts be changed by the diſtortion of one of the eyes, the object muſt again appear double as at the firſt. This ſeems to be verified by Mr. Cheſelden, who informs us, that a gentleman, who, from a blow on his head, had one eye diſtorted, found every object to appear double, but by degrees the moſt familiar ones came to appear ſingle again, and in time all objects did ſo without amendment of the diſtortion. A ſimilar caſe is mentioned by Dr. Smith.

On the other hand, Dr Reid is of opinion, that the correſpondence of the centres of two eyes, on which ſingle viſion depends, does not ariſe from cuſtom, but from ſome natural conſtitution of the eye, and of the mind.

M. du Tour adopts an opinion, long before ſuggeſted by Gaſſendi, that the mind attends to no more than the image made in one eye at a time; in ſupport of which, he produces ſeveral curious experiments; but as M. Buffon obſerves, it is a ſufficient anſwer to this hypotheſis, that we ſee more diſtinctly with two eyes than with one; and that when a round object is near us, we plainly ſee more of the ſurface in one caſe than in the other.

With reſpect to ſingle viſion with two eyes, Dr. Hartley obſerves, that it deſerves particular attention, that the optic nerves of man, and ſuch other animals as look the ſame way with both eyes, unite in the ſella turcica in a ganglion, or little brain, as it may be called, peculiar to themſelves, and that the aſſociations between ſynchronous impreſſions on the two retinas, muſt be made ſooner and cemented ſtronger on this account; alſo that they ought to have a much greater power over one another's image, than in any other part of the body. And thus an impreſſion made on the right eye alone by a ſingle object, propagates itſelf into the left, and there raiſes up an image almoſt equal in vividneſs to itſelf; and, conſequently, when we ſee with one eye only, we may however have pictures in both eyes.

It is a common obſervation, ſays Dr. Smith, that objects ſeen with both eyes appear more vivid and ſtronger than they do to a ſingle eye, eſpecially when both of them are equally good. Porterfield on the Eye, vol. ii, pa. 285, 315. Smith's Optics, Remarks pa. 31. Reid's Inquiry, pa. 267. Mem. Préſentes, pa. 514. Acad. Par. 1747. Mem. Pr. 334. Hartley on Man, vol. i, pa. 207. Prieſtley's Hiſt. of Light and Colours, pa. 663, &c.

Whence it is that we ſee objects erect, when it is certain, that the images thereof are painted invertedly on the retina, is another difficulty in the theory of Seeing. Des Cartes accounts for it hence, that the notice which the ſoul takes of the object, does not depend on any image, nor any action coming from the object, but merely on the ſituation of the minute parts of the brain, whence the nerves ariſe. Ex. gr. the ſituation of a capillament brain, which occaſions the

ſoul

soul to see all those places lying in a right line with it.

But Mr. Molyneux gives another account of this matter. The eye, he observes, is only the organ, or instrument; it is the soul that sees. To enquire then, how the soul perceives the object erect by an inverted image, is to enquire into the soul's faculties. Again, imagine that the eye receives an impulse on its lower part, by a ray from the upper part of an object; must not the visive faculty be hereby directed to consider this stroke as coming from the top, rather than the bottom of the object, and consequently be determined to conclude it the representation of the top?

Upon these principles, we are to consider, that inverted is only a relative term, and that there is a very great difference between the real object, and the means or image by which we perceive it. When all the parts of a distant prospect are painted upon the retina (supposing that to be the seat of vision), they are all right with respect to one another, as well as the parts of the prospect itself; and we can only judge of an object being inverted, when it is turned reverse to its natural position with respect to other objects which we see and compare it with.

The eye or visive faculty (says Molyneux) takes no notice of the internal surface of its own parts, but uses them as an instrument only, contrived by nature for the exercise of such a faculty. If we lay hold of an upright stick in the dark, we can tell which is the upper or lower part of it, by moving our hand upward or downward; and very well know that we cannot feel the upper end by moving our hand downward. Just so, we find by experience and habit, that by directing our eyes towards a tall object, we cannot see its top by turning our eyes downward, nor its foot by turning our eyes upward; but must trace the object the same way by the eye to see it from head to foot, as we do by the hand to feel it; and as the judgement is informed by the motion of the hand in one case, so it is also by the motion of the eye in the other.

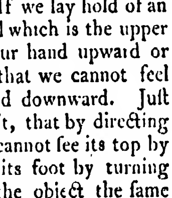
SEGMENT, in Geometry, is a part cut off the top of a figure by a line or plane; and the part remaining at the bottom, after the Segment is cut off, is called a *frustum*, or a *zone*. So, a

SEGMENT *of a Circle*, is a part of the circle cut off by a chord, or a portion comprehended by an arch and its chord; and may be either greater or less than a semicircle. Thus, the portion ABCA is a Segment less than a semicircle; and ADCA a Segment greater.



The angle formed by lines drawn from the extremities of a chord to meet in any point of the arc, is called an angle *in* the Segment. So the angle ABC is an angle *in* the Segment ABCA; and the angle ADC, an angle *in* the Segment ADCA.

Also the angle B is said to be the angle *upon* the Segment ADC, and D the angle *on* the Segment ABC.

The angle which the chord AC makes with a tangent EF, is called the angle *of* a Segment; and it is equal to the angle in the alternate or supplemental Segment, or equal to the supplement of the angle in the same Segment. So the angle ACE is the angle *of* the Segment ABC, and is equal to the angle ADC, or to the supplement of the angle B; also the angle ACF is the angle *of* the Segment ADC, and is equal to the angle B, or to the supplement of the angle D.

The area of a Segment ABC, is evidently equal to the difference between the sector OABC of the same arc, and the triangle OAC on the same chord; the triangle being subtracted from the sector, to give the Segment, when less than a semicircle; but to be added when greater. See more rules for the Segment in my Mensuration, pa. 132 &c, 2d edition.

Similar SEGMENTS, are those that have their chords directly proportional to their radii or diameters, or that have similar arcs, or such as contain the same number of degrees.

SEGMENT *of a Sphere*, is a part cut off by a plane.

The base of a Segment is always a circle. And the convex surfaces of different Segments, are to each other as their altitudes, or versed sines. And as the whole convex surface of the sphere is equal to 4 of its great circles, or 4 circles of the same diameter; so the surface of any Segment, is equal to 4 circles on a diameter equal to the chord of half the arc of the Segment. So that if d denote the diameter of the sphere, or the chord of half the circumference, and c the chord of half the arc of any other Segment, also a the altitude or versed sine of the same; then,

$3{\cdot}1416d^2$ is the surface of the whole sphere, and
$3{\cdot}1416c^2$, or $3{\cdot}1416ad$, the surface of the Segment.

For the solid content of a Segment, there are two rules usually given; viz, 1. To 3 times the square of the radius of its base, add the square of its height; multiply the sum by the height, and the product by ·5236. Or, 2dly, From 3 times the diameter of the sphere, subtract twice the height of the frustum; multiply the remainder by the square of the height, and the product by ·5236. That is, in symbols, the solid content is either

$$= {\cdot}5236a \times \overline{3r^2 + a^2}, \text{ or } = {\cdot}5236a^2 \times \overline{3d - 2a};$$

where a is the altitude of the Segment, r the radius of its base, and d the diameter of the whole sphere.

Line of SEGMENTS, are two particular lines, so called, on Gunter's sector. They lie between the lines of sines and superficies, and are numbered with 5, 6, 7, 8, 9, 10. They represent the diameter of a circle, so divided into 100 parts, as that a right line drawn through those parts, and perpendicular to the diameter, shall cut the circle into two Segments, the greater of which shall have the same proportion to the whole circle, as the parts cut off have to 100.

SELENOGRAPHY, the description and representation of the moon, with all the parts and appearances of her disc or face; like as geography does those of the earth.

Since the invention of the telescope, Selenography is very much improved. We have now distinct names for most of the regions, seas, lakes, mountains, &c, visible in the moon's body. Hevelius, a celebrated astronomer of Dantzic, and who published the first Selenography, named the several places of the moon from those of the earth. But Riccioli afterwards called them after the names of the most celebrated astronomers and philosophers. Thus, what the one calls *mons Porphyrites*, the other calls *Aristarchus*; what the one calls *Ætna*, *Sinai*, *Athos*, *Apenninus*, &c, the other calls, *Copernicus*, *Posidonius*, *Tycho*, *Gassendus*, &c.

M. Cassini has published a work called *Instructions Seleniques*, and has published the best map of the moon.

SELEUCIDÆ, in Chronology, the era of the Seleucidæ, or the Syro-Macedonian era, which is a computation of time, commencing from the establishment of the Seleucidæ, a race of Greek kings, who reigned as successors of Alexander the Great, in Syria, as the Ptolomies did in Egypt. According to the best accounts, the first year of this era falls in the year 311 before Christ, which was 12 years after the death of Alexander.

SELL, in Building, is of two kinds, viz, *Ground-Sill*, which denotes the lowest piece of timber in a wooden building, and that upon which the whole superstructure is raised. And Sell of a window, or of a door, which is the bottom piece in the frame of them, upon which they rest.

SEMICIRCLE, in Geometry, is half a circle, or a figure comprehended between the diameter of a circle, and half the circumference.

Semicircle is also an instrument in Surveying, sometimes called the *graphometer*.

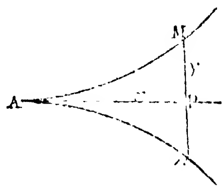
It consists of a semicircular limb or arch, as FIG (fig. 3, pl. 26) divided into 180 degrees, and sometimes subdivided diagonally or otherwise into minutes. This limb is subtended by a diameter FG, having two sights erected at its extremities. In the centre of the Semicircle, or the middle of the diameter, is fixed a box and needle; and on the same centre is fitted an alidade, or moveable index, carrying two other sights, as H, I: the whole being mounted on a staff, with a ball and socket &c.

Hence it appears, that the Semicircle is nothing but half a theodolite; with this only difference, that whereas the limb of the theodolite, being an entire circle, takes in all the 360° successively; while in the Semicircle the degrees only going from 1 to 180, it is usual to have the remaining 180°, or those from 180° to 360°, graduated in another line on the limb within the former.

To take an Angle with a Semicircle.—Place the instrument in such manner, as that the radius CG may hang over one leg of the angle to be measured, with the centre C over the vertex of the same. The first is done by looking through the sights F and G, at the extremities of the diameter, to a mark fixed up in one extremity of the leg; and the latter is had by letting fall a plummet from the centre of the instrument. This done, turn the moveable index HI on its centre towards the other leg of the angle, till through the sights fixed in it, you see a mark in the extremity of the leg. Then the degree which the index cuts on the limb, is the quantity or measure of the angle.

Other uses are the same as in the theodolite.

SEMICUBICAL PARABOLA, a curve of the 2d order, of such a nature that the cubes of the ordinates are proportional to the squares of the abscisses. Its equation is $ay^2 = x^3$. This curve, AMm, is one of



Newton's five diverging parabolas, being his 70th species; having a cusp at its vertex at A. It is otherwise named the Neilian parabola, from the name of the author who first treated of it.

The area of the space APM, is $= \frac{4}{5}xy = \frac{4}{5}$AP × PM, or $\frac{4}{5}$ of the circumscribing rectangle.

The content of the solid generated by the revolution of the space APM about the axis AP, is $\frac{1}{4}pxy^2 = \cdot 7854$AP × PM², or $\frac{1}{4}$ of the circumscribing cylinder. And a circle equal to the surface of that solid may be found from the quadrature of an hyperbolic space.

Also the length of any arc AM of the curve may be easily obtained from the quadrature of a space contained under part of the curve of the common parabola, two semiordinates to the axis, and the part of the axis contained between them.

This curve may be described by a continued motion, viz, by fastening the angle of a square in the vertex of a common parabola; and then carrying the intersection of one side of this square and a long ruler (which ruler always moves perpendicularly to the axis of the parabola) along the curve of that parabola. For the intersection of the ruler, and the other side of the square will describe a Semicubical parabola. Maclaurin performs this without a common parabola, in his Geometria Organica.

SEMIDIAMETER, or *Radius*, of a circle or sphere, is a line drawn from the centre to the circumference. And in any curve that has diameters and a centre, it is the radius, or half diameter, or a line drawn from the centre to some point in the curve.

The distances, diameters, &c, of the heavenly bodies, are usually estimated by astronomers in Semidiameters of the earth; the number of which terrestrial Semidiameters, contained in that of each of those planets, is as below.

The Earth - -	1 Semidiam.
The Sun - -	111¼
The Moon - -	0·27
Mercury - -	0·38
Venus - -	1·15
Mars - -	0·65
Jupiter - -	11·81
Saturn - -	9·77
Herschel - -	4·32

SEMIDIAPENTE, in Music, a defective or imperfect fifth, called usually by the Italians, *falsa quinta*, and by us a false fifth.

SEMIDIAPASON, in Mufic, a defective or imperfect octave; or an octave diminifhed by a leffer femitone, or 4 commas.

SEMIDIATESSARON, in Mufic, a defective fourth, called alfo a falfe fourth.

SEMIDITONE, in Mufic, is the leffer third, having its terms as 6 to 5.

SEMIORDINATES, in Geometry, the halves of the ordinates or applicates, being the lines applied between the abfcifs and the curve.

SEMIPARABOLA, &c, in Geometry, the half of the whole parabola, &c.

SEMIQUADRATE, or SEMIQUARTILE, is an afpect of the planets, when diftant from each other one fign and a half, or 45 degrees.

SEMIQUAVER, in Mufic, the half of a quaver.

SEMIQUINTILE, is an afpect of the planets when diftant from each other the half of a 5th of the circle, or by 36 degrees.

SEMISEXTILE, an afpect of two planets, when they are diftant from each other 30 degrees, or the half of a fextile, which is 2 figns or 60°. The Semifextile is marked *s. s.*

SEMITONE, in Mufic, a half tone or half note, one of the degrees or intervals of concords.

There are three degrees, or lefs intervals, by which a found can move upwards and downwards, fucceffively from one extreme of any concord to the other, and yet produce true melody. Thefe degrees are the greater tone, the lefs tone, and the femitone. The ratios defining thefe intervals are thefe, viz, the greater tone 8 to 9, the lefs tone 9 to 10, and the Semitone 15 to 16. Its compafs is 5 commas, and it has its name from being nearly half a whole, though it is really fomewhat more.

There are feveral fpecies of Semitones; but thofe that ufually occur in practice are of two kinds, diftinguifhed by the addition of greater and lefs. The firft is expreffed by the ratio of 16 to 15, or $\frac{16}{15}$; and the fecond by 25 to 24, or $\frac{25}{24}$. The octave contains 10 Semitones major, and 2 diefes, nearly, or 17 Semitones minor, nearly; for the meafure of the octave being expreffed by the logarithm - 1,00000, the Semitone major will be meafured by 0,09311, and the Semitone minor by - - 0,05889. Thefe two differ by a whole enharmonic diefis; which is an interval practicable by the voice. It was much in ufe among the Ancients, and is not unknown among modern practitioners. Euler Tent. Nov. Theor. Muf. pa. 107. See INTERVAL.

Thefe Semitones are called *fictitious notes*; and, with refpect to the natural ones, they are expreffed by characters called *flats* and *fharps*. The ufe of them is to remedy the defects of inftruments, which, having their founds fixed, cannot always be made to anfwer to the diatonic fcale. By means of thefe, we have a new kind of fcale, called the

SEMITONIC *Scale*, or the *Scale of Semitones*, which is a fcale or fyftem of mufic, confifting of 12 degrees, or 13 notes, in the octave, being an improvement on the natural or diatonic fcale, by inferting between each two notes of it, another note, which divides the interval or tone into two unequal parts, called Semitones.

The ufe of this fcale is for inftruments that have fixed founds, as the organ, harpfichord, &c, which are exceedingly defective on the foot of the natural or diatonic fcale. For the degrees of the fcale being unequal, from every note to its octave there is a different order of degrees; fo that from any note we cannot find every interval in a feries of fixed founds; which yet is neceffary, that all the notes of a piece of mufic, carried through feveral keys, may be found in their juft tune, or that the fame fong may be begun indifferently at any note, as may be neceffary for accommodating fome inftrument to others, or to the voice, when they are to accompany each other in unifon.

The diatonic fcale, beginning at the loweft note, being firft fettled on an inftrument, and the notes of it diftinguifhed by their names *a, b, c, d, e, f, g*; the inferted notes, or Semitones, are called fictitious notes, and take the name or letter below with a ✻, as *c* ✻ called *c* fharp; fignifying that it is a femitone higher than the found of *c* in the natural feries; or this mark ♭, called a flat, with the name of the note above fignifying it to be a Semitone lower.

Now $\frac{15}{16}$ and $\frac{128}{135}$ being the two Semitones the greater tone is divided into, and $\frac{15}{16}$ and $\frac{24}{25}$, the Semitones the lefs tone is divided into, the whole octave will ftand as in the following fcheme, where the ratios of each term to the next are written fraction-wife between them below.

Scale of Semitones.

c. *c*✻. *d.* *d*✻. *e.* *f.* *f*✻. *g.* *g*✻. *a*♭. *b.* *cc.*

$\frac{15}{16}$ $\frac{128}{135}$ $\frac{15}{16}$ $\frac{24}{25}$ $\frac{15}{16}$ $\frac{128}{135}$ $\frac{15}{16}$ $\frac{15}{16}$ $\frac{24}{25}$ $\frac{15}{16}$ $\frac{128}{135}$ $\frac{15}{16}$

for the names of the intervals in this fcale, it may be confidered, that as the notes added to the natural fcale are not defigned to alter the fpecies of melody, but leave it ftill diatonic, and only correct certain defects arifing from fomething foreign to the office of the fcale of mufic, viz, the fixing and limiting the founds; we fee the reafon why the names of the natural fcale are continued, only making a diftinction of each into a greater and lefs. Thus an interval of one Semitone, is called a lefs fecond; of two Semitones, a greater fecond; of three Semitones, a lefs third; of four, a greater third, &c.

A fecond kind of Semitonic fcale we have from another divifion of the octave into Semitones, which is performed by taking an harmonical mean between the extremes of the greater and lefs tone of the natural fcale, which divides it into two Semitones nearly equal. Thus, the greater tone 8 to 9 is divided into two Semitones, which are 16 to 17, and 17 to 18; where 16, 17, 18, is an arithmetical divifion, the numbers reprefenting the lengths of the chords; but if they reprefent the vibration, the lengths of the chords are reciprocal; viz as 1, $\frac{16}{17}$, $\frac{8}{9}$; which puts the greater Semitone

mitone $\frac{16}{17}$ next the lower part of the tone, and the leſſer $\frac{17}{18}$ next the upper, which is the property of the harmonical diviſion. And after the ſame manner the leſs tone 9 to 10 is divided into two Semitones, 18 to 19, and 19 to 20; and the whole octave ſtands thus:

c.	c*.	d.	d*.	e.	f.	f*.	g.	g*.	a.	♭.	b.	c.
$\frac{16}{17}$	$\frac{17}{18}$	$\frac{18}{19}$	$\frac{19}{20}$	$\frac{15}{16}$	$\frac{16}{17}$	$\frac{17}{18}$	$\frac{18}{19}$	$\frac{19}{20}$	$\frac{16}{17}$	$\frac{17}{18}$	$\frac{15}{16}$.	

This ſcale, Mr. Salmon tells us, in the Philoſophical Tranſactions, he made an experiment of before the Royal Society, on chords, exactly in theſe proportions, which yielded a perfect concert with other inſtruments, touched by the beſt hands. Mr. Malcolm adds, that, having calculated the ratios of them, for his own ſatiſfaction, he found more of them falſe than in the preceding ſcale, but then their errors were conſiderably leſs, which made amends. Malcolm's Muſic, chap. 10. § 2.

SENSIBLE *Horizon*, or *Point*, or *Quality*, &c. See the ſubſtantives.

SEPTUAGESIMA, in the Calendar, is the 9th Sunday before Eaſter, ſo called, as ſome have ſuppoſed, becauſe it is near 70 days, though in reality it is only 63 days, before it.

SERIES, in Algebra, denotes a rank or progreſſion of quantities or terms, which uſually proceed according to ſome certain law.

As the Series $1 + \frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \frac{1}{16}$ &c,

or the Series, $1 + \frac{1}{2} + \frac{1}{3} + \frac{1}{4} + \frac{1}{5}$ &c.

where the former is a geometrical Series, proceeding by the conſtant diviſion by 2, or the denominators multiplied by 2; and the latter is an harmonical Series, being the reciprocals of the arithmetical Series 1, 2, 3, 4, &c, or the denominators being continually increaſed by 1.

The doctrine and uſe of Series, one of the greateſt improvements of the preſent age, we owe to Nicholas Mercator; though it ſeems he took the firſt hint of it from Dr. Wallis's Arithmetic of Infinites; but the genius of Newton firſt gave it a body and a form.

It is chiefly uſeful in the quadrature of curves; where, as we often meet with quantities which cannot be expreſſed by any preciſe definite numbers, ſuch as is the ratio of the diameter of a circle to the circumference, we are glad to expreſs them by a Series, which, infinitely continued, is the value of the quantity ſought, and which is called an Infinite Series.

The Nature, Origin, &c, of SERIES.

Infinite Series commonly ariſe, either from a continued diviſion, as was practiſed by Mercator, or the extraction of roots, as firſt performed by Newton, who alſo explained other general ways for the expanding of quantities into infinite Series, as by the binomial theorem. Thus, to divide 1 by 3, or to expand the fraction $\frac{1}{3}$ into an infinite Series; by diviſion in decimals in the ordinary way, the ſeries is 0·3333 &c, or $\frac{3}{10} + \frac{3}{100} + \frac{3}{1000} + \frac{3}{10000}$ &c, where the law of continuation is manifeſt. Or, if the ſame fraction $\frac{1}{3}$ be ſet in this form $\frac{1}{2+1}$, and diviſion be performed in the algebraic manner, the quotient will be

$$\frac{1}{3} = \frac{1}{2+1} = \frac{1}{2} - \frac{1}{4} + \frac{1}{8} - \frac{1}{16} + \frac{1}{32} \text{ \&c.}$$

Or, if it be expreſſed in this form $\frac{1}{3} = \frac{1}{4-1}$, by a like diviſion there will ariſe the Series,

$$\frac{1}{3} = \frac{1}{4} + \frac{1}{16} + \frac{1}{64} \text{ \&c} = \frac{1}{4} + \frac{1}{4^2} + \frac{1}{4^3} \text{ \&c.}$$

And, thus, by dividing 1 by $5-2$, or $6-3$, or $7-4$, &c, the Series anſwering to the fraction $\frac{1}{3}$, may be found in an endleſs variety of infinite Series; and the finite quantity $\frac{1}{3}$ is called the value or radix of the Series, or alſo its ſum, being the number or ſum to which the Series would amount, or the limit to which it would tend or approximate, by ſumming up its terms, or by collecting them together one after another.

In like manner, by dividing 1 by the algebraic ſum $a + c$, or by $a - c$, the quotient will be in theſe two caſes, as below, viz,

$$\frac{1}{a+c} = \frac{1}{a} - \frac{c}{a^2} + \frac{c^2}{a^3} - \frac{c^3}{a^4} \text{ \&c,}$$

$$\frac{1}{a-c} = \frac{1}{a} + \frac{c}{a^2} + \frac{c^2}{a^3} + \frac{c^3}{a^4} \text{ \&c.}$$

where the terms of each Series are the ſame, and they differ only in this, that the ſigns are alternately poſitive and negative in the former, but all poſitive in the latter.

And hence, by expounding a and c by any numbers whatever, we obtain an endleſs variety of infinite Series, whoſe ſums or values are known. So, by taking a or c equal to 1 or 2 or 3 or 4, &c, we obtain theſe Series, and their values;

$$\frac{1}{1+1} = \frac{1}{2} = 1 - 1 + 1 - 1 + 1 - 1 \text{ \&c,}$$

$$\frac{1}{3-1} = \frac{1}{2} = \frac{1}{3} + \frac{1}{3^2} + \frac{1}{3^3} + \frac{1}{3^4} \text{ \&c,}$$

$$\frac{1}{2+1} = \frac{1}{3} = \frac{1}{2} - \frac{1}{2^2} + \frac{1}{2^3} - \frac{1}{2^4} \text{ \&c,}$$

$$\frac{1}{1+2} = \frac{1}{3} = 1 - 2 + 2^2 - 2^3 \text{ \&c,}$$

$$\frac{1}{3+1} = \frac{1}{4} = \frac{1}{3} - \frac{1}{3^2} + \frac{1}{3^3} - \frac{1}{3^4} \text{ \&c.}$$

And hence it appears, that the ſame quantity or radix may be expreſſed by a great variety of infinite Series, or that many different Series may have the ſame radix or ſum.

Another way in which an infinite Series ariſes, is by the extraction of roots. Thus, by extracting the ſquare root of the number 3 in the common way, we obtain its value in a ſeries as follows, viz, $\sqrt{3} = 1{\cdot}73205 \text{ \&c} = 1 + \frac{7}{10} + \frac{3}{100} + \frac{2}{1000} + \frac{5}{100000}$ &c;

in which way of reſolution the law of the progreſſion of

of the Series is not visible, as it is when found by division. And the square root of the algebraic quantity $a^2 + c^2$ gives

$$\sqrt{a^2 + c^2} = a + \frac{c^2}{2a} - \frac{c^4}{8a^3} + \frac{c^6}{16a^5} \text{ \&c.}$$

And a 3d way is by Newton's binomial theorem, which is a universal method, that serves for all sorts of quantities, whether fractional or radical ones: and by this means the same root of the last given quantity becomes $\sqrt{a^2 + c^2} =$

$$= a + \frac{c^2}{2a} - \frac{1.c^4}{2.4a^3} + \frac{1.3c^6}{2.4.6a^5} + \frac{1.3.5c^8}{2.4.6.8a^7} \text{ \&c.}$$

where the law of continuation is visible.

See Extraction *of Roots*, and Binomial *Theorem*.

From the specimens above given, it appears that the signs of the terms may be either all plus, or alternately plus and minus. Though they may be varied in many other ways. It also appears that the terms may be either continually smaller and smaller, or larger and larger, or else all equal. In the first case therefore the Series is said to be a *decreasing* one, in the 2d case an *increasing* one, and in the 3d case an *equal* one. Also the first Series is called a *converging* one, because that by collecting its terms successively, taking in always one term more, the successive sums approximate or converge to the value or sum of the whole infinite Series. So, in the Series

$$\frac{1}{3-1} = \frac{1}{2} = \frac{1}{3} + \frac{1}{9} + \frac{1}{27} + \frac{1}{81}, \text{ \&c,}$$

the first term $\frac{1}{3}$ is too little, or below $\frac{1}{2}$ which is the value or sum of the whole infinite Series proposed; the sum of the first two terms $\frac{1}{3} + \frac{1}{9}$ is $\frac{4}{9} = {}^{\cdot}4444$ &c, is also too little, but nearer to $\frac{1}{2}$ or $\cdot 5$ than the former; and the sum of three terms $\frac{1}{3} + \frac{1}{9} + \frac{1}{27}$ is $\frac{13}{27} =$ $\cdot 481481$ &c, is nearer than the last, but still too little; and the sum of four terms

$$\frac{1}{3} + \frac{1}{9} + \frac{1}{27} + \frac{1}{81}, \text{ is } \frac{40}{81} = {}^{\cdot}493827 \text{ \&c.}$$

which is again nearer than the former, but still too little; which is always the case when the terms are all positive. But when the converging Series has its terms alternately positive and negative, then the successive sums are alternately too great and too little, though still approaching nearer and nearer to the final sum or value. Thus in the Series

$$\frac{1}{3+1} = \frac{1}{4} = 0{\cdot}25 = \frac{1}{3} - \frac{1}{9} + \frac{1}{27} - \frac{1}{81} \text{ \&c,}$$

the 1st term $\frac{1}{3} = {}^{\cdot}333$ &c, is too great,

two terms $\frac{1}{3} - \frac{1}{9} = {}^{\cdot}222$ &c, are too little,

three terms $\frac{1}{3} - \frac{1}{9} + \frac{1}{27} = {}^{\cdot}259259$ &c, are too great,

four terms $\frac{1}{3} - \frac{1}{9} + \frac{1}{27} - \frac{1}{81} = {}^{\cdot}246913$ &c, are too great, and so on, alternately too great and too small, but every succeeding sum still nearer than the former, or converging.

In the second case, or when the terms grow larger and larger, the Series is called a *diverging* one, because that by collecting the terms continually, the successive sums diverge, or go always farther and farther from the true value or radix of the Series; being all too great when the terms are all positive, but alternately too great and too little when they are alternately positive and negative. Thus, in the Series

$$\frac{1}{1+2} = \frac{1}{3} = 1 - 2 + 4 - 8 \text{ \&c.}$$

the first term $+ 1$ is too great,
two terms $1 - 2 = - 1$ are too little,
three terms $1 - 2 + 4 = + 3$ are too great,
four terms $1 - 2 + 4 - 8 = - 5$ are too little.

and so on continually, after the 2d term, diverging more and more from the true value or radix $\frac{1}{3}$, but alternately too great and too little, or positive and negative. But the alternate sums would be always more and more too great if the terms were all positive, and always too little if negative.

But in the third case, or when the terms are all equal, the Series of equals, with alternate signs, is called a *neutral* one, because the successive sums, found by a continual collection of the terms, are always at the same distance from the true value or radix, but alternately positive and negative, or too great and too little. Thus, in the Series

$$\frac{1}{1+1} = \frac{1}{2} = 1 - 1 + 1 - 1 + 1 - 1 \text{ \&c,}$$

the first term 1 is too great,
two terms $1 - 1 = 0$ are too little,
three terms $1 - 1 + 1 = 1$ too great,
four terms $1 - 1 + 1 - 1 = 0$ too little,

and so on continually, the successive sums being alternately 1 and 0, which are equally different from the true value or radix $\frac{1}{2}$, the one as much above it, as the other below it.

A Series may be terminated and rendered finite, and accurately equal to the sum or value, by assuming the supplement, after any particular term, and combining it with the foregoing terms. So, in the Series $\frac{1}{2} - \frac{1}{4} + \frac{1}{8} - \frac{1}{16}$ &c, which is equal to $\frac{1}{3}$, and found by dividing 1 by $2 + 1$, after the first term, $\frac{1}{2}$, of the quotient, the remainder is $-\frac{1}{2}$, which divided by $2 + 1$, or 3, gives $-\frac{1}{6}$ for the supplement, which combined

combined with the first term $\frac{1}{2}$, gives $\frac{1}{2} - \frac{1}{6} = \frac{1}{3}$ the true sum of the Series. Again, after the first two terms $\frac{1}{2} - \frac{1}{4}$, the remainder is $+ \frac{1}{4}$, which divided by the same divisor 3, gives $\frac{1}{12}$ for the supplement, and this combined with those two terms $\frac{1}{2} - \frac{1}{4}$, makes $\frac{1}{2} - \frac{1}{4} + \frac{1}{12} = \frac{1}{4} + \frac{1}{2} = \frac{4}{12}$ or $\frac{1}{3}$ the same sum or value as before. And in general, by dividing 1 by $a + c$, there is obtained

$$\frac{1}{a+c} = \frac{1}{a} - \frac{c}{a^2} + \frac{c^2}{a^3} \cdots \pm \frac{c^n}{a^{n+1}} \mp \frac{c^{n+1}}{a^{n+1}(a+c)};$$

where, stopping the division at any term as $\frac{c^n}{a^{n+1}}$, the remainder after this term is $\frac{c^{n+1}}{a^{n+1}}$, which being divided by the same divisor $a + c$, gives $\frac{c^{n+1}}{a^{n+1}(a+c)}$ for the supplement as above.

The Law of Continuation.—A Series being proposed, one of the chief questions concerning it, is to find the law of its continuation. Indeed, no universal rule can be given for this; but it often happens that the terms of the Series, taken two and two, or three and three, or in greater numbers, have an obvious and simple relation, by which the Series may be determined and produced indefinitely. Thus, if 1 be divided by $1 - x$, the quotient will be a geometrical progression, viz, $1 + x + x^2 + x^3$ &c, where the succeeding terms are produced by the continual multiplication by x. In like manner, in other cases of division, other progressions are produced.

But in most cases the relation of the terms of a Series is not constant, as it is in those that arise by division. Yet their relation often varies according to a certain law, which is sometimes obvious on inspection, and sometimes it is found by dividing the successive terms one by another, &c. Thus, in the Series

$1 + \frac{2}{3}x + \frac{8}{15}x^2 + \frac{16}{35}x^3 + \frac{128}{315}x^4$ &c, by dividing the 2d term by the 1st, the 3d by the 2d, the 4th by the 3d, and so on, the quotients will be

$$\frac{2}{3}x,\ \frac{4}{5}x,\ \frac{6}{7}x,\ \frac{8}{9}x, \text{ \&c};$$

and therefore the terms may be continued indefinitely by the successive multiplication by these fractions. Also in the following Series

$1 + \frac{1}{6}x + \frac{3}{40}x^2 + \frac{5}{128}x^3 + \frac{35}{1152}x^4$ &c, by dividing the adjacent terms successively by each other, the Series of quotients is

$$\frac{1}{6}x,\ \frac{9}{20}x,\ \frac{25}{42}x,\ \frac{49}{72}x, \text{ \&c, or}$$

$$\frac{1 \cdot 1}{2 \cdot 3}x,\ \frac{3 \cdot 3}{4 \cdot 5}x,\ \frac{5 \cdot 5}{6 \cdot 7}x,\ \frac{7 \cdot 7}{8 \cdot 9}x, \text{ \&c};$$

and therefore the terms of the Series may be continued by the multiplication of these fractions.

Another method of expressing the law of a Series, is one that defines the Series itself, by its *general term*, shewing the relation of the terms generally by their distances from the beginning, or by differential equations. To do this, Mr. Stirling conceives the terms of the Series to be placed as so many ordinates on a right line given by position, taking unity as the common interval between these ordinates. The terms of the Series he denotes by the initial letters of the alphabet, A, B, C, D, &c; A being the first, B the 2d, C the 3d, &c: and he denotes any term in general by the letter T, and the rest following it in order by T', T'', T''', T'''', &c; also the distance of the term T from any given term, or from any given intermediate point between two terms, he denotes by the indeterminate quantity z: so that the distances of the terms T', T'', T''', &c, from the said term or point, will be $z + 1$, $z + 2$, $z + 3$, &c; because the increment of the abscis is the common interval of the ordinates, or terms of the Series, applied to the abscis.

These things being premised, let this Series be proposed, viz,

$$1,\ \frac{1}{2}x,\ \frac{3}{8}x^2,\ \frac{5}{16}x^3,\ \frac{35}{128}x^4,\ \frac{63}{256}x^5, \text{ \&c};$$

in which it is found, by dividing the terms by each other, that the relations of the terms are,

$$B = \frac{1}{2}Ax,\ C = \frac{3}{4}Bx,\ D = \frac{5}{6}Cx,\ E = \frac{7}{8}Dx, \text{ \&c}:$$

then the relation in general will be defined by the equation $T' = \frac{2z+1}{2z+2}Tx$ or $\frac{z+\frac{1}{2}}{z+1}Tx$, where z denotes the distance of T from the first term of the Series. For by substituting 0, 1, 2, 3, 4, &c, successively instead of z, the same relations will arise as in the proposed Series above. In like manner, if z be the distance of T from the 2d term of the Series, the equation will be $T' = \frac{2z+3}{2z+4}Tx$ or $\frac{z+\frac{3}{2}}{z+2}Tx$, as will appear by substituting the numbers -1, 0, 1, 2, 3, &c, successively for z. Or, if z denote the place or number of the term T in the Series, its successive values will be 1, 2, 3, 4, &c, and the equation or general term will be $T' = \frac{2z-1}{2z}Tx$.

It appears therefore, that innumerable differential equations may define one and the same Series, according to the different points from whence the origin of the abscis z is taken. And, on the contrary, the same equation defines innumerable different Series, by taking different successive values of z. For in the equation $T' = \frac{2z-1}{2z}Tx$, which defines the foregoing Series

when

when 1, 2, 3, 4, &c are the successive values of the abscisses; if $1\frac{1}{2}$, $2\frac{1}{2}$, $3\frac{1}{2}$, $4\frac{1}{2}$, &c, be successively substituted for z, the relations of the terms arising will be,

$B = \frac{2}{3}Ax$, $C = \frac{4}{5}Bx$, $D = \frac{6}{7}Cx$, &c, from whence will arise the Series

A, $\frac{2}{3}Ax$, $\frac{8}{15}Ax^2$, $\frac{16}{35}Ax^3$, $\frac{128}{315}Ax^4$, &c,

which is different from the former.

And thus the equation will always determine the Series from the given values of the abscis and of the first term, when the equation includes but two terms of the Series, as in the last example, where the first term being given, all the rest will be given.

But when the equation includes three terms, then two must be given; and three must be given, when it includes four; and so on. So, if there be proposed the

Series x, $\frac{1}{6}x^3$, $\frac{3}{40}x^5$, $\frac{5}{128}x^7$, $\frac{35}{1152}x^9$, &c,

where the relations of the terms are,

$B = \frac{1.1}{2.3}Ax^2$, $C = \frac{3.3}{4.5}Bx^2$, $D = \frac{5.5}{6.7}Cx^2$, &c.

the equation defining this Series will be

$$T' = \frac{\overline{2z-1}\,.\,\overline{2z-1}}{2z\,.\,\overline{2z+1}}Tx^2 = \frac{4zz-4z+1}{4zz+2z}Tx^2,$$

where the successive values of z are 1, 2, 3, 4, &c. See Stirling's Methodus Differentialis, in the introduction.

This may suffice to give a notion of these differential equations, defining the nature of Series. But as to the application of these equations in interpolations, and finding the sums of Series, it would require a treatise to explain it. We must therefore refer to that excellent one just quoted, as also to De Moivre's Miscellanea Analytica; and several curious papers by Euler in the Acta Petropolitana.

A Series often converges so slowly, as to be of no use in practice. Thus, if it were required to find the sum of the Series

$$\frac{1}{1.2} + \frac{1}{3.4} + \frac{1}{5.6} + \frac{1}{7.8} + \frac{1}{9.10} \text{ \&c,}$$

which Lord Brouncker found for the quadrature of the hyperbola, true to 9 figures, by the mere addition of the terms of the Series; Mr. Stirling computes that it would be necessary to add a thousand millions of terms for that purpose; for which the life of man would be too short. But by that gentleman's method, the sum of the Series may be found by a very moderate computation. See Method. Differ. pa. 26.

Series are of various kinds or descriptions. So,

An *Ascending* SERIES, is one in which the powers of the indeterminate quantity increase; as

$1 + ax + bx^2 + cx^3$ &c. And a

Descending SERIES, is one in which the powers decrease, or else increase in the denominators, which is the same thing; as

$1 + ax^{-1} + bx^{-2} + cx^{-3}$ &c, or $1 + \frac{a}{x} + \frac{b}{x^2} + \frac{c}{x^3}$ &c.

A Circular SERIES, which denotes a Series whose sum depends on the quadrature of the circle. Such is the Series $1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9}$ &c: See Demoivre Miscel. Analyt. pa. 111, or my Mensur. pa. 119. Or the sum of the Series $1 + \frac{1}{4} + \frac{1}{9} + \frac{1}{16} + \frac{1}{25}$ &c, continued ad infinitum, according to Euler's discovery.

Continued Fraction or *Series*, is a fraction of this kind, to infinity,

$$\cfrac{a}{b + \cfrac{c}{d + \cfrac{e}{f + \cfrac{g}{h \text{ \&c.}}}}}$$

The first Series of this kind was given by Lord Brouncker, first president of the Royal Society, for the quadrature of the circle, as related by Dr. Wallis, in his Algebra, pa. 317. His series is

$$1 + \cfrac{1}{2 + \cfrac{9}{2 + \cfrac{25}{2 + \cfrac{49}{2 + \cfrac{81}{2 + \text{\&c,}}}}}}$$

which denotes the ratio of the square of the diameter of a circle to its area. Mr. Euler has treated on this kind of Series, in the Petersburgh Commentaries, vol. 11, and in his Analys. Infinit. vol. 1, pa. 295, where he shews various uses of it, and how to transform ordinary fractions and common Series into continued fractions. A common fraction is transformed into a continued one, after the manner of seeking the greatest common measure of the numerator and denominator, by dividing the greater by the less, and the last divisor always by the last remainder. Thus to change $\frac{1461}{59}$ to a continued fraction.

```
59) 1461 (24
    118
    281
    236
     45) 59 (1
         45
         14) 45 (3
             42

```

Theref. $\frac{1461}{59} = 24 + \cfrac{1}{1 + \cfrac{1}{3 + \cfrac{1}{4 + \cfrac{1}{1 + \frac{1}{2}}}}}$.

Also $\sqrt{2} = 1 + \cfrac{1}{2 + \cfrac{1}{2 + \cfrac{1}{2 + \frac{1}{2} \text{ \&c.}}}}$

Converging

Converging SERIES, is a Series whose terms continually decrease, or the successive sums of whose terms approximate or converge always nearer to the ultimate sum of the whole Series. And, on the contrary, a

Diverging SERIES, is one whose terms continually increase, or that has the successive sums of its terms diverging, or going off always the farther, from the sum or value of the Series.

Determinate SERIES, is a Series whose terms proceed by the powers of a determinate quantity; as $1 + \frac{1}{2} + \frac{1}{2^2} + \frac{1}{2^3} +$ &c. If that determinate quantity be unity, the Series is said to be determined by unity. De Moivre, Miscel. Analyt. pa. 111. And an

Indeterminate SERIES is one whose terms proceed by the powers of an indeterminate quantity x; as $x + \frac{1}{2}x^2 + \frac{1}{3}x^3 + \frac{1}{4}x^4$ &c; or sometimes also with indeterminate exponents, or indeterminate coefficients.

The *Form of a* SERIES, is used for that affection of an indeterminate Series, such as $ax^n + bx^{n+r} + cx^{n+2r} + dx^{n+3r}$ &c, which arises from the different values of the indices of x. Thus,

If $n = 1$, and $r = 1$, the Series will take the form

$$ax + bx^2 + cx^3 + dx^4 \text{ \&c.}$$

If $n = 1$, and $r = 2$, the form will be

$$ax + bx^3 + cx^5 + dx^7 \text{ \&c.}$$

If $n = \frac{1}{2}$, and $r = 1$, the form is

$$ax^{\frac{1}{2}} + bx^{\frac{3}{2}} + cx^{\frac{5}{2}} + dx^{\frac{7}{2}} \text{ \&c.}$$ And

If $n = 0$, and $r = -1$, the form will be

$$a + bx^{-1} + cx^{-2} + dx^{-3} \text{ \&c.}$$

When the value of a quantity cannot be found exactly, it is of use in algebra, as well as in common arithmetic, to seek an approximate value of that quantity, which may be useful in practice. Thus, in arithmetic, as the true value of the square root of 2 cannot be assigned, a decimal fraction is found to a sufficient degree of exactness in any particular case; which decimal fraction is in reality, no more than an infinite series of fractions converging or approximating to the true value of the root sought. For the expression $\sqrt{2} = 1{\cdot}414213$ &c, is equivalent to this $\sqrt{2} = 1 + \frac{4}{10} + \frac{1}{100} + \frac{4}{1000}$ &c; or supposing $x = 10$, to this

$$\sqrt{2} = 1 + \frac{4}{x} + \frac{1}{x^2} + \frac{4}{x^3} + \frac{2}{x^4} \text{ \&c.}$$

$$\text{or} = 1 + 4x^{-1} + x^{-2} + 4x^{-3} + 2x^{-4} \text{ \&c,}$$

which last Series is a particular case of the more general indeterminate Series $ax^n + bx^{n+r} + cx^{n+2r}$ &c, viz, when $n = 0$, $r = -1$, and the coefficients $a = 1$, $b = 4$, $c = 1$, $d = 4$, &c.

But the application of the notion of approximations in numbers, to species, or to algebra, is not so obvious. Newton, with his usual sagacity, took the hint, and prosecuted it; by which were discovered general methods in the doctrine of infinite Series, which had before been treated only in a particular manner, though with great acuteness, by Wallis and a few others. See Newton's Method of Fluxions and Infinite Series, with Colson's Comment; as also the Analysis per Æquationes Numero Terminorum Infinitas, published by Jones in 1711, and since translated and explained by Stewart, together with Newton's Tract on Quadratures, in 1745. To these may be added Maclaurin's Algebra, part 2, chap. 10, pa. 244; and Cramer's Analyse des Lignes Courbes Algebraiques, chap. 7, pa. 148; and many other authors.

Among the various methods for determining the value of a quantity by a converging Series, that seems preferable to the rest, which consists in assuming an indeterminate Series as equal to the quantity whose value is sought, and afterwards determining the values of the terms of this assumed Series. For instance, suppose a logarithm were given, to find the natural number answering to it. Suppose the logarithm to be z, and the corresponding number sought $1 + x$: then by the nature of logarithms and fluxions, $\dot{z} = \frac{\dot{x}}{1 + x}$, or $\dot{x} + x\dot{z} = \dot{x}$. Now assume a Series for the value of the unknown quantity x, and substitute it and its fluxion instead of x and $\dot{x}$ in the last equation, then determine the assumed coefficients by comparing or equating the like terms of the equation. Thus,

$$\begin{aligned} &\text{assume } x = az + bz^2 + cz^3 + dz^4 \text{ \&c,} \\ &\text{then } \dot{x} = a\dot{z} + 2bz\dot{z} + 3cz^2\dot{z} + 4dz^3\dot{z} \text{ \&c;} \\ &\text{and } \dot{x} = (\dot{z} + x\dot{z}) = \dot{z} + az\dot{z} + bz^2\dot{z} + cz^3\dot{z} \text{ \&c;} \end{aligned}$$

hence, comparing the like terms of these two values of $\dot{x}$, there arises $a = 1$, $b = \frac{1}{2}$, $c = \frac{1}{6}$, $d = \frac{1}{24}$, &c; which values being substituted for a, b, c, &c, in the assumed Series $ax + bx^2 + cx^3$ &c, it gives

$$x = z + \frac{1}{2}z^2 + \frac{1}{6}z^3 + \frac{1}{24}z^4 + \frac{1}{120}z^5, \text{ \&c, or}$$

$$x = z + \frac{1}{1.2}z^2 + \frac{1}{1.2.3}z^3 + \frac{1}{1.2.3.4}z^4 + \frac{1}{1.2.3.4.5}z^5$$

&c; and consequently the number sought will be

$$1 + x = 1 + z + \frac{1}{1.2}z^2 + \frac{1}{1.2.3}z^3 \text{ \&c.}$$

But the indeterminate Series $az + bz^2 + cz^3$ &c, was here assumed arbitrarily, with regard to its exponents 1, 2, 3, &c, and will not succeed in all cases, because some quantities require other forms for the exponents. For instance, if from an arc given, it were required to find the tangent. Let x = the tangent, and z the arc, the radius being = 1. Then, from the nature of the circle we shall have $\frac{\dot{x}}{1 + x^2} = \dot{z}$, or $\dot{x} = \dot{z} + x^2\dot{z}$. Now if, to find the value of x, we suppose $x = az + bz^2 + cz^3$ &c, and proceed as before, we shall find all the alternate coefficients b, d, f, &c, or those of the even powers of z, to be each $= 0$; and therefore the Series assumed is not of a proper form.

But

But suppofing $x = az + bz^3 + cz^5 + dz^7$, &c, then we find $a = 1$, $b = \frac{1}{3}$, $c = \frac{2}{15}$, $d = \frac{17}{315}$, &c, and confequently $x = z + \frac{1}{3}z^3 + \frac{2}{15}z^5 + \frac{17}{315}z^7$ &c.

And other quantities require other forms of Series.

Now to find a proper indeterminate Series in all cafes, tentatively, would often be very laborious, and even impracticable. Mathematicians have therefore endeavoured to find out a general rule for this purpofe; though till lately the method has been but imperfectly underftood and delivered. Moft authors indeed have explained the manner of finding the coefficients a, b, c, d, &c, of the indeterminate Series $ax^n + bx^{n+r} + cx^{n+2r}$ &c, which is eafy enough; but the values of n and r, in which the chief difficulty lies, have been affigned by many in a manner as if they were felf-evident, or at leaft difcoverable by an eafy trial or two, as in the laft example.

As to the number n, Newton himfelf has fhewn the method of determining it, by his rule for finding the firft term of a converging Series, by the application of his parallelogram and ruler. For the particulars of this method, fee the authors above cited; fee alfo PARALLELOGRAM.

Taylor, in his Methodus Incrementorum, inveftigates the number r; but Stirling obferves that his rule fometimes fails. Lineæ Tert. Ordin. Newton. pa. 28. Mr. Stirling gives a correction of Taylor's rule, but fays he cannot affirm it to be univerfal, having only found it by chance. And again

Gravefande obferves, that though he thinks Stirling's rule never leads into an error, yet that it is not perfect. See Gravefande, De Determin. Form. Seriei Infinit. printed at the end of his Mathefeos Univerfalis Elementa. This learned profeffor has endeavoured to rectify the rule. But Cramer has fhewn that it is ftill defective in feveral refpects; and he himfelf, to avoid the inconveniences to which the methods of former authors are fubject, has had recourfe to the firft principles of the method of infinite Series, and has entered into a more exact and inftructive detail of the whole method, than is to be met with elfewhere; for which reafon, and many others, his treatife deferves to be particularly recommended to beginners.

But it is to be obferved, that in determining the value of a quantity by a converging Series, it is not always neceffary to have recourfe to an indeterminate Series: for it is often better to find it by divifion, or by extraction of roots. See Newton's Meth. of Flux. and Inf. Series, above cited. Thus, if it were required to find the arc of a circle from its given tangent, that is, to find the value of z in the given fluxional equation, $\dot{z} = \frac{\dot{x}}{1 + xx}$, by an infinite Series: dividing $\dot{x}$ by $1 + xx$, the quotient will be the Series $\dot{x} - x^2\dot{x} + x^4\dot{x} - x^6\dot{x}$ &c $= \dot{z}$; and taking the fluents of the terms, there refults $z = x - \frac{1}{3}x^3 + \frac{1}{5}x^5 - \frac{1}{7}x^7$ &c, which is the Series often ufed for the quadrature of the circle. If $x = 1$, or the tangent of 45°, then will $z = 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7}$ &c, = the length of an arc of 45°, or $\frac{1}{8}$ of the circumference, to the radius 1, or $\frac{1}{4}$ of the circumference to the diameter 1. Confequently, if 1 be the diameter, then $1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7}$ &c will be the area of the circle, becaufe $\frac{1}{4}$ of the circumference multiplied by the diameter, gives the area of the circle. And this Series was firft given by Leibnitz and James Gregory.

See the form of the Series for the binomial theorem, determined, both as to the coefficients and exponents, in my Tracts, vol. 1, pa. 79.

Harmonical SERIES, the reciprocal of arithmeticals. See HARMONICAL.

Hyperbolic SERIES, is ufed for a Series whofe fum depends upon the quadrature of the hyperbola. Such is the Series $\frac{1}{1} + \frac{1}{2} + \frac{1}{3} + \frac{1}{4}$ &c. De Moivre's Mifcel. Analyt. pa. 111.

Interpolation of SERIES, the inferting of fome terms between others, &c. See INTERPOLATION.

Interfcendent SERIES. See INTERSCENDENT.

Mixt SERIES, one whofe fum depends partly on the quadrature of the circle, and partly on that of the hyperbola. De Moivre, Mifcel. Analyt. pa. 111.

Recurring SERIES, is ufed for a Series which is fo conftituted, that having taken at pleafure any number of its terms, each following term fhall be related to the fame number of preceding terms according to a conftant law of relation. Thus, in the following Series,

$$\begin{array}{cccccc} a & b & c & d & e & f \\ 1 & + 2x & + 3x^2 & + 10x^3 & + 34x^4 & + 97x^5 \text{ \&c,} \end{array}$$

in which the terms being refpectively reprefented by the letters a, b, c, &c, fet over them, we fhall have

$$d = 3cx - 2bx^2 + 5ax^3,$$
$$e = 3dx - 2cx^2 + 5bx^3,$$
$$f = 3ex - 2dx^2 + 5cx^3,$$
&c, &c,

where it is evident that the law of relation between d and e, is the fame as between e and f, each being formed in the fame manner from the three terms which precede it in the Series.

The quantities $3x - 2x^2 + 5x^3$, taken together and connected by their proper figns, form what De Moivre calls the *index*, or the *fcale of relation*; though fometimes the bare coefficients $3 - 2 + 5$ are called the fcale of relation. And the fcale of relation fubtracted from unity, is called the *differential fcale*. On the fubject of Recurring Series, fee De Moivre's Mifcel. Analyt. pa. 27 and 72, and his Doctrine of Chances, 3d edit. pa. 220; alfo Euler's Analyf. Infinit. tom. 1, pa. 175.

Having given a recurring Series, with its fcale of relation, the fum of the whole infinite Series will alfo be given. For inftance, fuppofe a Series $a +$

$a + bx + cx^2 + dx^3$ &c, where the relation between the coefficient of any term and the coefficients of any two preceding terms may be expressed by $f - g$; that is, $e = fd - gc$, and $d = fc - gb$, &c; then will the sum of the Series, infinitely continued, be $\frac{a + (b - fa)x}{1 - fx + gx^2}$.

Thus, for example, assume 2 and 5 for the coefficients of the first two terms of a recurring Series; and suppose f and g to be respectively 2 and 1; then the recurring Series will be

$$2 + 5x + 8x^2 + 11x^3 + 14x^4 + 18x^5 \text{ \&c},$$

and its sum $= \frac{2 + 5x - 4x}{1 - 2x + xx} = \frac{2 + x}{(1 - x)^2}$. For the proof of which divide $2 + x$ by $(1 - x)^2$, and there arises the said Series $2 + 5x + 8x^2 + 11x^3$ &c. And similar rules might be derived for more complex cases.

De Moivre's general rule is this: 1. Take as many terms of the Series as there are parts in the scale of relation. 2. Subtract the scale of relation from unity, and the Remainder is the differential scale. 3. Multiply the terms taken in the Series by the differential scale, beginning at unity, and so proceeding orderly, remembering to leave out what would naturally be extended beyond the last of the terms taken. Then will the product be the numerator, and the differential scale will be the denominator of the fraction expressing the sum required.

But it must here be observed, that when the sum of a recurring Series extended to infinity, is found by De Moivre's rule, it ought to be supposed that the Series converges indefinitely, that is, that the terms may become less than any assigned quantity. For if the Series diverge, that is, if its terms continually increase, the rule does not give the true sum. For the sum in such case is infinite, or greater than any given quantity, whereas the sum exhibited by the rule, will often be finite. The rule therefore in this case only gives a fraction expressing the radix of the Series, by the expansion of which the Series is produced. Thus $\frac{1}{(1 - x)^2}$ by expansion becomes the recurring Series $1 + 2x + 3x^2$ &c, whose scale of relation is $2 - 1$, and its sum by the rule will be $\frac{a + bx - fax}{1 - fx + gxx} = \frac{1 + 2x - 2x}{1 - 2x + xx} = \frac{1}{(1 - x)^2}$, the quantity from which the Series arose. But this quantity cannot in all cases be deemed equal to the infinite Series $1 + 2x + 3x^2$ &c: for stop where you will, there will always want a supplement to make the product of the quotient by the divisor equal to the dividend. Indeed when the Series converges infinitely, the supplement, diminishing continually, becomes less than any assigned quantity, or equal to nothing; but in a diverging Series, this supplement becomes infinitely great, and the Series deviates indefinitely from the truth. See Colson's Comment on Newton's Method of Fluxions and Infinite Series, pa. 152; Stirling's Method. Differ. pa. 36; Bernoulli de Seieb. Infin. pa. 249; and Cramer's Analyse des Lignes Courbes, pa. 174.

A recurring Series being given, the sum of any finite number of the terms of that Series may be found. This is prob. 3, pa. 73, De Moivre's Miscel. Analyt. and prob. 5, pa. 223 of his Doctrine of Chances. The solution is effected, by taking the difference between the sums of two infinite Series, differing by the terms answering to the given number; viz, from the sum of the whole infinite Series, commencing from the beginning, subtract the sum of another infinite number of terms of the same Series, commencing after so many of the first terms whose sum is required; and the difference will evidently be the sum of that number of terms of the Series. For example, to find the sum of n terms of the infinite geometrical Series $a + ax + ax^2 + ax^3$ &c. Here are two infinite Series; the one beginning with a, and the other with ax^n, which is the next term after the first n terms of the original Series. By the rule, the sum of the first infinite progression will be $\frac{a}{1 - x}$, and the sum of the second $\frac{ax^n}{1 - x}$; the difference of which is $\frac{a - ax^n}{1 - x}$, which is therefore the sum of the first n terms of the Series. This quantity $\frac{a - ax^n}{1 - x}$ is equal to $\frac{ax^n - a}{x - 1}$ which last expression, putting $ax^{n-1} = l$, will be equivalent to this, $\frac{lx - a}{x - 1}$, which is the common rule for finding the sum of any geometric progression, having given the first term a, the last term l, and the ratio x. See Miscel. Analyt. pa. 167, 168.

In a recurring Series, any term may be obtained whose place is assigned. For after having taken so many terms of the Series as there are terms in the scale of relation, the Series may be protracted till it reach the place assigned. But when that place is very distant from the beginning of the Series, the continuing the terms is very laborious; and therefore other methods have been contrived. See Miscel. Analyt. pa. 33; and Doctrine of Chances, pa. 224.

These questions have been resolved in many cases, besides those of recurring Series. But as there is no universal method for the quadrature of curves, neither is there one for the summation of Series; indeed there is a great analogy between these things, and similar difficulties arising in both. See the authors above cited.

The investigation of Daniel Bernoulli's method for finding the roots of algebraic equations, which is inserted in the Petersburgh Acts, tom. 3, pa. 92, depends upon the doctrine of recurring Series. See Euler's Analysis Infinitorum, tom 1, pa. 276.

Reversion of SERIES. See REVERSION *of Series*.

Summable SERIES, is one whose sum can be accurately found. Such is the Series $\frac{1}{2} + \frac{1}{4} + \frac{1}{8}$ &c, the sum of which is said to be unity, or, to speak more accurately, the limit of its sum is unity or 1.

An indefinite number of summable infinite Series may

may be assigned: such are, for instance, all infinite recurring converging Series, and many others, for which, consult De Moivre, Bernoulli, Stirling, Euler, and Maclaurin; viz, Miscel. Analyt. pa. 110; De Serieb. Infinit. passim; Method. Different. pa. 34; Acta Petrop. passim; Fluxions, art. 350.

The obtaining the sums of infinite Scrieses of fractions has been one of the principal objects of the modern method of computation; and these sums may often be found, and often not. Thus the sums of the two following Series of geometrical progressionals are easily found to be 1 and $\frac{1}{2}$,

$$\text{viz, } 1 = \frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \frac{1}{16} \text{ \&c,}$$

$$\text{and } \frac{1}{2} = \frac{1}{3} + \frac{1}{9} + \frac{1}{27} + \frac{1}{81} \text{ \&c.}$$

But the Serieses of fractions that occur in the solution of problems, can seldom be reduced to geometric progressions; nor can any general rule, in cases so infinitely various, be given. The art here, as in most other cases, is only to be acquired by examples, and by a careful observation of the arts used by great authors in the investigation of such Series of fractions as they have considered. And the general methods of infinite Series, which have been carried so far by De Moivre, Stirling, Euler, &c, are often found necessary to determine the sum of a very simple Series of fractions. See the quotations above.

The sum of a Series of fractions, though decreasing continually, is not always finite. This is the case of the Series $\frac{1}{1} + \frac{1}{2} + \frac{1}{3} + \frac{1}{4} + \frac{1}{5}$ &c, which is the harmonic Series, consisting of the reciprocals of arithmeticals, the sum of which exceeds any given number whatever; and this is shewn from the analogy between this progression and the space comprehended by the common hyperbola and its asymptote; though the same may be shewn also from the nature of progressions. See James Bernoulli, de Seriebus Infin. But, what is curious, the square of it is finite, for if the same terms of the harmonic Series, $\frac{1}{1} + \frac{1}{2} + \frac{1}{3}$ &c, be squared, forming the Series $\frac{1}{1} + \frac{1}{4} + \frac{1}{9}$ &c, being the reciprocals of the squares of the natural Series of numbers; the sum of this Series of fractions will not only be limited, but it is remarkable that this sum will be precisely equal to the 6th part of the number which expresses the ratio of the square of the circumference of a circle to the square of its diameter. That is, if c denote 3·14159 &c, the ratio of the circumference to the diameter, then is $\frac{1}{6}c^2 = \frac{1}{1} + \frac{1}{4} + \frac{1}{9} + \frac{1}{16} + \frac{1}{25}$ &c. This property was first discovered by Euler; and his investigation may be seen in the Acta Petrop. vol. 7. And Maclaurin has since observed, that this may easily be deduced from his Fluxions, art. 822. Philos. Trans. numb. 469.

It would require a whole treatise to enumerate the various kinds of Series of fractions which may or may not be summed. Sometimes the sum cannot be assigned, either because it is infinite, as in the harmonic Series $\frac{1}{1} + \frac{1}{2} + \frac{1}{3} + \frac{1}{4}$ &c, or although its sum be finite (as in the Series $\frac{1}{1} + \frac{1}{4} + \frac{1}{9}$ &c), yet its sum cannot be assigned in finite terms, or by the quadrature of the circle or hyperbola, which was the case of this Series before Euler's discovery; but yet the sum of any given number of the terms of the Series may be expeditiously found, and the whole sum may be assigned by approximation, independent of the circle. See Stirling's Method. Different. and De Moivre's Miscel. Analyt.

Besides the Serieses of fractions, the sums of which converge to a certain quantity, there sometimes occur others, which converge by a continued multiplication. Of this kind is the Series found by Wallis, for the quadrature of the circle, which he expresses thus,

$$\square = \frac{3 \times 3 \times 5 \times 5 \times 7 \times 7 \times 9 \times 9 \times \text{ \&c}}{2 \times 4 \times 4 \times 6 \times 6 \times 8 \times 8 \times 10 \times \text{ \&c}},$$

where the character $\square$ denotes the ratio of the square of the diameter to the area of the circle. Hence the denominator of this fraction, is to its numerator, both infinitely continued, as the circle is to the square of the diameter. It may farther be observed that this Series is equivalent to

$$\frac{9}{8} \times \frac{25}{24} \times \frac{49}{48} \times \text{ \&c, or to } \frac{3^2}{3^2-1} \times \frac{5^2}{5^2-1} \times \frac{7^2}{7^2-1} \times$$

&c, that is, the product of the squares of all the odd numbers 3, 5, 7, 9, &c, is to the product of the same squares severally diminished by unity, as the square of the diameter is to the area of the circle. See Arithmet. Infinit. prop. 191, Oper. vol. 1, pa. 469. Id. Oper. vol. 2, pa. 819. And these products of fractions, and the like quantities arising from the continued multiplication of certain factors, have been particularly considered by Euler, in his Analysis Infinit. vol. 1, chap. 15, pa. 221.

For an easy and general method of summing all alternate Series, such as $a - b + c - d$ &c, see my Tracts, vol. 1, pa. 11; and in the same vol. may be seen many other curious tracts on infinite Series.

Summation of Infinite SERIES, is the finding the value of them, or the radix from which they may be raised. For which, consult all the authors upon this science.

To find an infinite Series by extracting of roots; and to find an infinite Series by a presupposed Series; see QUADRATURE *of the Circle*.

To extract the roots of an infinite Series, see EXTRACTION *of Roots*.

To raise an infinite Series to any power, see INVOLUTION, and POWER.

Transcendental SERIES. See TRANSCENDENTAL.

There are many other important writings upon the subject of Infinite Series, besides those above quoted. A very good elementary tract on this science is that of James Bernoulli, intituled, *Tractatus de Seriebus Infinitis*,

tis, and annexed to his *Ars Conjectandi*, published in 4to, 1713.

SERPENS, in Astronomy, a constellation in the northern hemisphere, being one of the 48 old constellations mentioned by all the Ancients, and is called more particularly *Serpens Ophiuchi*, being grasped in the hands of the constellation Ophiuchus. The Greeks, in their fables, have ascribed it sometimes to one of Triptolemus's dragons, killed by Carnabos; and sometimes to the serpent of the river Segaris, destroyed by Hercules. This is by some supposed to be the same as the author of the book of Job calls the *Crooked Serpent*; but this expression more probably meant the constellation Draco, near the north pole.

The stars in the constellation Serpens, in Ptolomy's catalogue are 18, in Tycho's 13, in Hevelius's 22, and in the Britannic catalogue 64.

SERPENTARIUS, a constellation of the northern hemisphere, being one of the 48 old constellations mentioned by all the Ancients. It is called also Ophiuchus, and anciently Æsculapius. It is in the figure of a man grasping the serpent.

The Greeks had different fables about this, and other constellations, because they were ignorant of the true meaning of them. Some of them say, it represents Carnabos, who killed one of the dragons of Triptolemus. Others say, it was Hercules, killing the serpent at the river Segaris. And others again say, it represents the celebrated physician Æsculapius, to denote his skill in medicine to cure the bite of the serpent.

The stars in the constellation Serpentarius, in Ptolomy's catalogue are 29, in Tycho's 15, in Hevelius's 40, and in the Britannic catalogue they are 74.

SERPENTINE *Line*, the same with spiral.

SESQUI, an expression of a certain ratio, viz, the second ratio of inequality, called also *superparticular* ratio; being that in which the greater term contains the less once, and some certain part over; as 3 to 2, where the first term contains the second once, and unity over, which is a quota part of 2. Now if this part remaining be just half the less term, the ratio is called *sesquialtera*; if the remaining part be a 3d part of the less term, as 4 to 3, the ratio is called *sesquitertia*, or *sesquiterza*; if a 4th part, as 5 to 4, the ratio is called *sesquiquarta*; and so on continually, still adding to Sesqui the ordinal number of the smaller term.

In English we sometimes say, *sesquialteral*, or *sesquialterate*, *sesquithird*, *sesquifourth*, &c.

As to the kinds of triples expressed by the particle *sesqui*, they are these:

SESQUIALTERATE, *the greater perfect*, which is a triple, where the breve is three measures, or semibreves.

SESQUIALTERATE, *greater imperfect*, which is where the breve, when pointed, contains three measures, and without any point, two.

SESQUIALTERATE, *less imperfect*, a triple, where the semibreve with a point contains three measures, and two without.

SESQUIALTERATE, in Arithmetic and Geometry, is a ratio between two numbers, or lines, &c, where the greater is equal to once and a half of the less. Thus 6 and 9 are in a Sesquialterate ratio, as also 20 and 30.

SESQUIDITONE, in Music, a concord resulting from the sounds of two strings whose vibrations, in equal times, are to each other in the ratio of 5 to 6.

SESQUIDUPLICATE *Ratio*, is that in which the greater term contains the less, twice and a half; as the ratio of 15 to 6, or 50 to 20.

SESQUIQUADRATE, an aspect or position of the planets, when they are distant by 4 signs and a half, or 135 degrees.

SESQUIQUINTILE, is an aspect of the planets when they are distant $\frac{1}{5}$ of the circle and a half, or 108 degrees.

SESQUITERTIONAL *Proportion*, is that in which the greater term contains the less once and one third; as 4 to 3, or 12 to 9.

SETTING, in Astronomy, the withdrawing of a star or planet, or its sinking below the horizon.

Astronomers and poets count three different kinds of Setting of the stars, viz, ACHRONICAL, COSMICAL, and HELIACAL. See these terms respectively.

SETTING, in Navigation, Surveying, &c, denotes the observing the bearing or situation of any distant object by the compass, &c, to discover the angle it makes with the nearest meridian, or with some other line. See BEARING.

Thus, to *set the land*, or *the sun*, by the compass, is to observe how the land bears on any point of the compass, or on what point of the compass the sun is. Also, when two ships come in sight of each other, to mark on what point the chace bears, is termed *Setting the chace by the compass*.

SETTING also denotes the direction of the wind, current, or sea, particularly of the two latter.

SEVEN STARS, a common denomination given to the cluster of stars in the neck of the sign Taurus, the bull, properly called the pleiades. They are so called from their number Seven which appear to the naked eye, though some eyes can discover only 6 of them; but by the help of telescopes there appears to be a great multitude of them.

SEVENTH, *Septima*, an interval in Music, called by the Greeks *heptachordon*.

SEXAGENARY, something relating to the number 60.

SEXAGENARY *Arithmetic*. See SEXAGESIMAL.

SEXAGENARY *Tables*, are tables of proportional parts, shewing the product of two Sexagenaries that are to be multiplied, or the quotient of two that are to be divided.

SEXAGESIMA, the eighth Sunday before Easter; being so called because near 60 days before it.

SEXAGESIMAL or SEXAGENARY *Arithmetic*, a method of computation proceeding by 60ths. Such is that used in the division of a degree into 60 minutes, of the minute into 60 seconds, of the second into 60 thirds, &c.

SEXAGESIMALS, or SEXAGESIMAL *Fractions*, are fractions whose denominators proceed in a sexagecuple ratio; that is, a prime, or the first minute $= \frac{1}{60}$, a second $= \frac{1}{3600}$, a third $= \frac{1}{216000}$.

Anciently there were no other than Sexagesimals used in astronomical operations, for which reason they are sometimes called *astronomical fractions*, and they are still retained in many cases, as in the divisions of time and of a circle; but decimal arithmetic is now much used

ufed in the calculations. Sexagefimals were probably firft ufed for the divifions of a circle, 360, or 6 times 60 making up the whole circumference, on account that 360 days made up the year of the Ancients, in which time the fun was fuppofed to complete his courfe in the circle of the ecliptic.

In thefe fractions, the denominator being always 60, or a multiple of it, it is ufually omitted, and the numerator only written down: thus, $3^{\circ}\ 45'\ 24''\ 40'''$ &c, is to be read, 3 degrees, 45 minutes, 24 feconds, 40 thirds, &c.

SEXANGLE, in Geometry, a figure having 6 angles, and confequently 6 fides alfo.

SEXTANS, a fixth part of certain things.

The Romans divided their *as*, which was a pound of brafs, into 12 ounces, called *uncia*, from *unum*; and the quantity of 2 ounces was called *fextans*, as being the 6th part of the pound.

Sextans was alfo a meafure, which contained 2 ounces of liquor, or 2 cyathi.

Sextans, the Sextant, in Aftronomy, a new conftellation, placed acrofs the equator, but on the fouth fide of the ecliptic, and by Hevelius made up of fome unformed ftars, or fuch as were not included in any of the 48 old conftellations. In Hevelius's catalogue it contains 11 ftars, but in the Britannic catalogue 41.

SEXTANT, denotes the 6th part of a circle, or an arch containing 60 degrees.

Sextant is more particularly ufed for an aftronomical inftrument. It is made like a quadrant, excepting that its limb only contains 60 degrees. Its ufe and application are the fame with thofe of the Quadrant; which fee.

SEXTARIUS, an ancient Roman meafure, containing 2 cotylæ, or 2 heminæ.

SEXTILE, the afpect or pofition of two planets, when they are diftant the 6th part of the circle, viz, 2 figns or 60 degrees; and it is marked thus ✱.

SEXTUPLE, denotes 6 fold in general. But in mufic it denotes a mixed fort of triple time, which is beaten in double time.

SHADOW, *Shade*, in Optics, a certain fpace deprived of light, or where the light is weakened by the interpofition of fome opaque body before the luminary.

The doctrine of Shadows makes a confiderable article in optics, aftronomy, and geography; and is the general foundation of dialling.

As nothing is feen but by light, a mere fhadow is invifible; and therefore when we fay we fee a fhadow, we mean, partly that we fee bodies placed in the Shadow, and illuminated by light reflected from collateral bodies, and partly that we fee the confines of the light.

When the opaque body, that projects the Shadow, is perpendicular to the horizon, and the plane it is projected on is horizontal, the Shadow is called a *right* one: fuch as the Shadows of men, trees, buildings, mountains, &c. But when the body is placed parallel to the horizon, it is called a *verfed Shadow*; as the arms of a man when ftretched out, &c.

Laws of the Projection of Shadows.

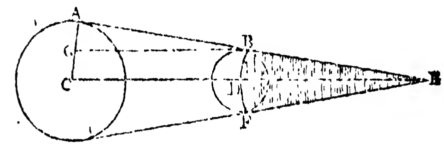
1. Every opaque body projects a Shadow in the fame direction with the rays of light; that is, towards the part oppofite to the light. Hence, as either the luminary or the body changes place, the Shadow likewife changes its place.

2. Every opaque body projects as many Shadows as there are luminaries to enlighten it.

3. As the light of the luminary is more intenfe, the fhadow is the deeper. Hence, the intenfity of the Shadow is meafured by the degrees of light that fpace is deprived of. In reality, the Shadow itfelf is not deeper; but it appears fo, becaufe the furrounding bodies are more intenfely illuminated.

4. When the luminous body and opaque one are equal, the Shadow is always of the fame breadth with the opaque body. But when the luminous body is the larger, the Shadow grows always lefs and lefs, the farther from the body. And when the luminous body is the fmaller of the two, the Shadow increafes always the wider, the farther from the body. Hence, the Shadow of an opaque globe is, in the firft cafe a cylinder, in the fecond cafe it is a cone verging to a point, and in the third cafe a truncated cone that enlarges ftill the more the farther from the body. Alfo, in all thefe cafes, a tranfverfe Section of the Shadow, by a plane, is a circle, refpectively, in the three cafes, equal, lefs, or greater than a great circle of the globe.

5. To find the length of the Shadow, or the axis of the fhady cone, projected by a fphere, when it is illuminated by a larger one; the diameters and diftance of the two fpheres being known. Let C and D be the



centres of the two fpheres, CA the femidiameter of the larger, and DB that of the fmaller, both perpendicular to the fide of the conical Shadow BEF, whofe axis is DE, continued to C; and draw BG parallel to the fame axis. Then, the two triangles AGB and BDE being fimilar, it will be AG : GB or CD :: BD : DE, that is, as the difference of the femidiameters is to the diftance of the centres, fo is the femidiameter of the opaque fphere to the axis of the Shadow, or the diftance of its vertex from the faid opaque fphere.

Ex. gr. If BD = 1 be the femidiameter of the earth, and AC = 101 the mean femidiameter of the fun, alfo their diftance CD or GB = 24000; then as 100 : 24000 :: 1 : 240 = DE, which is the mean height of the earth's Shadow, in femidiameters of the bafe.

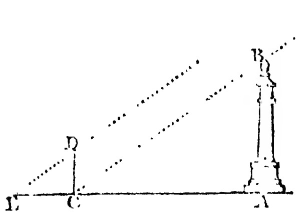
6. To find the length of the fhadow AC projected by an opaque body AB; having given the altitude of the luminary, for ex. of the fun, above the horizon, viz, the angle C, and the height of the object AB. Here the proportion is, as tang. ∠ C : radius :: AB : AC.

Or, if the length of the Shadow AC be given, to find the height AB, it will be,

as radius : tang. ∠ C :: AC : AB.

Or,

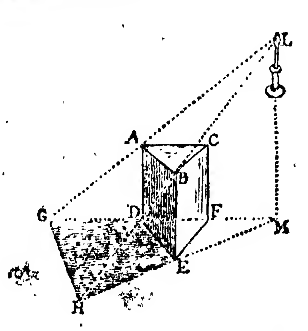
Or, if the length of the Shadow AC, and of the object AB, be given, to find the sun's altitude above the horizon, or the angle at C. It will be, as AC : AB : : radius : tang. ∠ C sought.



7. To measure the height of any object, ex. gr. a tower AB, by means of its shadow projected on an horizontal plane.—At the extremity of the shadow, at C, erect a stick or pole CD, and measure the length of its shadow CE ; also measure the length of the Shadow AC of the tower. Then, by similar triangles, it will be, as EC : CD : : CA : AB. So if EC = 10 feet, CD = 6 feet, and CA = 95 feet; then as 10 : 6 : : 95 : 57 feet = AB, the height of the tower sought.

SHADOW, in Geography. The inhabitants of the earth are divided, with respect to their shadows, into ASCII, AMPHISCII, HETEROSCII, and PERISCII. See these terms in their places.

SHADOW, in Perspective, is of great use in this art.—Having given the appearance of an opaque body, and a luminous one, whose rays diverge, as a candle, or lamp, &c ; to find the just appearance of the Shadow, according to the laws of perspective. The method is this : From the luminous body, which is here considered as a point, let fall a perpendicular to the perspective plane or table ; and from the several angles, or raised points of the body, let fall perpendiculars to the same plane ; then connect the points on which these latter perpendiculars fall, by right lines, with the point on which the first falls; continuing these lines beyond the side opposite to the luminary, till they meet with as many other lines drawn from the centre of the luminary through the said angles or raised points; so shall the points of intersection of these lines be the extremes or bounds of the Shadow.



For Example, to project the appearance of the Shadow of a prism ABCDEF, scenographically delineated. Here M is the place of the perpendicular of the light L, and D, E, F those of the raised points A, B, C, of the prism ; therefore, draw MEH, MDG, &c, and LBH, LAG, &c, which will give DEGH &c for the appearance of the Shadow.

As for those Shadows that are intercepted by other objects, it may be observed, that when the Shadow of a line falls upon any object, it must necessarily take the form of that object. If it fall upon another plane, it will be a right line; if upon a globe, it will be circular; and if upon a cylinder or cone, it will be circular, or oval, &c. If the body intercepting it be a plane, whatever be the situation of it, the shadow falling upon it might be found by producing that plane till it intercepted the perpendicular let fall upon it from the luminous body ; for then a line drawn from that point would determine the Shadow, just as if no other plane had been concerned. But the appearance of all these Shadows may be drawn with less trouble, by first drawing it through these intercepted objects, as if they had not been in the way, and then making the Shadow to ascend perpendicularly up every perpendicular plane, and obliquely on those that are situated obliquely, in the manner described by Dr. Priestley, in his Perspective, pa. 73 &c.

Here we may observe in general, that since the Shadows of all objects which are cast upon the ground, will vanish into the horizontal line ; so, for the same reason, the vanishing points of all Shadows, which are cast upon any inclined or other plane, will be somewhere in the vanishing line of that plane.

When objects are not supposed to be viewed by the light of the sun, or of a candle, &c, but only in the light of a cloudy day, or in a room into which the sun does not shine, there is no sensible Shadow of the upper part of the object, and the lower part only makes the neighbouring parts of the ground, on which it stands, a little darker than the rest. This imperfect obscure kind of Shadow is easily made, being nothing more than a shade on the ground, opposite to the side on which the light comes ; and it may be continued to a greater or less distance, according to the supposed brightness of the light by which it is made. It is in this manner (in order to save trouble, and sometimes to prevent confusion) that the Shadows in most drawings are made. On this subject, see Priestley's Perspect. above quoted ; also Kirby's Persp. book 2, ch. 4.

SHAFT *of a Column*, in Building, is the body of it; thus called from its straightness : but by architects more commonly the Fust.

SHAFT is also used for the spire of a church steeple ; and for the shank or tunnel of a chimney.

SHARP (ABRAHAM), an eminent mathematician, mechanist, and astronomer, was descended from an ancient family at Little-Horton, near Bradford, in the West Riding of Yorkshire, where he was born about the year 1651. At a proper age he was put apprentice to a merchant at Manchester; but his genius led him so strongly to the study of mathematics, both theoretical and practical, that he soon became uneasy in that situation of life. By the mutual consent therefore of his master and himself, though not altogether with that of his father, he quitted the business of a merchant. Upon this he removed to Liverpool, where he

give

gave himſelf up wholly to the ſtudy of mathematics, aſtronomy, &c; and where, for a ſubſiſtance, he opened a ſchool, and taught writing and accounts, &c.

He had not been long at Liverpool when he accidentally fell in company with a merchant or tradeſman viſiting that town from London, in whoſe houſe it ſeems the aſtronomer Mr. Flamſteed then lodged. With the view therefore of becoming acquainted with this eminent man, Mr. Sharp engaged himſelf with the merchant as a book-keeper. In conſequence he ſoon contracted an intimate acquaintance and friendſhip with Mr. Flamſteed, by whoſe intereſt and recommendation he obtained a more profitable employment in the dock-yard at Chatham; where he continued till his friend and patron, knowing his great merit in aſtronomy and mechanics, called him to his aſſiſtance, in contriving, adapting, and fitting up the aſtronomical apparatus in the Royal Obſervatory at Greenwich, which had been lately built, namely about the year 1676; Mr. Flamſteed being then 30 years of age, and Mr. Sharp 25.

In this ſituation he continued to aſſiſt Mr. Flamſteed in making obſervations (with the mural arch, of 80 inches radius, and 140 degrees on the limb, contrived and graduated by Mr. Sharp) on the meridional zenith diſtances of the fixed ſtars, ſun, moon, and planets, with the times of their tranſits over the meridian; alſo the diameters of the ſun and moon, and their eclipſes, with thoſe of Jupiter's ſatellites, the variation of the compaſs, &c. He aſſiſted him alſo in making a catalogue of near 3000 fixed ſtars, as to their longitudes and magnitudes, their right aſcenſions and polar diſtances, with the variations of the ſame while they change their longitude by one degree.

But from the fatigue of continually obſerving the ſtars at night, in a cold thin air, joined to a weakly conſtitution, he was reduced to a bad ſtate of health; for the recovery of which he deſired leave to retire to his houſe at Horton; where, as ſoon as he found himſelf on the recovery, he began to fit up an obſervatory of his own; having firſt made an elegant and curious engine for turning all kinds of work in wood or braſs, with a maundril for turning irregular figures, as ovals, roſes, wreathed pillars, &c. Beſide theſe, he made himſelf moſt of the tools uſed by joiners, clockmakers, opticians, mathematical inſtrument-makers, &c. The limbs or arcs of his large equatorial inſtrument, ſextant, quadrant, &c, he graduated with the niceſt accuracy, by diagonal diviſions into degrees and minutes. The teleſcopes he made uſe of were all of his own making, and the lenſes ground, figured, and adjuſted with his own hands.

It was at this time that he aſſiſted Mr. Flamſteed in calculating moſt of the tables in the ſecond volume of his *Hiſtoria Cœleſtis*, as appears by their letters, to be ſeen in the hands of Mr. Sharp's friends at Horton. Likewiſe the curious drawings of the charts of all the conſtellations viſible in our hemiſphere, with the ſtill more excellent drawings of the planiſpheres both of the northern and ſouthern conſtellations. And though theſe drawings of the conſtellations were ſent to be engraved at Amſterdam by a maſterly hand, yet the originals far exceeded the engravings in point of beauty and elegance: theſe were publiſhed by Mr. Flamſteed, and both copies may be ſeen at Horton.

The mathematician meets with ſomething extraordinary in Sharp's elaborate treatiſe of *Geometry Improved* (in 4to 1717, ſigned A. S. Philomath.), 1ſt, by a large and accurate table of ſegments of circles, its conſtruction and various uſes in the ſolution of ſeveral difficult problems, with compendious tables for finding a true proportional part; and their uſe in theſe or any other tables exemplified in making logarithms, or their natural numbers, to 60 places of figures; there being a table of them for all primes to 1100, true to 61 figures. 2d, His conciſe treatiſe of Polyedra, or ſolid bodies of many baſes, both the regular ones and others: to which are added twelve new ones, with various methods of forming them, and their exact dimenſions in ſurds, or ſpecies, and in numbers: illuſtrated with a variety of copper-plates, neatly engraved by his own hands. Alſo the models of theſe polyedra he cut out in box wood with amazing neatneſs and accuracy. Indeed few or none of the mathematical inſtrument-makers could exceed him in exactly graduating or neatly engraving any mathematical or aſtronomical inſtrument, as may be ſeen in the equatorial inſtrument above mentioned, or in his ſextant, quadrants and dials of various ſorts; alſo in a curious armillary ſphere, which, beſide the common properties, has moveable circles &c, for exhibiting and reſolving all ſpherical triangles; alſo his double ſector, with many other inſtruments, all contrived, graduated and finiſhed, in a moſt elegant manner, by himſelf. In ſhort, he poſſeſſed at once a remarkably clear head for contriving, and an extraordinary hand for executing, any thing, not only in mechanics, but likewiſe in drawing, writing, and making the moſt exact and beautiful ſchemes or figures in all his calculations and geometrical conſtructions.

The quadrature of the circle was undertaken by him for his own private amuſement in the year 1699, deduced from two different ſeries, by which the truth of it was proved to 72 places of figures; as may be ſeen in the introduction to Sherwin's tables of logarithms; that is, if the diameter of a circle be 1, the circumference will be found equal to 3·14159265358979323846264338327950288419716939937510582097494459230781640 5, &c. In the ſame book of Sherwin's may alſo be ſeen his ingenious improvements on the making of logarithms, and the conſtructing of the natural ſines, tangents, and ſecants.

He alſo calculated the natural and logarithmic ſines, tangents, and ſecants, to every ſecond in the firſt minute of the quadrant: the laborious inveſtigation of which may probably be ſeen in the archives of the Royal Society, as they were preſented to Mr. Patrick Murdoch for that purpoſe; exhibiting his very neat and accurate manner of writing and arranging his figures, not to be equalled perhaps by the beſt penman now living.

The late ingenious Mr. Smeaton ſays (Philoſ. Tranſ. an. 1786, pa. 5, &c):

"In the year 1689, Mr. Flamſteed completed his mural arc at Greenwich; and, in the Prolegomena to his Hiſtoria Cœleſtis, he makes an ample acknowledgment of the particular aſſiſtance, care, and induſtry of Mr. Abraham Sharp; whom, in the month of Auguſt 1688, he brought into the obſervatory, as his amanuenſis . and being as Mr. Flamſteed tells us, not only

only a very skilful mathematician, but exceedingly expert in mechanical operations, he was principally employed in the construction of the mural arc; which in the compass of 14 months he finished, so greatly to the satisfaction of Mr. Flamsteed, that he speaks of him in the highest terms of praise.

"This celebrated instrument, of which he also gives the figure at the end of the Prolegomena, was of the radius of 6 feet $7\frac{1}{2}$ inches; and, in like manner as the sextant, was furnished both with screw and diagonal divisions, all performed by the accurate hand of Mr. Sharp. But yet, whoever compares the different parts of the table for conversion of the revolutions and parts of the screw belonging to the mural arc into degrees, minutes, and seconds, with each other, at the same distance from the zenith on different sides; and with their halves, quarters, &c, will find as notable a disagreement of the screw-work from the hand divisions, as had appeared before in the work of Mr. Tompion: and hence we may conclude, that the method of Dr. Hook, being executed by two such masterly hands as Tompion and Sharp, and found defective, is in reality not to be depended upon in nice matters.

"From the account of Mr. Flamsteed it appears also, that Mr. Sharp obtained the zenith point of the instrument, or line of collimation, by observation of the zenith stars, with the face of the instrument on the east and on the west side of the wall: and that having made the index stronger (to prevent flexure) than that of the sextant, and thereby heavier, he contrived, by means of pulleys and balancing weights, to relieve the hand that was to move it from a great part of its gravity. Mr. Sharp continued in strict correspondence with Mr. Flamsteed as long as he lived, as appeared by letters of Mr. Flamsteed's found after Mr. Sharp's death; many of which I have seen.

"I have been the more particular relating to Mr. Sharp, in the business of constructing this mural arc; not only because we may suppose it the first good and valid instrument of the kind, but because I look upon Mr. Sharp to have been the first person that cut accurate and delicate divisions upon astronomical instruments; of which, independent of Mr. Flamsteed's testimony, there still remain considerable proofs: for, after leaving Mr. Flamsteed, and quitting the department above-mentioned, he retired into Yorkshire, to the village of Little Horton, near Bradford, where he ended his days about the year 1743 (should be, in 1742); and where I have seen not only a large and very fine collection of mechanical tools, the principal ones being made with his own hands, but also a great variety of scales and instruments made with them, both in wood and brass, the divisions of which were so exquisite, as would not discredit the first artists of the present times: and I believe there is now remaining a quadrant, of 4 or 5 feet radius, framed of wood, but the limb covered with a brass plate; the subdivisions being done by diagonals, the lines of which are as finely cut as those upon the quadrants at Greenwich. The delicacy of Mr. Sharp's hand will indeed permanently appear from the copper-plates in a quarto book, published in the year 1718, intituled *Geometry Improved* by A. Sharp, Philomath." (or rather 1717, by A. S. Philomath.) "whereof not only the geometrical lines upon the plates, but the whole of the engraving of letters and figures, were done by himself, as I was told by a person in the mathematical line, who very frequently attended Mr. Sharp in the latter part of his life. I therefore look upon Mr. Sharp as the first person that brought the affair of hand division to any degree of perfection."

Mr. Sharp kept up a correspondence by letters with most of the eminent mathematicians and astronomers of his time, as Mr. Flamsteed, Sir Isaac Newton, Dr. Halley, Dr. Wallis, Mr. Hodgson, Mr. Sherwin, &c, the answers to which letters are all written upon the backs, or empty spaces, of the letters he received, in a short-hand of his own contrivance. From a great variety of letters (of which a large chest full remain with his friends) from these and many other celebrated mathematicians, it is evident that Mr. Sharp spared neither pains nor time to promote real science. Indeed, being one of the most accurate and indefatigable computers that ever existed, he was for many years the common resource for Mr. Flamsteed, Sir Jonas Moore, Dr. Halley, and others, in all sorts of troublesome and delicate calculations.

Mr. Sharp continued all his life a bachelor, and spent his time as recluse as a hermit. He was of a middle stature, but very thin, being of a weakly constitution; he was remarkably feeble the last three or four years before he died, which was on the 18th of July 1742, in the 91st year of his age.

In his retirement at Little Horton, he employed four or five rooms or apartments in his house for different purposes, into which none of his family could possibly enter at any time without his permission. He was seldom visited by any persons, except two gentlemen of Bradford, the one a mathematician, and the other an ingenious apothecary: these were admitted, when he chose to be seen by them, by the signal of rubbing a stone against a certain part of the outside wall of the house. He duly attended the dissenting chapel at Bradford, of which he was a member, every Sunday; at which time he took care to be provided with plenty of halfpence, which he very charitably suffered to be taken singly out of his hand, held behind him during his walk to the chapel, by a number of poor people who followed him, without his ever looking back, or asking a single question.

Mr. Sharp was very irregular as to his meals, and remarkably sparing in his diet, which he frequently took in the following manner. A little square hole, something like a window, made a communication between the room where he was usually employed in calculations, and another chamber or room in the house where a servant could enter; and before this hole he had contrived a sliding board: the servant always placed his victuals in this hole, without speaking or making any the least noise; and when he had a little leisure he visited his cupboard to see what it afforded to satisfy his hunger or thirst. But it often happened, that the breakfast, dinner, and supper have remained untouched by him, when the servant has gone to remove what was left—so deeply engaged had he been in calculations.—Cavities might easily be perceived in an old English oak table where he sat to write, by the frequent rubbing and wearing of his elbows.—*Gutta cavat lapidem, &c.*

By

By Mr. Sharp's epitaph it appears that he was related to archbishop Sharp. And Mr. Sharp the eminent surgeon, who it seems has lately retired from business, is the nephew of our author. Another nephew was the father of Mr. Ramsden, the present celebrated instrument maker, who says that his grand uncle Abraham, our author, was some time in his younger days an exciseman; which occupation he quitted on coming to a patrimonial estate of about 200l. a year.

Sharp, in Music, a kind of artificial note, or character, thus formed ✱: this being prefixed to any note, shews that it is to be sung or played a semitone or half note higher than the natural note is. When a Sharp is placed at the beginning of a stave or movement, it shews that all notes that are found on the same line, or space, throughout, are to be raised half a tone above their natural pitch, unless a natural intervene. When a Sharp occurs accidentally, it only affects as many notes as follow it on the same line or space, without a natural, in the compass of a bar.

SHEAVE, in Mechanics, a solid cylindrical wheel, fixed in a channel, and moveable about an axis, as being used to raise or increase the mechanical powers applied to remove any body.

SHEERS, aboard a ship, an engine used to hoist or displace the lower masts of a ship.

SHEKEL, or Shekle, an ancient Hebrew coin and weight, equal to 4 Attic drachmas, or 4 Roman denarii, or 2s. 9¼d. sterling. According to father Mersenne, the Hebrew Shekel weighs 268 grains, and is composed of 20 oboli, each obolus weighing 16 grains of wheat.

SHILLING, an English silver coin, equal to 12 pence, or the 20th part of a pound sterling.

This was a Saxon coin, being the 48th part of their pound weight. Its value at first was 5 pence; but it was reduced to 4 pence about a century before the conquest. After the conquest, the French solidus of 12 pence, which was in use among the Normans, was called by the English name of Shilling; and the Saxon Shilling of 4 pence took a Norman name, and was called the *groat*, or *great* coin, because it was the largest English coin then known in England. From this time, the Shilling underwent many alterations.

Many other nations have also their Shillings. The English Shilling is worth about 23 French sols; those of Holland and Germany about half as much, or 11½ sols; those of Flanders about 9. The Dutch Shillings are also called *sols de gros*, because equal to 12 gros. The Danes have copper Shillings, worth about one fourth of a farthing sterling.

In the time of Edward the 1st, the pound troy was the same as the pound sterling of silver, consisting of 20 Shillings; so that the Shilling weighed the 20th part of a pound, or more than half an ounce troy. But some are of opinion, there were no coins of this denomination, till Henry the 7th, in the year 1504, first coined silver pieces of 12 pence value, which we call Shillings. Since the reign of Elizabeth, a Shilling weighs the 62nd part of a pound troy, or 3 dwts. $20\frac{8}{31}$ grs. the pound weight of silver making 62 Shillings. And hence the ounce of silver is worth 5s. 2d. or $5\frac{1}{6}$ Shillings.

SHIVERS, in a ship, the seamen's term for those little round wheels, in which the rope of a pully or block runs. They turn with the rope, and have pieces of brass in their centres, into which the pin of the block goes, and on which they turn.

SHORT-SIGHTEDNESS, *myopia*, a defect in the conformation of the eye, when the crystalline &c being too convex, the rays that enter the eye are refracted too much, and made to converge too fast, so as to unite before they reach the retina, by which means vision is rendered dim and confused.

It is commonly thought that Short-sightedness wears off in old age, on account of the eye becoming flatter; but Dr. Smith questions whether this be matter of fact, or only hypothesis. It is remarkable that Short sighted persons commonly write a small hand, and love a small print, because they can see more of it at one view. That it is customary with them not to look at the person they converse with, because they cannot well see the motion of his eyes and features, and are therefore attentive to his words only. That they see more distinctly, and somewhat farther off, by a strong light, than by a weak one; because a strong light causes a contraction of the pupil, and consequently of the pencils, both here and at the retina, which lessens their mixture, and consequently the apparent confusion; and therefore, to see more distinctly, they almost close their eye-lids, for which reason they were anciently called *myopes*. Smith's Optics, vol. 2, Rem. p. 10.

Dr. Jurin observes, that persons who are much and long accustomed to view objects at small distances, as students in general, watchmakers, engravers, painters in miniature, &c, see better at small distances, and worse at great distances, than other people. And he gives the reasons, from the mechanical effect of habit in the eye. Essay on Dist. and Indist. Vision.

The ordinary remedy for Short-sightedness is a concave lens, held before the eye; for this causing the rays to diverge, or at least diminishing much of their convergency, it makes a compensation for the too great convexity of the crystalline. Dr. Hook suggests another remedy; which is to employ a convex glass, in a position between the object and the eye, by means of which, the object may be made to appear at any distance from the eye, and so the eye be made to contemplate the picture in the same manner as if the object itself were in its place. But here unfortunately the image will appear inverted: for this however he has some whimsical expedients; viz, in reading to turn the book upside down, and to learn to write upside down. As to distant objects, the Doctor asserts, from his own experience, that with a little practice in contemplating inverted objects, one gets as good an idea of them as if seen in their natural posture.

SHOT, in the Military Art, includes all sorts of balls or bullets for fire arms, from the cannon to the pistol. As to those for mortars, they are usually called shells.

Shot are mostly of a round form, though there are other shapes. Those for cannon are of iron; but those for muskets and pistols are of lead.

Cannon shot and shells are usually set up in piles, or heaps, tapering from the base towards the top: the base being either a triangle, a square, or a rectangle; from

from which the number in the pile is easily computed. See PILE.

The weight and dimensions of balls may be found, the one from the other, whether they are of iron or of lead. Thus,

The weight of an iron ball of 4 inches diameter, is 9lb, and because the weight is as the cube of the diameter, therefore as $4^3 : 9 :: d^3 : \frac{9}{64} d^3 = w$, the weight of the iron ball whose diameter is d; that is, $\frac{9}{64}$ of the cube of its diameter. And, conversely, if the weight be given, to find the diameter, it will be $\sqrt[3]{\frac{64}{9} w} = d$; that is, take $\frac{64}{9}$ or $7\frac{1}{9}$ of the weight, and the cube root of that will be the diameter of the iron ball.

For leaden balls; one of $4\frac{2}{3}$ inches diameter weighs 17 pounds; therefore as the cube of $4\frac{2}{3}$ is to 17, or nearly as $9 : 2 :: d^3 : \frac{2}{9} d^3 = w$, the weight of the leaden ball whose diameter is d, that is, $\frac{2}{9}$ of the cube of the diameter. On the contrary, if the weight be given, to find the diameter, it will be $\sqrt[3]{\frac{9}{2} w} = d$; that is, $\frac{9}{2}$ or $4\frac{1}{2}$ of the weight, and the cube root of the product. See my Conic Sections and Select Exercises, pa. 141.

SHOULDER *of a Bastion*, in Fortification, is the angle where the face and the flank meet.

SHOULDERING, in Fortification. See *Epaulement*.

SHWAN-*pan*, a Chinese instrument, composed of a number of wires, with beads upon them, which they move backwards and forwards, and which serves to assist them in their computations. See ABACUS.

SIDE, *latus*, in Geometry. The side of a figure is a line making part of the periphery of any superficial figure, viz, a part between two successive angles.

In triangles, the sides are also called *legs*. In a right-angled triangle, the two sides that include the right angle, are called *catheti*, or sometimes the *base* and *perpendicular*; and the third side, the *hypothenuse*.

SIDE *of a Polygonal Number*, is the number of terms in the arithmetical progression that are summed up to form the number.

SIDE *of a Power*, is what is usually called the root or radix.

SIDES of *Horn-works*, *Crown-works*, *Double-tenailles*, &c, are the ramparts and parapets which inclose them on the right and left, from the gorge to the head.

SIDEREAL, or SIDERIAL, something relating to the stars. As Sidereal year, day, &c, being those marked out by the stars.

SIDEREAL *Year*. See YEAR.

SIDEREAL *Day*, is the time in which any star appears to revolve from the meridian to the meridian again; which is 23 hours 56′ 4″ 6‴ of mean solar time; there being 366 Sidereal days in a year, or in the time of 365 diurnal revolutions of the sun; that is, exactly, if the equinoctial points were at rest in the heavens. But the equinoctial points go backward, with respect to the stars, at the rate of 50″ of a degree in a Julian year; which causeth the stars to have an apparent progressive motion eastward 50″ in that time. And as the sun's mean motion in the ecliptic is only 11 signs 29° 45′ 40″ 15‴ in 365 days, it follows, that at the end of that time he will be 14′ 19″ 45‴ short of that point of the ecliptic from which he set out at the beginning; and the stars will be advanced 50″ of a degree with respect to that point.

Consequently, if the sun's centre be on the meridian with any star on any given day of the year, that star will be 14′ 19″ 45‴ + 50″ or 15′ 9″ 45‴ east of the sun's centre, on the 365th day afterward, when the sun's centre is on the meridian; and therefore that star will not come to the meridian on that day till the sun's centre has passed it by 1′ 0″ 38‴ 57⁗ of mean solar time; for the sun takes so much time to go through an arc of 15′ 9″ 45‴; and then, in 365da 0^{h} 1′ 0″ 38‴ 57⁗ the star will have just completed its 366th revolution to the meridian.

In the following table, of Sidereal revolutions, the first column contains the number of revolutions of the stars; the others next it shew the times in which these revolutions are made, as shewn by a well regulated clock; and those on the right hand shew the daily accelerations of the stars, that is, how much any star gains upon the time shewn by such a clock, in the corresponding revolutions.

Revol. of the stars.	Times in which the revolutions are made.						Accelerations of the stars.

friend, as to excite his amazement upon his return; in consequence of which he set himself about erecting a genethliacal figure, in order to a presage of Thomas's future fortune.

This position of the heavens having been maturely considered *secundum artem*, the wizard, with great confidence, pronounced, that, "within two years time Simpson would turn out a greater man than himself!"

In fact, our author profited so well by the encouragement and assistance of the pedlar, afforded him from time to time when he occasionally came to Nuneaton, that, by the advice of his friend, he at length made an open profession of casting nativities himself; from which, together with teaching an evening school, he derived a pretty pittance, so that he greatly neglected his weaving, to which indeed he had never manifested any great attachment, and soon became the oracle of Nuneaton, Bosworth, and the environs. Scarce a courtship advanced to a match, or a bargain to a sale, without previously consulting the infallible Simpson about the consequences. But as to helping people to stolen goods, he always declared that above his skill; and over life and death he declared he had no power: all those called *lawful questions* he readily resolved, provided the persons were certain as to the horary *data* of the horoscope: and, he has often declared, with such success, that if from very cogent reasons he had not been thoroughly convinced of the vain foundation and fallaciousness of his art, he never should have dropt it, as he afterwards found himself in conscience bound to do.

About this time he married the widow Swinfield, in whose house he lodged, though she was then almost old enough to be his grandmother, being upwards of fifty years of age. After this the family lived comfortably enough together for some short time, Simpson occasionally working at his business of a weaver in the day-time, and teaching an evening school or telling fortunes at night; the family being also farther assisted by the labours of young Swinfield, who had been brought up in the profession of his father.

But this tranquillity was soon interrupted, and our author driven at once from his home and the profession of astrology, by the following accident. A young woman in the neighbourhood had long wished to hear or know something of her lover, who had been gone to sea; but Simpson had put her off from time to time, till the girl grew at last so importunate, that he could deny her no longer. He asked her if she would be afraid if he should raise the devil, thinking to deter her; but she declared she feared neither ghost nor devil: so he was obliged to comply. The scene of action pitched upon was a barn, and young Swinfield was to act the devil or ghost; who being concealed under some straw in a corner of the barn, was, at a signal given, to rise slowly out from among the straw, with his face marked so that the girl might not know him. Every thing being in order, the girl came at the time appointed; when Simpson, after cautioning her not to be afraid, began muttering some mystical words, and chalking round about them, till, on the signal given, up rises the taylor slow and solemn, to the great terror of the poor girl, who, before she had seen half his shoulders, fell into violent fits, crying out it was the very image of her lover; and the effect upon her was so dreadful, that it was thought either death or madness must be the consequence. So that poor Simpson was obliged immediately to abandon at once both his home and the profession of a conjuror.

Upon this occasion it would seem he fled to Derby, where he remained some two or three years, viz, from 1733 till 1735 or 1736; instructing pupils in an evening school, and working at his trade by day.

It would seem that Simpson had an early turn for versifying, both from the circumstance of a song written here in favour of the Cavendish family, on occasion of the parliamentary election at that place, in the year 1733; and from his first two mathematical questions that were published in the Ladies Diary, which were both in a set of verses, not ill written for the occasion. These were printed in the Diary for 1736, and therefore must at latest have been written in the year 1735. These two questions, being at that time pretty difficult ones, shew the great progress he had even then made in the mathematics; and from an expression in the first of them, viz, where he mentions his residence as being in latitude 52°, it appears he was not then come up to London, though he must have done so very soon after.

Together with his astrology, he had soon furnished himself with arithmetic, algebra, and geometry sufficient to be qualified for looking into the Ladies Diary (of which he had afterwards for several years the direction), by which he came to understand that there was a still higher branch of the mathematical knowledge than any he had yet been acquainted with; and this was the method of *Fluxions*. But our young analyst was quite at a loss to discover any English author who had written on the subject, except Mr. Hayes; and his work being a folio, and then pretty scarce, exceeded his ability of purchasing: however an acquaintance lent him Mr. Stone's *Fluxions*, which is a translation of the *Marquis de l'Hospital's Analyse des Infiniment Petits*: by this one book, and his own penetrating talents, he was, as we shall see presently, enabled in a very few years to compose a much more accurate treatise on this subject than any that had before appeared in our language.

After he had quitted astrology and its emoluments, he was driven to hardships for the subsistence of his family, while at Derby, notwithstanding his other industrious endeavours in his own trade by day, and teaching pupils at evenings. This determined him to repair to London, which he did in 1735 or 1736.

On his first coming to London, Mr. Simpson wrought for some time at his business in Spitalfields, and taught mathematics at evenings, or any spare hours. His industry turned to so good account, that he returned down into the country, and brought up his wife and three children, she having produced her first child to him in his absence. The number of his scholars increasing, and his abilities becoming in some measure known to the public, he was encouraged to make proposals for publishing by subscription, A new Treatise of Fluxions: wherein the Direct and Inverse Methods are demonstrated after a new, clear, and concise Manner, with their Application to Physics and Astronomy: also the Doctrine of Infinite Series and Reverting Series universally, are amply explained, Fluxionary and Exponential Equations solved: together with a variety of new and curious Problems.

When

When Mr. Simpson first proposed his intentions of publishing such a work, he did not know of any English book, founded on the true principles of Fluxions, that contained any thing material, especially the practical part; and though there had been some very curious things done by several learned and ingenious gentlemen, the principles were nevertheless left obscure and defective, and all that had been done by any of them in *infinite series*, very inconsiderable.

The book was published in 4to, in the year 1737, although the author had been frequently interrupted from furnishing the press so fast as he could have wished, through his unavoidable attention to his pupils for his immediate support. The principles of fluxions treated of in this work, are demonstrated in a method accurately true and genuine, not essentially different from that of their great inventor, being entirely expounded by finite quantities.

In 1740, Mr. Simpson published a Treatise on The Nature and Laws of Chance, in 4to. To which are annexed, Full and clear Investigations of two important Problems added in the 2d Edition of Mr. De Moivre's Book on Chances, as also two New Methods for the Summation of Series.

Our author's next publication was a 4to volume of Essays on several curious and interesting Subjects in Speculative and Mixed Mathhmatics: printed in the same year 1740: dedicated to Francis Blake, Esq. since Fellow of the Royal Society, and our author's good friend and patron.—Soon after the publication of this book, he was chosen a member of the Royal Academy at Stockholm.

Our author's next work was, The Doctrine of Annuities and Reversions, deduced from general and evident Principles: with useful Tables, shewing the Values of Single and Joint Lives, &c. in 8vo, 1742. This was followed in 1743, by an Appendix containing some Remarks on a late book on the same Subject (by Mr. Abr. De Moivre, F. R. S.) with Answers to some personal and malignant Representations in the Preface thereof. To this answer Mr. De Moivre never thought fit to reply. A new edition of this work has lately been published, augmented with the tract upon the same subject that was printed in our author's Select Exercises.

In 1743 also was published his Mathematical Differtations on a variety of Physical and Analytical Subjects, in 4to; containing, among other particulars,

A Demonstration of the true Figure which the Earth, or any Planet, must acquire from its rotation about an Axis. A general Investigation of the Attraction at the Surfaces of Bodies nearly spherical. A Determination of the Meridional Parts, and the Lengths of the several Degrees of the Meridian, according to the true Figure of the Earth. An Investigation of the Height of the Tides in the Ocean. A new Theory of Astronomical Refractions, with exact Tables deduced from the same. A new and very exact Method for approximating the Roots of Equations in Numbers; which quintuples the number of Places at each Operation. Several new Methods for the Summation of Series. Some new and very useful Improvements in the Inverse Method of Fluxions. The work being dedicated to Martin Folkes, Esq. President of the Royal Society.

His next book was A Treatise of Algebra, wherein the fundamental Principles are demonstrated, and applied to the Solution of a variety of Problems. To which he added, The Construction of a great Number of Geometrical Problems, with the Method of resolving them numerically.

This work, which was designed for the use of young beginners, was inscribed to William Jones, Esq. F. R. S. and printed in 8vo, 1745. And a new edition appeared in 1755, with additions and improvements; among which was a new and general method of resolving all Biquadratic Equations, that are complete, or having all their terms. This edition was dedicated to James Earl of Morton, F. R. S. Mr. Jones being then dead. The work has gone through several other editions since that time: the 6th, or last, was in 1790.

His next work was, "Elements of Geometry, with their Application to the Mensuration of Superficies and Solids, to the Determination of Maxima and Minima, and to the Construction of a great Variety of geometrical Problems:" first published in 1747, in 8vo. And a second edition of the same came out in 1760, with great alterations and additions, being in a manner a new work, designed for young beginners, particularly for the gentlemen educated at the Royal Military Academy at Woolwich, and dedicated to Charles Frederick, Esq. Surveyor General of the Ordnance. And other editions have appeared since.

Mr. Simpson met with some trouble and vexation in consequence of the first edition of his Geometry. First, from some reflections made upon it, as to the accuracy of certain parts of it, by Dr. Robert Simson, the learned professor of mathematicks in the university of Glasgow, in the notes subjoined to his edition of Euclid's Elements. This brought an answer to those remarks from Mr. Simpson, in the notes added to the 2d edition as above; to some parts of which Dr. Simson again replied in his notes on the next edition of the said Elements of Euclid.

The second was by an illiberal charge of having stolen his Elements from Mr. Muller, the professor of fortification and artillery at the same academy at Woolwich, where our author was professor of geometry and mathematics. This charge was made at the end of the preface to Mr. Muller's Elements of Mathematics, in two volumes, printed in 1748; which was fully refuted by Mr. Simpson in the preface to the 2d edition of his Geometry.

In 1748 came out Mr. Simpson's Trigonometry, Plane and Spherical, with the Construction and Application of Logarithms, 8vo. This little book contains several things new and useful.

In 1750 came out, in two volumes, 8vo, The Doctrine and Application of Fluxions, containing, besides what is common on the Subject, a Number of new Improvements in the Theory, and the Solution of a Variety of new and very interesting Problems in different Branches of the Mathematics.—In the preface the author offers this to the world as a new book, rather than a second edition of that which was published in 1737, in which he acknowledges, that, besides errors of the press, there are several obscurities and defects, for want of experience, and the many disadvantages he then laboured under, in his first sally.

The

The idea and explanation here given of the firſt principles of Fluxions, are not eſſentially different from what they are in his former treatiſe, though expreſſed in other terms. The conſideration of *time* introduced into the general definition, will, he ſays, perhaps be diſliked by thoſe who would have fluxions to be *mere velocities*: but the advantage of conſidering them otherwiſe, viz. not as the velocities themſelves, but as magnitudes they would uniformly generate in a given time, appears to obviate any objection on that head. By taking fluxions as mere velocities, the imagination is confined as it were to a point, and without proper care inſenſibly involved in metaphyſical difficulties. But according to this other mode of explaining the matter, leſs caution in the learner is neceſſary, and the higher orders of fluxions are rendered much more eaſy and intelligible. Beſides, though Sir Iſaac Newton defines fluxions to be the velocities of motions, yet he has recourſe to the increments or moments generated in equal particles of time, in order to determine thoſe velocities; which he afterwards teaches to expound by finite magnitudes of other kinds. This work was dedicated to George earl of Macclesfield.

In 1752 appeared, in 8vo, the *Select Exerciſes for young Proficients in the Mathematics*. This neat volume contains, A great Variety of algebraical Problems, with their Solutions. A ſelect Number of Geometrical Problems, with their Solutions, both algebraical and geometrical. The Theory of Gunnery, independent of the Conic Sections. A new and very comprehenſive Method for finding the Roots of Equations in Numbers. A ſhort Account of the firſt Principles of Fluxions. Alſo the Valuation of Annuities for ſingle and joint Lives, with a Set of new Tables, far more extenſive than any extant. This laſt part was deſigned as a ſupplement to his Doctrine of Annuities and Reverſions; but being thought too ſmall to be publiſhed alone, it was inſerted here at the end of the Select Exercises; from whence however it has been removed in the laſt editions, and referred to its proper place, the end of the Annuities, as before mentioned. The examples that are given to each problem in this laſt piece, are according to the London bills of mortality; but the ſolutions are general, and may be applied with equal facility and advantage to any other table of obſervations. The volume is dedicated to John Bacon, Eſq. F. R. S.

Mr. Simpſon's Miſcellaneous Tracts, printed in 4to, 1757, were his laſt legacy to the public: a moſt valuable bequeſt, whether we conſider the dignity and importance of the ſubjects, or his ſublime and accurate manner of treating them.

The firſt of theſe papers is concerned in determining the Preceſſion of the Equinox, and the different Motions of the Earth's Axis, ariſing from the Attraction of the Sun and Moon. It was drawn up about the year 1752, in conſequence of another on the ſame ſubject, by M. de Sylvabelle, a French gentleman. Though this gentleman had gone through one part of the ſubject with ſucceſs and perſpicuity, and his concluſions were perfectly conformable to Dr. Bradley's obſervations; it nevertheleſs appeared to Mr. Simpſon, that he had greatly failed in a very material part, and that indeed the only very difficult one; that is, in the determination of the momentary alteration of the poſition of the earth's axis, cauſed by the forces of the ſun and moon; of which forces, the quantities, but not the effects, are truly inveſtigated. The ſecond paper contains the Inveſtigation of a very exact Method or Rule for finding the Place of a Planet in its Orbit, from a Correction of Biſhop Ward's circular Hypotheſis, by Means of certain Equations applied to the Motion about the upper Focus of the Ellipſe. By this Method the Reſult, even in the Orbit of Mercury, may be found within a Second of the Truth, and that without repeating the Operation. The third ſhews the Manner of transferring the Motion of a Comet from a parabolic Orbit, to an elliptic one; being of great Uſe, when the obſerved Places of a (new) Comet are found to differ ſenſibly from thoſe computed on the Hypotheſis of a parabolic Orbit. The fourth is an Attempt to ſhew, from mathematical Principles, the Advantage ariſing from taking the Mean of a Number of Obſervations, in practical Aſtronomy; wherein the Odds that the Reſult in this Way, is more exact than from one ſingle Obſervation, is evinced, and the Utility of the Method in Practice clearly made appear. The fifth contains the Determination of certain Fluents, and the Reſolution of ſome very uſeful Equations, in the higher Orders of Fluxions, by Means of the Meaſures of Angles and Ratios, and the right and verſed Sines of circular Arcs. The 6th treats of the Reſolution of algebraical Equations, by the Method of Surd-diviſors; in which the Grounds of that Method, as laid down by Sir Iſaac Newton, are inveſtigated and explained. The 7th exhibits the Inveſtigation of a general Rule for the Reſolution of Iſoperimetrical Problems of all Orders, with ſome Examples of the Uſe and Application of the ſaid Rule. The 8th, or laſt part, comprehends the Reſolution of ſome general and very important Problems in Mechanics and Phyſical Aſtronomy; in which, among other Things, the principal Parts of the 3d and 9th Sections of the firſt Book of Newton's Principia are demonſtrated in a new and conciſe Manner. But what may perhaps beſt recommend this excellent tract, is the application of the general equations, thus derived, to the determination of the Lunar Orbit.

According to what Mr. Simpſon had intimated at the concluſion of his Doctrine of Fluxions, the greateſt part of this arduous undertaking was drawn up in the year 1750. About that time M. Clairaut, a very eminent mathematician of the French Academy, had ſtarted an objection againſt Newton's general law of gravitation. This was a motive to induce Mr. Simpſon (among ſome others) to endeavour to diſcover whether the motion of the moon's apogee, on which that objection had its whole weight and foundation, could not be truly accounted for, without ſuppoſing a change in the received law of gravitation, from the inverſe ratio of the ſquares of the diſtances. The ſucceſs anſwered his hopes, and induced him to look farther into other parts of the theory of the moon's motion, than he had at firſt intended: but before he had completed his deſign, M. Clairaut arrived in England, and made Mr. Simpſon a viſit; from whom he learnt, that he had a little before printed a piece on that ſubject, a copy of which Mr. Simpſon afterwards received as a preſent, and found in it the ſame things demonſtrated, to which he himſelf had directed his enquiry, beſides ſeveral others.

The

The facility of the method Mr. Simpson fell upon, and the extensiveness of it, will in some measure appear from this, that it not only determines the motion of the apogee, in the same manner, and with the same ease, as the other equations, but utterly excludes all that dangerous kind of terms that had embarrassed the greatest mathematicians, and would, after a great number of revolutions, entirely change the figure of the moon's orbit. From whence this important consequence is derived, that the moon's mean motion, and the greatest quantities of the several equations, will remain unchanged, unless disturbed by the intervention of some foreign or accidental cause. These tracts are inscribed to the Earl of Macclesfield, President of the Royal Society.

Besides the foregoing, which are the whole of the regular books or treatises that were published by Mr. Simpson, he wrote and composed several other papers and fugitive pieces, as follow:

Several papers of his were read at the meetings of the Royal Society, and printed in their Transactions: but as most, if not all of them, were afterwards inserted, with alterations or additions, in his printed volumes, it is needless to take any farther notice of them here.

He proposed, and resolved many questions in the Ladies Diaries, &c; sometimes under his own name, as in the years 1735 and 1736; and sometimes under feigned or fictitious names; such as, it is thought, Hurlothrumbo, Kubernetes, Patrick O'Cavenah, Marmaduke Hodgson, Anthony Shallow, Esq, and probably several others; see the Diaries for the years 1735, 1736, 42, 43, 53, 54, 55, 56, 57, 58, 59, and 60. Mr. Simpson was also the editor or compiler of the Diaries from the year 1754 till the year 1760, both inclusive, during which time he raised that work to the highest degree of respect. He was succeeded in the Editorship by Mr. Edw. Rollinson. See my Diarian Miscellany, vol. 3.

It has also been commonly supposed that he was the real editor of, or had a principal share in, two other periodical works of a miscellaneous mathematical nature; viz, the Mathematician, and Turner's Mathematical Exercises, two volumes, in 8vo, which came out in periodical numbers, in the years 1750 and 1751, &c. The latter of these seems especially to have been set on foot to afford a proper place for exposing the errors and absurdities of Mr. Robert Heath, the then conductor of the Ladies Diary and the Palladium; and which controversy between them ended in the disgrace of Mr. Heath, and expulsion from his office of editor to the Ladies Diary, and the substitution of Mr. Simpson in his stead, in the year 1753.

In the year 1760, when the plans proposed for erecting a new bridge at Blackfriars were in agitation, Mr. Simpson, among other gentlemen, was consulted upon the best form for the arches, by the New-bridge Committee. Upon this occasion he gave a preference to the semicircular form; and, besides his report to the Committee, some letters also appeared, by himself and others, on the same subject, in the public newspapers, particularly in the Daily Advertiser, and in Lloyd's Evening Post. The same were also collected in the Gentleman's Magazine for that year, page 143 and 144.

It is probable that this reference to him, gave occasion to the turning his thoughts more seriously to this subject, so as to form the design of composing a regular treatise upon it: for his family have often informed me, that he laboured hard upon this work for some time before his death, and was very anxious to have completed it, frequently remarking to them, that this work, when published, would procure him more credit than any of his former publications. But he lived not to put the finishing hand to it. Whatever he wrote upon this subject, probably fell, together with all his other remaining papers, into the hands of major Henry Watson, of the engineers, in the service of the India Company, being in all a large chest full of papers. This gentleman had been a pupil of Mr. Simpson's, and had lodged in his house. After Mr. Simpson's death, Mr. Watson prevailed upon the widow to let him have the papers, promising either to give her a sum of money for them, or else to print and publish them for her benefit. But neither of these was ever done; this gentleman always declaring, when urged on this point by myself and others, that no use could be made of any of the papers, owing to the very imperfect state in which he found they were left. And yet he persisted in his refusal to give them up again.

From Mr. Simpson's writings, I now return to himself. Through the interest and solicitations of the beforementioned William Jones, Esq, he was, in 1743, appointed professor of mathematics, then vacant by the death of Mr. Derham, in the Royal Academy at Woolwich; his warrant bearing date August 25th. And in 1745 he was admitted a fellow of the Royal Society, having been proposed as a candidate by Martin Folkes, Esq. President, William Jones, Esq. Mr. George Graham, and Mr. John Machin, Secretary; all very eminent mathematicians. The president and council, in consideration of his very moderate circumstances, were pleased to excuse his admission fees, and likewise his giving bond for the settled future payments.

At the academy he exerted his faculties to the utmost, in instructing the pupils who were the immediate objects of his duty, as well as others, whom the superior officers of the ordnance permitted to be boarded and lodged in his house. In his manner of teaching, he had a peculiar and happy address; a certain dignity and perspicuity, tempered with such a degree of mildness, as engaged both the attention, esteem and friendship of his scholars; of which the good of the service, as well as of the community, was a necessary consequence.

It must be acknowledged however, that his mildness and calmness of temper, united with a more inactive state of mind, in the latter years of his life, rendered his services less useful; and the same very easy disposition, with an innocent, unsuspecting simplicity, and playfulness of mind, rendered him often the dupe of the little tricks of his pupils. Having discovered that he was fond of listening to little amusing stories, they took care to furnish themselves with a stock; so that, having neglected to learn their lessons perfect, they would get round him in a crowd, and, instead of demonstrating a proposition, would amuse him with some comical story, at which he would laugh and shake very heartily, especially if it were tinctured with somewhat of the ludicrous

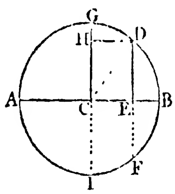
ludicrous or smutty; by which device they would contrive imperceptibly to wear out the hours allotted for instruction, and so avoid the trouble of learning and repeating their lesson. They tell also of various tricks that were practised upon him in consequence of the loss of his memory in a great degree, in the latter stage of his life.

It has been said that Mr. Simpson frequented low company, with whom he used to guzzle porter and gin: but it must be observed that the misconduct of his family put it out of his power to keep the company of gentlemen, as well as to procure better liquor.

In the latter stage of his existence, when his life was in danger, exercise and a proper regimen were prescribed him, but to little purpose; for he sunk gradually into such a lowness of spirits, as often in a manner deprived him of his mental faculties, and at last rendered him incapable of performing his duty, or even of reading the letters of his friends; and so trifling an accident as the dropping of a tea-cup would flurry him as much as if a house had tumbled down.

The physicians advised his native air for his recovery; and in February, 1761, he set out, with much reluctance (believing he should never return) for Bosworth, along with some relations. The journey fatigued him to such a degree, that upon his arrival he betook himself to his chamber, where he grew continually worse and worse, to the day of his death, which happened the 14th of May, in the fifty-first year of his age.

SINE, or *Right* Sine, of an arc, in Trigonometry, a right line drawn from one extremity of the arc, perpendicular to the radius drawn to the other extremity of it: Or, it is half the chord of double the arc. Thus the line DE is the sine of the arc BD; either because it is drawn from one end D of that arc, perpendicular to CB the radius drawn to the other end B of the arc; or also because it is half the chord DF of double the arc DBF. For the same reason also DE is the Sine of the arc AD, which is the supplement of BD to a semicircle or 180 degrees; that is, every Sine is common to two arcs, which are supplements to each other, or whose sum make up a semicircle, or 180 degrees.



Hence the Sines increase always from nothing at B till they become the radius CG, which is the greatest, being the Sine of the quadrant BG. From hence they decrease all the way along the second quadrant from G to A, till they quite vanish at the point A, thereby shewing that the Sine of the semicircle BGA, or 180 degrees, is nothing. After this they are negative all the way along the next semicircle, or 3d and 4th quadrants AFB, being drawn on the opposite side, or downwards from the diameter AB.

Whole Sine, or *Sinus Totus*, is the Sine of the quadrant BG, or of 90 degrees; that is, the Whole Sine is the same with the radius CG.

Sine-*Complement*, or *Cosine*, is the sine of an arc DG, which is the complement of another arc BD, to a quadrant. That is, the line DH is the Cosine of the arc BD; because it is the sine of DG which is the complement of BD. And for the same reason DE is the Cosine of DG. Hence the sine and Cosine and radius, of any arc, form a right-angled triangle CDE or CDH, of which the radius CD is the hypotenuse; and therefore the square of the radius is equal to the sum of the squares of the sine and Cosine of any arc, that is, $CD^2 = CE^2 + ED^2$ or $= CH^2 + DH^2$.

It is evident that the Cosine of 0 or nothing, is the whole radius CB. From B, where this Cosine is greatest, the Cosine decreases as the arc increases from B along the quadrant BDG, till it become 0 for the complete quadrant BG. After this, the Cosines, decreasing, become negative more and more all the way to the complete semicircle at A. Then the Cosines increase again all the way from A through I to B; at I the negation is destroyed, and the Cosine is equal to 0 or nothing; from I to B it is positive, and at B it is again become equal to the radius. So that, in general, the Cosines in the 1st and 4th quadrants are positive, but in the 2d and 3d negative.

Versed-Sine, is the part of the diameter between the sine and the arc. So BE is the Versed Sine of the arc BD, and AE the Versed Sine of AD, also GH the Versed Sine of DG, &c. All Versed Sines are affirmative. The sum of the Versed Sine and cosine, of any arc or angle, is equal to the radius, that is, $BE + EC = AC$.—The sine, cosine, and Versed Sine, of an arc, are also the same of an angle, or the number of degrees &c, which it measures.

The Sines &c, of every degree and minute in a quadrant, are calculated to the radius 1, and ranged in tables for use. But because operations with these natural Sines require much labour in multiplying and dividing by them, the logarithms of them are taken, and ranged in tables also; and these logarithmic Sines are commonly used in practice, instead of the natural ones, as they require only additions and subtractions, instead of the multiplications and divisions. For the method of constructing the scales of Sines &c, see the article Scale.

The Sines were introduced into trigonometry by the Arabians. And for the etymology of the word *Sine* see Introduction to my Logarithms, pa. 17 &c. And the various ways of calculating tables of the Sines, may be seen in the same place, pa. 13 &c.

Theorems for the Sines, Cosines, &c, one from another. From the definitions of them, and the common property of right-angled triangles, with that of the circle, viz, that $DE^2 = CD^2 - CE^2 = AE \times EB$, are easily deduced these following values of the Sines, &c, viz, putting

$s =$ the sine DE,
$c =$ the cosine CE,
$v =$ versed sine BE,
$\mathrm{v} =$ suppl. versed sine AE,
$r =$ radius AC or CB,
$a =$ arc BD; then

$$s = \sqrt{r^2 - c^2} = \sqrt{\mathrm{v}v} = \sqrt{2rv - vv} = \sqrt{2r\mathrm{v} - \mathrm{vv}}$$

$$c = \sqrt{r^2 - s^2} = r - v = \mathrm{v} - r = \tfrac{1}{2}\mathrm{v} - \tfrac{1}{2}v.$$

$$v = r - c = 2r - \mathrm{v} = r - \sqrt{r^2 - s^2} = \mathrm{v} - 2c.$$

$$\mathrm{v} = r + c = 2r - v = r + \sqrt{r^2 - s^2} = v + 2c.$$

The

The tangent $= \frac{rs}{\sqrt{r^2 - s^2}}$. And Cotang. $= \frac{r\sqrt{r^2 - s^2}}{s}$.

The Secant $= \frac{rr}{\sqrt{r^2 - s^2}}$. And Cosec. $= \frac{rr}{s}$.

$$s = a - \frac{a^3}{2.3r^2} + \frac{a^5}{2.3.4.5r^4} - \frac{a^7}{2.3.4.5.6.7r^6} \text{ \&c.}$$

$$a = s + \frac{s^3}{2.3r^2} + \frac{1.3s^5}{2.4.5r^4} + \frac{1.3.5s^7}{2.4.6.7r^6} \text{ \&c.}$$

$$\text{Log. } s = \text{log. } a - \text{M}\left(\frac{a^2}{6} + \frac{a^4}{180} + \frac{a^6}{2835} + \frac{a^8}{37800} \text{ \&c}\right)$$

or Log. $s = -\frac{1}{2}\text{M}\,(c^2 + \frac{1}{2}c^4 + \frac{1}{3}c^6 + \frac{1}{4}c^8 \text{ \&c})$

or Log. $s = -2\text{M}\,(z + \frac{1}{3}z^3 + \frac{1}{5}z^5 + \frac{1}{7}z^7 \text{ \&c.})$

when $z = \frac{1-s}{1+s}$, radius 1, and M $= \cdot 43429448$ &c.

If A be any other arc, S its sine, and C its cosine. Then

Sin. $\overline{A+a} = \frac{Sc + sC}{r}$. Cos. $\overline{A+a} = \frac{Cc - Ss}{r}$.

Sin. $\overline{A-a} = \frac{Sc - sC}{r}$. Cos. $\overline{A-a} = \frac{Cc + Ss}{r}$.

Sin. A $\times$ cos. $a = \frac{1}{2}$ sin. $\overline{A-a} + \frac{1}{2}$ sin. $\overline{A+a}$.

Sin. A $\times$ sin. $a = \frac{1}{2}$ cos. $\overline{A-a} - \frac{1}{2}$ cos. $\overline{A+a}$.

Cos. A $\times$ cos. $a =$ cos. $\frac{A-a}{2}$ + cos. $\frac{A+a}{2}$.

If $h = 2{\cdot}718281828$ &c, the number whose hyp. log. is 1; then

$$\text{Sin. } a = s = \frac{h^{a\sqrt{-1}} - h^{-a\sqrt{-1}}}{2\sqrt{-1}}.$$

$$\text{Cos. } a = c = \frac{h^{a\sqrt{-1}} + h^{-a\sqrt{-1}}}{2}.$$

See many other curious expressions of this kind in Bougainville's Calcul Integral, and in Bertrand's Mathematics.

From some of the foregoing theorems the Sines of a great variety of angles, or number of degrees, may be computed. Ex. gr. as below.

Angles.	*Sines.*
90°	r
75	$\frac{1}{2}r\sqrt{2+\sqrt{3}} = r \times \frac{\sqrt{6}+\sqrt{2}}{4}$
72	$\frac{1}{2}r\sqrt{\frac{5+\sqrt{5}}{2}}$
$67\frac{1}{2}$	$\frac{1}{2}r\sqrt{2+\sqrt{2}}$
60	$\frac{1}{2}r\sqrt{3}$
54	$\frac{1}{2}r\sqrt{\frac{3+\sqrt{5}}{2}} = r \times \frac{\sqrt{5}+1}{4}$
45	$\frac{1}{2}r\sqrt{2}$
36	$\frac{1}{2}r\sqrt{\frac{5-\sqrt{5}}{2}}$
30	$\frac{1}{2}r$
$22\frac{1}{2}$	$\frac{1}{2}r\sqrt{2-\sqrt{2}}$
18	$\frac{1}{2}r\sqrt{\frac{3-\sqrt{5}}{2}} = r \times \frac{\sqrt{5}-1}{4}$
15	$\frac{1}{2}r\sqrt{2-\sqrt{3}} = r \times \frac{\sqrt{6}-\sqrt{2}}{4}$

Radius being 1. Then for multiple arcs:

the Sin. $\overline{n+1}.a = 2c \times$ sin. na − sin. $\overline{n-1}.a$,

and Cos. $\overline{n+1}.a = 2c \times$ cos. na − cos. $\overline{n-1}.a$;

That is, multiplying any Sine or cosine by $2c$, and the next preceding Sine or cosine subtracted from it, it gives the next following Sine or cosine. Hence

sin. $0a = 0$.	cos. $0a = 1$ or radius.
sin. $a = s$.	cos. $a = c$.
sin. $2a = 2sc$.	cos. $2a = c^2 - s^2$.
sin. $3a = 3sc^2 - s^3$.	cos. $3a = c^3 - 3cs^2$.
sin. $4a = 4sc^3 - 4s^3c$.	cos. $4a = c^4 - 6c^2s^2 + s^4$.
sin. $5a = 5sc^4 - 10s^3c^2 + s^5$.	cos. $5a = c^5 - 10c^3s^2 + 5cs^4$.
&c.	&c.

And, in general,

$$\text{Sin. } na = nsc^{n-1} - \frac{n.\overline{n-1}.\overline{n-2}}{1.2.3}s^3c^{n-3} + \frac{n.\overline{n-1}.\overline{n-2}.\overline{n-3}.\overline{n-4}}{1.2.3.4.5}s^5c^{n-5} \text{ \&c.}$$

$$\text{or Sin. } na = ns - \frac{n.\overline{n^2-1^2}}{2.3}s^3 + \frac{n.\overline{n^2-1^2}.\overline{n^2-3^2}}{2.3.4.5}s^5 \text{ \&c.}$$

$$\text{Cos. } na = c^n - \frac{n.\overline{n-1}}{2}s^2c^{n-2} + \frac{n.\overline{n-1}.\overline{n-2}.\overline{n-3}}{2.3.4}s^4c^{n-4} \text{ \&c.}$$

$$\text{or Cos. } na = 1 - \frac{n^2}{1.2}s^2 + \frac{n^2.\overline{n^2-2^2}}{2.3.4}s^4 - \frac{n^2.\overline{n^2-2^2}.\overline{n^2-4^2}}{2.3.4.5.6}s^6 \text{ \&c.}$$

$$\text{Sin. } \tfrac{1}{2}a = r\sqrt{\frac{r-c}{2r}}. \text{ And cos. } \tfrac{1}{2}a = r\sqrt{\frac{r+c}{2r}}. \text{ Radius being } r.$$

Of the Tables of Sines, &c.

In estimating the quantity of the Sines &c, we assume radius for unity; and then compute the quantity of the Sines, tangents, and secants, in fractions of it. From Ptolomy's Almagest, we learn, that the ancients divided the radius into 60 parts, which they called degrees, and thence determined the chords in minutes,

nutes, seconds, and thirds; that is, in sexagesimal fractions of the radius, which they likewise used in the resolution of triangles. As to the Sines, tangents and secants, they are modern inventions; the Sines being introduced by the Moors or Saracens, and the tangents and secants afterwards by the Europeans. See Introd. to my Logs. pa. 1 to 19.

Regiomontanus, at first, with the ancients, divided the radius into 60 degrees; and determined the Sines of the several degrees in decimal fractions of it. But he afterwards found it would be more convenient to assume 1 for radius, or 1 with any number of cyphers, and take the Sines in decimal parts of it; and thus he introduced the present method in trigonometry. In this way, different authors have divided the radius into more or fewer decimal parts; but in the common tables of Sines and tangents, the radius is conceived as divided into 10000000 parts; by which all the Sines are estimated.

An idea of some of the modes of constructing the tables of Sines, may be conceived from what here follows: First, by common geometry the sides of some of the regular polygons inscribed in the circle are computed, from the given radius, which will be the chords of certain portions of the circumference, denoted by the number of the sides; viz, the side of the triangle the chord of the 3d part, or 120 degrees; the side of the pentagon the chord of the 5th part, or 72 degrees; the side of the hexagon the chord of the 6th part, or 60 degrees; the side of the octagon the chord of the 8th part, or 45 degrees; and so on. By this means there are obtained the chords of several of such arcs; and the halves of these chords will be the Sines of the halves of the same arcs. Then the theorem $c = \sqrt{1 - s^2}$ will give the cosines of the same half arcs. Next, by bisecting these arcs continually, there will be found the Sines and cosines of a continued series as far as we please by these two theorems,

$$\text{Sin. } \tfrac{1}{2} a = \sqrt{\frac{1-c}{2}}; \text{ and cos. } \tfrac{1}{2} a = \sqrt{\frac{1+c}{2}}.$$

Then, by the theorems for the sums and differences of arcs, from the foregoing series, will be derived the Sines and cosines of various other arcs, till we arrive at length at the arc of 1′, or 1″, &c, whose Sine and cosine thus become known.

Or, rather, the sine of 1 minute will be much more easily found from the series

$$s = a - \frac{a^3}{6} + \frac{a^5}{120} \text{ \&c,}$$

because the arc is equal to its Sine in small arcs; whence $s = a$ only in such small arcs. But the length of the arc of 180° or 10800′ is known to be 3·14159265, &c; therefore, by proportion, as 10800′ : 1′ :: 3·14159265 : 0·0002908882 = a the arc or s the sine of 1′, which number is true to the last place of decimals. Then, for the cosine of 1′, it is $c = \sqrt{1 - s^2}$ = 0·9999999577 the cosine of the same 1′.

Hence we shall readily obtain the Sines and cosines of all the multiples of 1′, as of 2′, 3′, 4′, 5′, &c, by the application of these two theorems,

$$\text{Sin. } \overline{n+1}.\, a = 2c \times \text{sin. } na - \text{sin. } \overline{n-1}.\, a,$$
$$\text{Cos. } \overline{n+1}.\, a = 2c \times \text{cos. } na - \text{cos. } \overline{n-1}.\, a;$$

for supposing a = the arc of 1′, then c = 0·9999999577, and taking n successively equal to 1, 2, 3, 4, &c, the theorems for the Sines and cosines give severally the Sines and cosines of 1′, 2′, 3′, 4′, &c; viz, the Sines thus:

$$\begin{array}{ll}
\text{sin. } 1' = s \text{ - - - - - - - - - -} & = \cdot0002908882 \\
\text{sin. } 2' = 2c \times \text{sin. } 1' - \text{sin. } 0' & = \cdot0005817764 \\
\text{sin. } 3' = 2c \times \text{sin. } 2' - \text{sin. } 1' & = \cdot0008726645 \\
\text{sin. } 4' = 2c \times \text{sin. } 3' - \text{sin. } 2' & = \cdot0011635526 \\
\text{sin. } 5' = 2c \times \text{sin. } 4' - \text{sin. } 3' & = \cdot0014544406 \\
\text{\&c.} &
\end{array}$$

And the Cosines thus,

$$\begin{array}{ll}
\text{cos. } 1' = c \text{ - - - - - - - - - -} & = \cdot9999999577 \\
\text{cos. } 2' = 2c \times \text{cos. } 1' - \text{cos. } 0' & = \cdot9999998308 \\
\text{cos. } 3' = 2c \times \text{cos. } 2' - \text{cos. } 1' & = \cdot9999996192 \\
\text{cos. } 4' = 2c \times \text{cos. } 3' - \text{cos. } 2' & = \cdot9999993231 \\
\text{cos. } 5' = 2c \times \text{cos. } 4' - \text{cos. } 3' & = \cdot9999989423 \\
\text{\&c.} &
\end{array}$$

In this manner then all the Sines and cosines are made, by only one constant multiplication and a subtraction, up to 30 degrees, forming thus the Sines of the first and last 30 degrees of the quadrant, or from 0 to 30° and from 60° to 90°; or, which will be much the same thing, the Sines only may be thus computed all the way up to 60°.

Then the Sines of the remaining 30°, from 60 to 90, will be found by one addition only for each of them, by means of this theorem, viz,

$$\text{Sin. } \overline{60 + a} = \text{sin. } \overline{60 - a} + \text{sin. } a;$$

that is, to the sine of any arc below 60°, add the Sine of its defect below 60, and the sum will be the Sine of another arc which is just as much above 60.

The Sines of all arcs being thus found, they give also very easily the versed sines, the tangents, and the secants. The versed sines are only the arithmetical complements to 1, that is, each cosine taken from the radius 1.

The tangents are found by these three theorems:

1. As cosine to sine, so is radius to tangent.

2. Radius is a mean proportional between the tangent and cotangent.

3. Half the difference between the tangent and cotangent, is equal to the tangent of the difference between the arc and its complement. Or, the sum arising from the addition of double the tangent of an arc with the tangent of half its complement, is equal to the tangent of the sum of that arc and the said half complement.

By the 1st and 2d of these theorems, the tangents are to be found for one half of the quadrant: then the other half of them will be found by one single addition, or subtraction, for each, by the 3d theorem.

This done, the secants will be all found by addition or subtraction only, by these two theorems: 1st. The secant of an arc, is equal to the sum of its tangent and the tangent of half its complement. 2nd. The secant of

of an arc, is equal to the difference between the tangent of that arc and the tangent of the arc added to half its complement.

Artificial SINES, are the logarithmic Sines, or the logarithms of the Sines.

Curve or *Figure of the* SINES. See FIGURE *of the Sines, &c.* To what is there said of the figure of the Sines, may be here added as follows, from a property just given above, viz, if x denote the abscis of this curve, or the corresponding circular arc, and y its ordinate, or the Sine of that arc; then the equation of the curve will be this,

$$y = \text{sin.}\ x = \frac{b^{x\sqrt{-1}} - b^{-x\sqrt{-1}}}{2\sqrt{-1}};$$

where $b = 2{\cdot}718281828$, &c, the number whose hyp. log. is 1.

Line of SINES, is a line on the sector, or Gunter's scale, &c, divided according to the Sines, or expressing the Sines. See those articles.

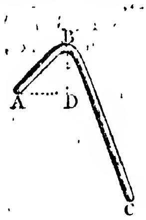
SINE *of Incidence*, or *of Reflection*, or *of Refraction*, is used for the Sine of the *angle* of incidence, &c.

SINICAL *Quadrant*, is a quadrant, made of wood or metal, with lines drawn from each side intersecting one another, with an index, divided by sines, also with 90 degrees on the limb, and two sights at the edge. Its use is to take the altitude of the sun. Instead of the lines, it is sometimes divided all into equal parts; and then it is used by seamen to resolve, by inspection, any problem of plane sailing.

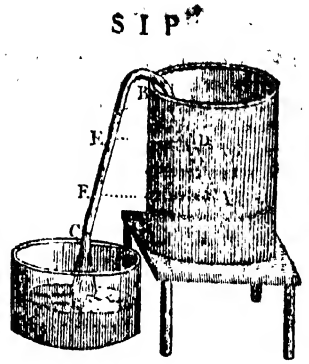
SIPHON, or SYPHON, in Hydraulics, a crooked pipe or tube used in the raising of fluids, emptying of vessels, and in various hydrostatical experiments. It is otherwise called a crane.

Wolfius describes two vessels under the name of Siphons; the one cylindrical in the middle and conical at the two extremes; the other globular in the middle, with two narrow tubes fitted to it axis-wise; both serving to take up a quantity of liquid, and to retain it when up.

But the most usual Syphon is that which is here represented; where ABC is any crooked tube, having two legs of unequal lengths; but such however that, in any position, the perpendicular altitude BD, of B above A, when AB is filled with any fluid, the weight of that fluid may not be more than about 15lb. upon every square inch of the base, or equal to the pressure of the atmosphere, because the pressure of the atmosphere will raise or suspend the fluid so high, when the tube is exhausted of air. This height is about 30 inches when the fluid is quicksilver, and about 34 feet when it is water; and so on for other fluids, according to the rarity of them.



To use the Siphon, in drawing off any fluid; immerse the shorter end A into the fluid, then suck or draw the air out by the other or lower end C, and the fluid will presently follow, and run out by the Siphon, from the vessel at A to the vessel at C; till such time as the surface of the fluid sink as low as the orifice at A,



when the decanting will cease, and the Siphon will empty itself of the fluid, the whole of that which is in it running out at C. The principle upon which the Siphon acts, is this: when the tube is exhausted of air, the pressure of the atmosphere upon the surface of the fluid at D, forces it into the tube by the orifice at A, as in the barometer tube, and down the leg BC, if B is not above the surface at D more than 34 feet for water, or 30 inches for quicksilver, &c. Here, if the external leg of the Siphon terminate at F, on a horizontal level with the immersed end at A, or rather on a level with the water at D, the perpendicular pressures of the fluid in each leg, and of the external air, against each orifice, being alike in both, the fluid will be at rest in the Siphon, completely filling it, but without running or preponderating either way. But if the external end be the lower, terminating at C, then the fluid in this end being the heavier, or having more pressure, will preponderate and run out by the orifice at C; this would leave a vacuum at B but for the continual pressure of the atmosphere at D, which forces the fluid up by A to B, and so producing a continued motion of it through the tube, and a discharge or stream at C.

Instead of sucking out the air at C, another method is, first to fill the tube completely with the fluid, in an inverted position with the angle B downward; and, stopping the two orifices with the fingers, revert the tube again, and immerge the end A in the fluid; then take off the fingers, and immediately the stream commences from the end C.

Either of the two foregoing methods can be conveniently practised when the Siphon is small, and easily managed by the hand; as in decanting off liquors from casks, &c. But when the Siphon is very large, and many feet in height, as in exhausting water from a valley or pit, the following method is then recommended: Stop the orifice C, and, by means of an opening made in the top at B, fill the tube completely with water; then stop the opening at B with a plug, and open that at C; upon which the water will presently flow out at C, and

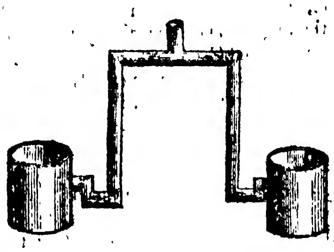
so continue till that at A is exhausted. And this method of conveying water over a hill, from one valley to another, is described by Hero, the chief author of any consequence upon this subject among the Ancients. But in this experiment it must be noted, that the effect will not be produced when the hill at B is more than 33 or 34 feet above the surface of the water at A.

In an experiment of this kind, it is even said the water in the legs, unless it be purged of its air, will not rest at a height of quite 30 feet above the water in the vessels; because air will extricate itself out of the water, and getting above the water in the legs, press it downward, so that its height will be less to balance the pressure of the atmosphere. But with very fine, or capillary tubes, the experiment will succeed to a height somewhat greater; because the attraction of the matter of the very fine tube will attract the fluid, and support it at some certain height, independent of the pressure of the atmosphere. For which reason also it is, that the experiment succeeds for small heights in the exhausted receiver; as has been tried both with water and mercury, by Desaguliers and many other philosophers. Exper. Philos. vol. 2, pa. 168.

The figure of the vessel may be varied at pleasure, provided the orifice C be but below the level of the surface of the water to be drawn up, but still the farther it is below it, the quicker will the fluid run off. And if, in the course of the efflux, the orifice A be drawn out of the fluid; all the liquor in the Siphon will issue out at the lower orifice C; that in the leg BC dragging, as it were, that in the shorter leg AB after it.

But if a filled Siphon be so disposed, as that both orifices, A and C, be in the same horizontal line; the fluid will remain pendant in each leg, how unequal soever the length of the legs may be. So that fluids in Siphons seem, as it were, to form one continued body; the heavier part descending like a chain, and drawing the lighter after it.

The *Wirtemberg* SIPHON, is a very extraordinary



machine, performing several things which the common Siphon will not reach. This Siphon was projected by Jordan Pelletier, and executed at the expence of prince Frederic Charles, administrator of Wittemberg, by his mathematician Shahackard, who made each branch 30 feet long, and set them 18 feet apart; and the description of it was published by Reiselius, the duke's physician. This gave occasion to Papin to invent another, which performed the same things, and is described in the Philos. Trans. vol. 14, or Abr. vol. 1. Reiselius, in another paper in the same volume, ingenuously owns that this is the same with the Wirtemberg Siphon.

In this engine, though the legs be on the same level, yet the water rises up the one, and descends through the other: The water rises even through the aperture if the less leg be only half immerged in water: The Siphon has its effect after continuing dry a long time: Either of the apertures being opened, the other remaining shut for a whole day, and then opened, the water flows out as usual: Lastly, the water rises and falls indifferently through either leg.

Musschenbroek, in accounting for the operation of this Siphon, observes that no discharge could be made by it, unless the water applied to either leg cause the one to be shorter, and the other longer by its own weight. Introd. ad Phil. Nat. tom. 2, pa. 853, ed. 4to. 1762.

SIRIUS, the *Dog-star*; a very bright star of the first magnitude, in the mouth of the constellation *Canis Major*, or the Great Dog.

This is the brightest of all the stars in our firmament, and therefore probably, says Dr. Maskelyne, the astronomer royal, the nearest to us of them all, in a paper recommending the discovery of its parallax, Philos. Trans. vol. 2, pa. 889. Some however suppose Arcturus to be the nearest.

The Arabs call it *Aschere*, *Elschecre*, *Scera*; the Greeks, *Sirius*; and the Latins, *Canicula*, or *Canis candens*. See CANICULA.

This is one of the earliest named stars in the whole heavens. Hesiod and Homer mention only four or five constellations, or stars, and this is one of them. Sirius and Orion, the Hyades, Pleiades, and Arcturus are almost the whole of the old poetical astronomy. The three last the Greeks formed of their own observation, as appears by the names; the two others were Egyptian. Sirius was so called from the Nile, one of the names of that river being Siris; and the Egyptians, seeing that river begin to swell at the time of a particular rising of this star, paid divine honours to the star, and called it by a name derived from that of the river, expressing the star of the Nile.

SITUS, in Algebra and Geometry, denotes the situation of lines, surfaces, &c. Wolfius delivers some things in geometry, which are not deduced from the common analysis, particularly matters depending on the *Situs* of lines and figures. Leibnitz has even founded a particular kind of analysis upon it, called *Calculus Situs*.

SKY, the blue expanse of the air or atmosphere.

The azure colour of the sky is attributed, by Newton, to vapours beginning to condense, having attained consistence enough to reflect the most reflexible rays, viz, the violet ones; but not enough to reflect any of the less reflexible ones.

De la Hire attributes it to our viewing a black object, viz the dark space beyond the regions of the atmosphere, through a white or lucid one, viz the air illuminated by the sun; a mixture of black and white always appearing blue. But this hypothesis is not originally his; being as old as Leonardo da Vinci.

SLIDING, in Mechanics, is when the same point of a body, moving along a surface, describes a line on that

that furface. Such is the motion of a parallelopipedon moved along a plane.

From Sliding arifes friction.

Sliding *Rule*, a mathematical inftrument ferving to perform computations in gauging, meafuring, &c, without the ufe of compaffes; merely by the fliding of the parts of the inftrument one by another, the lines and divifions of which give the anfwer or amount by infpection.

This inftrument is varioufly contrived and applied by different authors, particularly Gunter, Partridge, Hunt, Everard, and Coggefhall; but the moft ufual and ufeful ones are thofe of the two latter.

Everard's Sliding *Rule* is chiefly ufed in cafk gauging. It is commonly made of box, 12 inches long, 1 inch broad, and $\frac{6}{10}$ of an inch thick. It confifts of three parts; viz, the ftock juft mentioned, and two thin flips, of the fame length, fliding in fmall grooves in two oppofite fides of the ftock: confequently, when both thefe pieces are drawn out to their full extent, the inftrument is 3 feet long.

On the firft broad face of the inftrument are four logarithmic lines of numbers; for the properties &c, of which, fee Gunter's *Line*. The firft, marked A, confifting of two radii numbered 1, 2, 3, 4, 5, 6, 7, 8, 9, 1; and then 2, 3, 4, 5, &c, to 10. On this line are four brafs centre-pins, two in each radius; one in each of them being marked MB, for malt-bufhel, is fet at 2150·42 the number of cubic inches in a malt-bufhel; the other two are marked with A, for ale-gallon, at 282, the number of cubic inches in an ale gallon. The 2d and 3d lines of numbers are on the fliding pieces, and are exactly the fame with the firft; but they are diftinguifhed by the letter B. In the firft radius is a dot, marked *Si*, at ·707, the fide of a fquare infcribed in a circle whofe diameter is 1. Another dot, marked *Se*, ftands at ·886, the fide of a fquare equal to the area of the fame circle. A third dot, marked W, is at 231, the cubic inches in a wine gallon. And a fourth, marked C, at 3·14, the circumference of the fame circle whofe diameter is 1. The fourth line of numbers, marked MD, to fignify malt-depth, is a broken line of two radii, numbered 2, 10, 9, 8, 7, 6, 5, 4, 3, 2, 1, 9, 8, 7, &c; the number 1 being fet directly againft MB on the firft radius.

On the fecond broad face, marked *cd*, are feveral lines: as 1ft, a line marked D, and numbered 1, 2, 3, &c, to 10. On this line are four centre pins: the firft, marked WG, for wine-gauge, is at 17·15, the gauge-point for wine gallons, being the diameter of a cylinder whofe height is one inch, and content 231 cubic inches, or a wine gallon: the fecond centre-pin, marked AG, for ale-gauge, is at 18·95, the like diameter for an ale gallon: the 3d, marked MS, for malt fquare, is at 46·37, the fquare root of 2150·42, or the fide of a fquare whofe content is equal to the number of inches in a folid bufhel: and the fourth, marked MR, for malt-round, is at 52·32, the diameter of a cylinder, or bufhel, the area of whofe bafe is the fame 2150·42, the inches in a bufhel. 2dly, Two lines of numbers on the fliding piece, on the other fide, marked C. On thefe are two dots; the one, marked *c*, at ·0795, the area of a circle whofe circumference is 1; and the other, marked *d*, at ·785, the area of the circle whofe diameter is 1. 3dly, Two lines of fegments, each numbered 1, 2, 3, to 100; the firft for finding the ullage of a cafk, taken as the middle fruftum of a fpheroid, lying with its axis parallel to the horizon; and the other for finding the ullage of a cafk ftanding.

Again, on one of the narrow fides, noted *e*, are, 1ft, a line of inches, numbered 1, 2, 3, &c to 12, each fubdivided into 10 equal parts. 2dly, A line by which, with that of inches, we find a mean diameter for a cafk, in the figure of the middle fruftum of a fpheroid: it is marked *Spheroid*, and numbered 1, 2, 3, &c to 7. 3dly, A line for finding the mean diameter of a cafk, in the form of the middle fruftum of a parabolic fpindle, which gaugers call the fecond variety of cafks; it is therefore marked *Second Variety*, and is numbered 1, 2, 3, &c.

4thly, A line by which is found the mean diameter of a cafk of the third variety, confifting of the fruftums of two parabolic conoids, abutting on a common bafe; it is therefore marked *Third Variety*, and is numbered 1, 2, 3, &c.

On the other narrow face, marked *f*, are 1ft, a line of a foot divided into 100 equal parts, marked FM. 2dly, A line of inches, like that before mentioned, marked IM. 3dly, A line for finding the mean diameter of the fourth variety of cafks, which is formed of the fruftums of two cones, abutting on a common bafe. It is numbered 1, 2, 3, &c; and marked FC, for fruftum of a cone.

On the backfide of the two fliding pieces is a line of inches, from 12 to 36, for the whole extent of the 3 feet, when the pieces are put endwife, and againft that, the correfpondent gallons, and 100th parts, that any fmall tub, or the like open veffel, will contain at 1 inch deep.

For the various ufes of this inftrument, fee the authors mentioned above, and moft other writers on Gauging.

Coggefhall's Sliding-*Rule* is chiefly ufed in meafuring the fuperficies and folidity of timber, mafonry, brick-work, &c.

This confifts of two rulers, each a foot long, which are united together in various ways. Sometimes they are made to flide by one another, like glaziers' rules: fometimes a groove is made in the fide of a common two-foot joint rule, and a thin fliding piece in one fide, and Coggefhall's lines added on that fide; thus forming the common or Carpenter's rule: and fometimes one of the two rulers is made to flide in a groove made in the fide of the other.

On the Sliding fide of the rule are four lines of numbers, three of which are double, that is, are lines to two radii, and the fourth is a fingle broken line of numbers. The firft three, marked A, B, C, are figured 1, 2, 3, &c to 9; then 1, 2, 3, &c to 10; the conftruction and ufe of them being the fame as thofe on Everard's Sliding rule. The fingle line, called the *girt line*, and marked D, whofe radius is equal to the two radii of any of the other lines, is broken for the eafier meafuring of timber, and figured 4, 5, 6, 7, 8, 9, 10, 20, 30, &c. From 4 to 5 it is divided into 10 parts, and each 10th fubdivided into 2; and fo on from 5 to 10, &c.

On the backfide of the rule are, 1ft, a line of inch meafure, from 1 to 12; each inch being divided and fubdivided. 2dly, A line of foot meafure, confifting of

of one foot divided into 100 equal parts, and figured 10, 20, 30, &c.

The backside of the sliding piece is divided into inches, halves, &c, and figured from 12 to 24; so that when the slide is out, there may be a measure of 2 feet.

In the Carpenter's rule, the inch measure is on one side, continued all the way from 1 to 24, when the rule is unfolded, and subdivided into 8ths or half-quarters: on this side are also some diagonal scales of equal parts. And upon the edge, the whole length of 2 feet is divided into 200 equal parts, or 100ths of a foot.

SLING, a sling instrument, serving for the casting of stones &c with the greater violence.

Pliny, lib. 76, chap. 5, attributes the invention of the Sling to the Phœnicians; but Vegetius ascribes it to the inhabitants of the Balearic islands, who were celebrated in antiquity for the dextrous management of it. Florus and Strabo say, those people bore three kinds of Slings; some longer, others shorter, which they used according as their enemies were more remote or nearer hand. Diodorus adds, that the first served them for a head-band, the 2d for a girdle, and that the third they constantly carried with them in the hand. But it must be impossible to tell who were the first inventors of the Sling, as the instrument is so simple, and has been in general use by almost all nations. The instrument is much spoken of in the wars and history of the Israelites. David was so expert a slinger, that he ventured to go out, with one in his hand, against the giant and champion Goliath, and at a distance struck him on the forehead with the stone. And there were a number of left-handed men of one of the tribes of Israel, who it is said could Sling a stone at an hair's breadth.

The motion of a stone discharged from a Sling arises from its centrifugal force, when whirled round in a circle. The velocity with which it is discharged, is the same as that which it had in the circle, and is much greater than what can be given to it by the hand alone. And the direction in which it is discharged, is that of the tangent to the circle at the point of discharge. Whence its motion and effect may be computed as a projectile.

SLUSE, or SLUSIUS (*René Francis Walter*) of Vise, a small town in the county of Liege, where he enjoyed honours and preferment. He then became abbé of Amas, canon, councellor and chancellor of Liege, and made his name famous for his knowledge in theology, physics, and mathematics. The Royal Society of London elected him one of their members, and inserted several of his compositions in their Transactions. This very ingenious and learned man died at Liege in 1683, at 63 years of age.

Of Slusius's works there have been published, some learned letters, and a work intitled, *Mesolabium et Problemata solida*; beside the following pieces in the Philosophical Transactions, viz.

1. Short and Easy Method of drawing Tangents to all Geometrical Curves; vol. 7, pa. 5143.

2. Demonstration of the same; vol. 8, pa. 6059, 6119.

3. On the Optic Angle of Alhazen; vol. 8, pa. 6139.

SMEATON (JOHN), F. R. S. and a very celebrated civil engineer, was born the 28th of May 1724, at Austhorpe, near Leeds, in a house built by his grandfather, where the family have resided ever since, and where our author died the 28th of October 1792, in the 68th year of his age.

Mr. Smeaton seems to have been born an engineer. The originality of his genius and the strength of his understanding appeared at a very early age. His playthings were not those of children, but the tools men work with; and he had always more amusement in observing artificers work, and asking them questions, than in any thing else. Having watched some mill-wrights at work, he was one day, soon after, seen (to the distress of his family) on the top of his father's barn, fixing up something like a windmill. Another time, attending some men who were fixing a pump at a neighbouring village, and observing them cut off a piece of bored pipe, he contrived to procure it, of which he made a working pump that actually raised water. These anecdotes refer to circumstances that happened when he was hardly out of petticoats, and probably before he had reached the 6th year of his age. About his 14th or 15th year, he had made for himself an engine to turn rose-work; and he made several presents to his friends of boxes in ivory and wood, turned by him in that way.

His friend and partner in the Deptford Waterworks, Mr. John Holmes, an eminent clock and watch maker in the Strand, says, he visited Mr. Smeaton and spent a month with him at his father's house, in the year 1742, when consequently our author was about 18 years of age. Mr. Holmes could not but view young Smeaton's works with astonishment: he forged his own iron and steel, and melted his own metals; he had tools of every sort, for working in wood, ivory, and metals: he had made a lathe, by which he had cut a perpetual screw in brass, a thing very little known at that day.

Thus had Mr. Smeaton, by the strength of his genius, and indefatigable industry, acquired, at 18 years of age, an extensive set of tools, and the art of working in most of the mechanical trades, without the assistance of any master, and which he continued to do a part of every day when at the place where his tools were: and few men could work better.

Mr. Smeaton's father was an attorney, and was desirous of bringing him up to the same profession. He therefore came up to London in 1742, and for some time attended the courts in Westminster Hall. But finding that the profession of the law did not suit *the bent of his genius*, as his usual expression was, he wrote a strong memorial to his father on the subject, whose good sense from that moment left Mr. Smeaton to pursue the bent of his genius in his own way.

Mr. Smeaton after this continued to reside in London; and about 1750 he commenced philosophical instrument maker, which he continued for some time, and became acquainted with most of the ingenious men of that time; and this same year he made his first communication to the Royal Society, being an account of Dr. Knight's improvements of the mariner's compass. Continuing his very useful labours, and making experiments, he communicated to that learned body, the two following years, a number of other ingenious improvements,

ments, as will be enumerated in the lift of his writings, at the end of this account of him.

In 1751 he began a courfe of experiments, to try a machine of his invention, for meafuring a fhip's way at fea; and alfo made two voyages in company with Dr. Knight to try it, as well as a compafs of his own invention.

In 1753 he was elected a member of the Royal Society; and in 1759 he was honoured with their gold medal, for his paper concerning the natural powers of water and wind to turn mills, and other machines depending on a circular motion. This paper, he fays, was the refult of experiments made on working models in the years 1752 and 1753, but not communicated to the Society till 1759, having in the interval found opportunities of putting the refult of thefe experiments into real practice, in a variety of cafes, and for various purpofes, fo as to affure the Society he had found them to anfwer.

In 1754 his great thirft after experimental knowledge led him to undertake a voyage to Holland and the Low Countries, where he made himfelf acquainted with moft of the curious works of art fo frequent in thofe places.

In December 1755, the Edyftone lighthoufe was burnt down, and the proprietors, being defirous of rebuilding it in the moft fubftantial manner, enquired of the earl of Macclesfield, then prefident of the Royal Society, who he thought might be the fitteft perfon to rebuild it, when he immediately recommended our author. Mr. Smeaton accordingly undertook the work, which he completed with ftone in the fummer of 1759. Of this work he gives an ample defcription in a folio volume, with plates, publifhed in 1791. A work which contains, in a great meafure, the hiftory of four years of his life, in which the originality of his genius is fully difplayed, as well as his activity, induftry, and perfeverance.

Though Mr. Smeaton completed the building of the Edyftone lighthoufe in 1759, yet it feems he did not foon get into full bufinefs as a civil engineer; for in 1764, while in Yorkfhire, he offered himfelf a candidate for one of the receivers of the Derwentwater eftate; in which he fucceeded, though two other perfons, ftrongly recommended and powerfully fupported, were candidates for the employment. In this appointment he was very happy, by the affiftance and abilities of his partner Mr. Walton the younger, of Farnacres near Newcaftle, one of the prefent receivers, who, taking upon himfelf the management and the accounts, left Mr. Smeaton leifure and opportunity to exert his abilities on public works, as well as to make many improvements in the mills, and in the eftates of Greenwich hofpital.

By the year 1775, he had fo much bufinefs, as a civil engineer, that he was defirous of refigning the appointment for that hofpital, and would have done it then, had not his friends prevailed upon him to continue in the office about two years longer.

Mr. Smeaton having thus got into full bufinefs as a civil engineer, it would be an endlefs talk to enumerate all the variety of concerns he was engaged in. A very few of them however may be juft mentioned in this place. —He made the river Calder navigable: a work that required great fkill and judgment; owing to the very impetuous floods in that river.—He planned and attended the execution of the great canal in Scotland, for conveying the trade of the country, either to the Atlantic or German ocean; and having brought it to a conclufion, he declined a handfome yearly falary, that he might not be prevented from attending to the multiplicity of his other bufinefs.

On opening the great arch at London bridge, the excavation around and under the fterlings was fo confiderable, that it was thought the bridge was in great danger of falling; the apprehenfions of the people on this head being fo great, that few would pafs over or under it. He was then in Yorkfhire, where he was fent for by exprefs, and he arrived in town with the greateft expedition. He applied himfelf immediately to examine it, and to found about the fterlings as minutely as he could. The committee being called together, adopted his advice, which was, to repurchafe the ftones that had been taken from the middle pier, then lying in Moorfields, and to throw them into the river to guard the fterlings, a practice he had before adopted on other occafions. Nothing fhews the apprehenfions of the bridge falling, more than the alacrity with which his advice was purfued: the ftones were repurchafed that day; horfes, carts, and barges were got ready, and the work inftantly begun though it was Sunday morning. Thus Mr. Smeaton, in all human probability, faved London bridge from falling, and fecured it till more effectual methods could be taken.

In 1771, he became, jointly with his friend Mr. Holmes above mentioned, proprietor of the works for fupplying Deptford and Greenwich with water; which by their united endeavours they brought to be of general ufe to thofe they were made for, and moderately beneficial to themfelves.

About the year 1785, Mr. Smeaton's health began to decline; in confequence he then took the refolution to endeavour to avoid any new undertakings in bufinefs as much as he could, that he might thereby alfo have the more leifure to publifh fome account of his inventions and works. Of this plan however he got no more executed than the account of the Edyftone lighthoufe, and fome preparations for his intended treatife on mills; for he could not refift the folicitations of his friends in various works; and Mr. Aubert, whom he greatly loved and refpected, being chofen chairman of Ramfgate harbour, prevailed upon him to accept the office of engineer to that harbour; and to their joint efforts the public are chiefly indebted for the improvements that have been made there within thefe few years; which fully appears in a report that Mr. Smeaton gave in to the board of truftees in 1791, which they immediately publifhed.

It had for many years been the practice of Mr. Smeaton to fpend part of the year in town, and the remainder in the country, at his houfe at Aufthorpe; on one of thefe excurfions in the country, while walking in his garden, on the 16th of September 1792, he was ftruck with the palfy, which put an end to his ufeful life the 28th of October following, to the great regret of a numerous fet of friends and acquaintances.

The great variety of mills conftructed by Mr. Smeaton, fo much to the fatisfaction and advantage of the owners, will fhew the great ufe he made of his experiments

ments in 1752 and 1753. Indeed he scarcely trusted to theory in any case where he could have an opportunity to investigate it by experiment; and for this purpose he built a steam-engine at Austhorpe, that he might make experiments expressly to ascertain the power of Newcomen's steam-engine, which he improved and brought to a much greater degree of certainty, both in its construction and powers, than it was before.

During many years of his life, Mr Smeaton was a constant attendant on parliament, his opinion being continually called for. And here his natural strength of judgment and perspicuity of expression had their full display. It was his constant practice, when applied to, to plan or support any measure, to make himself fully acquainted with it, and be convinced of its merits, before he would be concerned in it. By this caution, joined to the clearness of his description, and the integrity of his heart, he seldom failed having the bill he supported carried into an act of parliament. No person was heard with more attention, nor had any one ever more confidence placed in his testimony. In the courts of law he had several compliments paid to him from the bench, by the late lord Mansfield and others, on account of the new light he threw upon difficult subjects.

As a civil engineer, he was perhaps unrivalled, certainly not excelled by any one, either of the present or former times. His building the Edystone light-house, were there no other monument of his fame, would establish his character. The Edystone rocks have obtained their name from the great variety of contrary *sets* of the tide or current in their vicinity. They are situated nearly S. S. W. from the middle of Plymouth Sound. Their distance from the port of Plymouth is about 14 miles. They are almost in the line which joins the Start and the Lizard points; and as they lie nearly in the direction of vessels coasting up and down the channel, they were unavoidably, before the establishment of a light-house there, very dangerous, and often fatal to ships. Their situation with regard to the Bay of Biscay and the Atlantic is such, that they lie open to the swells of the bay and ocean, from all the south-western points of the compass; so that all the heavy seas from the south-west quarter come uncontroled upon the Edystone rocks, and break upon them with the utmost fury. Sometimes, when the sea is to all appearance smooth and even, and its surface unruffled by the slightest breeze, the *ground swell* meeting the slope of the rocks, the sea beats upon them in a frightful manner, so as not only to obstruct any work being done on the rock, or even landing upon it, when, figuratively speaking, you might go to sea in a walnut-shell. That circumstances fraught with danger surrounding it should lead mariners to wish for a light-house, is not wonderful; but the danger attending the erection leads us to wonder that any one could be found hardy enough to undertake it. Such a man was first found in the person of Mr. H. Winstanley, who, in the year 1696, was furnished by the Trinity-house with the necessary powers. In 1700 it was finished; but in the great storm of November 1703, it was destroyed, and the projector perished in the ruins. In 1709 another, upon a different construction, was erected by a Mr. Rudyerd, which, in 1755, was unfortunately consumed by fire. The next building was under the direction of Mr. Smeaton, who, having considered the errors of the former constructions, has judiciously guarded against them, and erected a building, the demolition of which seems little to be dreaded, unless the rock on which it is erected should perish with it.—Of his works, in constructing bridges, harbours, mills, engines, &c, &c, it were endless to speak. Of his inventions and improvements of philosophical instruments, as of the air-pump, the pyrometer, hygrometer, &c, &c, some idea may be formed from the list of his writings inserted below.

In his person, Mr. Smeaton was of a middle stature, but broad and strong made, and possessed of an excellent constitution. He had a great simplicity and plainness in his manners: he had a warmth of expression that might appear, to those who did not know him well, to border on harshness; but such as were more closely acquainted with him, knew it arose from the intense application of his mind, which was always in the pursuit of truth, or engaged in the investigation of difficult subjects. He would sometimes break out hastily, when any thing was said that was contrary to his ideas of the subject; and he would not give up any thing he argued for, till his mind was convinced by sound reasoning.

In all the social duties of life, Mr. Smeaton was exemplary; he was a most affectionate husband, a good father, a warm, zealous and sincere friend, always ready to assist those he respected, and often before it was pointed out to him in what way he could serve them. He was a lover and an encourager of merit wherever he found it; and many persons now living are in a great measure indebted for their present situation to his assistance and advice. As a companion, he was always entertaining and instructive, and none could spend their time in his company without improvement.

As to the list of his writings; beside the large work abovementioned, being the History of Edystone Light-house, and numbers of reports and memorials, many of which were printed, his communications to the Royal Society, and inserted in their Transactions, are as follow:

1. An Account of Dr. Knight's Improvements of the Mariner's Compass; an. 1750, pa. 513.
2. Some improvements in the Air-pump; an. 1752, pa. 413.
3. An Engine for raising Water by Fire; being an improvement on Savary's construction, to render it capable of working itself: invented by M. de Moura, of Portugal. Ib. pa. 436.
4. Description of a new Tackle, or Combination of Pulleys. Ib. 494.
5. Experiments upon a machine for measuring the Way of a Ship at Sea. An. 1754, pa. 532.
6. Description of a new Pyrometer. Ib. pa. 598.
7. Effects of Lightning on the Steeple and Church of Lestwithial in Cornwall. An. 1757, pa. 198.
8. Remarks on the different Temperature of the Air at Edystone Light-house, and at Plymouth. An. 1758, pa. 488.
9. Experimental enquiry concerning the natural powers of Water and Wind to turn mills and other machines depending on a circular motion. An. 1759, pa. 100.

10. On

10. On the Menstrual Parallax arising from the mutual gravitation of the earth and moon, its influence on the observation of the sun and planets, with a method of observing it. An. 1768, pa. 156.

11. Description of a new method of Observing the heavenly bodies out of the meridian. An. 1768, pa. 170.

12. Observations on a Solar Eclipse. An. 1769, pa. 286.

13. Description of a new Hygrometer. An. 1771, pa. 198.

14. An Experimental Examination of the quantity and proportion of Mechanical Power, necessary to be employed in giving different degrees of velocity to heavy bodies from a state of rest. An. 1776, pa. 450.

SMOKE, or *Smoak*, a humid matter exhaled in form of vapour by the action of heat, either external or internal; or Smoke consists of palpable particles, elevated by means of the rarefying heat, or by the force of the ascending current of air, from certain bodies exposed to heat; which particles vary much in their properties, according to the substances from which they are produced.

Sir Isaac Newton observes, that Smoke ascends in the chimney by the impulse of the air it floats in: for that air, being rarefied by the heat of the fire underneath, has its specific gravity diminished; and thus, being disposed to ascend itself, it carries up the Smoke along with it. The tail of a comet, the same author supposes, ascends from the nucleus after the same manner.

Smoke of fat unctuous woods, as fir, beech, &c, makes what is called lamp-black.

There are various inventions for preventing and curing smoky chimneys: as the æolipiles of Vitruvius, the ventiducts of Cardan, the windmills of Bernard, the capitals of Serlio, the little drums of Paduanus, and several artifices of De Lorme. See also the philosophical works of Dr. Franklin. Pans, resembling sugar pans, placed over the tops of chimneys, are useful to make them draw better; and the fire-grates called register-stoves, are always a sure remedy.

In the Philosophical Transactions is the description of an engine, invented by M. Dalesme, which consumes the Smoke of all sorts of wood so effectually, that the eye cannot discover it in the room, nor the nose distinguish the smell of it, though the fire be made in the middle of the room. It consists of several iron hoops, 4 or 5 inches in diameter, which shut into one another, and is placed on a trevet.

The late invention called Argand's lamp, also consumes the Smoke, and gives a very strong light. Its principle is a thin broad cotton wick, rolled into the form of a hollow cylinder; the air passes up the hollow of it, and the Smoke is almost all consumed.

SMOKE *Jack*, is a jack for turning a spit, turned by the Smoke of the kitchen fire, by means of thin iron sails set obliquely on an axis in the flue of the chimney. See JACK.

SNELL (RODOLPH), a respectable Dutch philosopher, was born at Oudewater in 1546. He was some time professor of Hebrew and mathematics at Leyden, where he died in 1613, at 67 years of age. He was author of several works on geometry, and on all parts of the philosophy of his time; but I have not obtained a particular list of them.

SNELL (*Willebrord*), son of Rodolph above mentioned, an excellent mathematician, was born at Leyden in 1591, where he succeeded his father in the mathematical chair in 1613, and where he died in 1626, at only 35 years of age.

Willebrord Snell was author of several ingenious works and discoveries. Thus, it was he who first discovered the true law of the refraction of the rays of light; a discovery which he made before it was announced by Des Cartes, as Huygens assures us. Though the work which Snell prepared upon this subject, and upon optics in general, was never published, yet the discovery was very well known to belong to him, by several authors about his time, who had seen it in his manuscripts.—He undertook also to measure the earth. This he effected by measuring a space between Alcmaer and Bergen-op zoom, the difference of latitude between these places being 1° 11′ 30″. He also measured another distance between the parallels of Alcmaer and Leyden; and from the mean of both these measurements, he made a degree to consist of 55021 French toises or fathoms. These measures were afterwards repeated and corrected by Musschenbroek, who found the degree to contain 57033 toises.—He was author of a great many learned mathematical works, the principal of which are,

1. *Apollonius Batavus*; being the restoration of some lost pieces of Apollonius, concerning Determinate Section, with the Section of a Ratio and Space: in 4to, 1608, published in his 17th year.

2. *Eratosthenes Batavus*; in 4to, 1617. Being the work in which he gives an account of his operations in measuring the earth.

3. A translation out of the Dutch language, into Latin, of Ludolph van Collen's book *De Circulo & Adscriptis*, &c; in 4to, 1619.

4. *Cyclometricus, De Circuli Dimensione* &c; 4to, 1621. In this work, the author gives several ingenious approximations to the measure of the circle, both arithmetical and geometrical.

5. *Tiphys Batavus*; being a treatise on Navigation and Naval Affairs; in 4to, 1624.

6. A posthumous treatise, being four books *Doctrinæ Triangulorum Canonicæ*; in 8vo, 1627. In which are contained the canon of secants; and in which the construction of sines, tangents, and secants, with the dimension or calculation of triangles, both plane and spherical, are briefly and clearly treated.

7. Hessian and Bohemian Observations; with his own notes.

8. *Libra Astronomica & Philosophica*; in which he undertakes the examination of the principles of Galileo concerning comets.

9. Concerning the Comet which appeared in 1618, &c.

SNOW, a well known meteor, formed by the freezing of the vapours in the atmosphere. It differs from hail and hoar-frost in being as it were crystallized, which they are not. This appears on examination of a flake of Snow by a magnifying glass; when the whole of it appears to be composed of fine shining spicula diverging like rays from a centre. As the flakes descend through

through the atmofphere, they are continually joined by more of thefe radiated fpicula, and thus increafe in bulk like the drops of rain or hailftones; fo that it feems as if the whole body of Snow were an infinite mafs of icicles irregularly figured.

The lightnefs of Snow, although it is firm ice, is owing to the excefs of its furface, in comparifon to the matter contained under it; as even gold itfelf may be extended iu furface, till it will float upon the leaft breath of air.

According to Beccaria, clouds of Snow differ in nothing from clouds of rain, but in the circumftance of cold that freezes them. Both the regular diffufion of the Snow, and the regularity of the ftructure of its parts, fhew that clouds of Snow are acted upon by fome uniform caufe like electricity; and he endeavours to fhew how electricity is capable of forming thefe figures. He was confirmed in his conjectures by obferving, that his apparatus for fhewing the electricity of the atmofphere, never failed to be electrified by Snow as well as by rain. Profeffor Wintrop fometimes found his apparatus electrified by Snow when driven about by the wind, though it had not been affected by it when the Snow itfelf was falling. A more intenfe electricity, according to Beccaria, unites the particles of hail more clofely than the more moderate electricity does thofe of Snow, in the fame manner as we fee that the drops of rain which fall from the thunder-clouds, are larger than thofe which fall from others, though the former defcend through a lefs fpace.

In the northern countries, the ground is covered with fnow for feveral months; which proves exceedingly favourable for vegetation, by preferving the plants from thofe intenfe frofts which are common in fuch countries, and which would certainly deftroy them. Bartholin afcribes great virtues to Snow-water, but experience does not feem to warrant his affertions. Snow-water, or ice-water, is always deprived of its fixed air: and thofe nations who live among the Alps, and ufe it for their conftant drink, are fubject to affections of the throat, which it is thought are occafioned by it.

From fome late experiments on the quantity of water yielded by Snow, it appears that the latter gives only about one-tenth of its bulk in water.

SOCIETY, an affemblage or union of feveral learned perfons, for their mutual affiftance, improvement, or information, and for the promotion of philofophical or other knowledge. There are various philofophical Societies inftituted in different parts of the world. See ROYAL *Society*.

American Philofophical SOCIETY, was eftablifhed at Philadelphia in the year 1769, for promoting ufeful knowledge, under the direction of a patron, a prefident, three vice-prefidents, a treafurer, four fecretaries, and three curators. The firft volume of their Tranfactions comprehends a period of two years, viz, from Jan. 1, 1769, to Jan. 1, 1771. Their labours feem to have been interrupted during the troubles in America, which commenced foon after; but fince their termination, fome more volumes have been publifhed, containing a number of very ingenious and ufeful memoirs.

American Academy of Arts and Sciences, was eftablifhed by a law of the Commonwealth of Maffachufetts in North America, in the year 1780.

Bofton Academy of Arts and Sciences. This is a Society fimilar to the former, which has lately been eftablifhed at Bofton in New England, under the title of the Academy of Arts and Sciences &c.

Berlin SOCIETY. The Society of Natural Hiftorians at Berlin, was founded by Dr. Martini. There is alfo a Philofophical Society in the fame place.

Bruffels SOCIETY. The Imperial and Royal Academy of Sciences and Belles Lettres of Bruffels was founded in 1773. Several volumes of their Tranfactions have now been publifhed.

Dublin SOCIETY. This is an Experimental Society, for promoting natural knowledge, which was inftituted in 1777: the members meet once a week, and diftribute three honorary gold medals annually for the moft approved difcovery, invention, or effay, on any mathematical or philofophical fubject. The Society is under the direction of a prefident, two vice-prefidents, and a fecretary.

Edinburgh Philofophical SOCIETY, fucceeded the Medical Society, and was formed upon the plan of including all the different branches of natural knowledge and the antiquities of Scotland. The meetings of this Society, interrupted in 1745, were revived in 1752; and in 1754 the firft volume of their collection was publifhed, under the title of Effays or Obfervations Phyfical and Literary, which has been fucceeded by other volumes. This Society has been lately incorporated by royal charter, under the name of the Royal Society of Scotland, inftituted for the advancement of learning and ufeful knowledge. The members are divided into two claffes, phyfical and literary; and thofe who are near enough to Edinburgh to attend the meetings, pay a guinea on admiffion, and the fame fum annually. The firft meeting was held on the firft Monday of Auguft 1783; when there were chofen, a prefident, two vice-prefidents, a fecretary, treafurer, and a council of 12 perfons. Three of the volumes of their Tranfactions have been publifhed, which are very refpectable both for their magnitude and contents.

In *France* there have been feveral inftitutions of this kind for the improvement of fcience, befides thofe recounted under the word ACADEMY: As, the Royal Academy at Soiffons, founded in 1674; at Villefranche, Beaujolois, in 1679; at Nifmes, in 1682; at Angers, in 1685; the Royal Society at Montpelier, in 1706, which is fo intimately connected with the Royal Academy of Sciences of Paris, as to form with it, in fome refpects, one body; the literary productions of this Society are publifhed in the memoirs of the academy: the Royal Academy of Sciences and Belles Lettres at Lyons, in 1700; at Bourdeaux, in 1703; at Marfeilles, in 1726; at Rochelle, in 1734; at Dijon, in 1740; at Pau in Bern, in 1721; at Beziers, in 1723; at Montauban, in 1744; at Rouen, in 1744; at Amiens, in 1750; at Touloufe, in 1750; at Befançon, in 1752; at Metz, in 1760; at Arras, in 1773; and at Chalons fur Maine, in 1775. For other inftitutions of a fimilar nature, and their literary productions, fee the articles ACADEMY, JOURNAL, and TRANSACTIONS.

Manchefter Literary and Philofophical SOCIETY, is of confiderable reputation, and has been lately eftablifhed there, under the direction of two prefidents, four vice-prefidents, and two fecretaries. The number of

of members is limited to 50; besides these there are several honorary members, all of whom are elected by ballot; and the officers are chosen annually in April. Several valuable essays have been already read at the meetings of this Society.

Newcastle-upon-Tyne Literary and Philosophical Society. This Society was instituted the 7th of February 1793, under the direction of a president, four vice-presidents, two secretaries, a treasurer, which together with four of the ordinary members form a committee, all annually elected at a general meeting. The subjects proposed for the consideration and improvement of this Society, comprehend the mathematics, natural philosophy and history, chemistry, polite literature, antiquities, civil history, biography, questions of general law and policy, commerce, and the arts. From such ample scope in the objects of the Society, with the known respectability, zeal, and talents of the members, the greatest improvements and discoveries may be expected to be made in those important branches of useful knowledge.

SOCRATES, the chief of the ancient philosophers, was born at Alopece, a small village of Attica, in the 4th year of the 77th olympiad, or about 467 years before Christ. Sophroniscus, his father, being a statuary or carver of images in stone, our author followed the same profession for some time, for a subsistence. But being naturally averse to this profession, he only followed it when necessity compelled him; and upon getting a little before-hand, would for a while lay it aside. These intermissions of his trade were bestowed upon philosophy, to which he was naturally addicted; and this being observed by Crito, a rich philosopher of Athens, Socrates was at length taken from his shop, and put into a condition of philosophising at his ease and leisure.

He had various instructors in the sciences, as Anaxagoras, Archylaus, Damon, Prodicus, to whom may be added the two learned women Diotyma and Aspasia, of the last of whom he learned rhetoric: of Euenus he learned poetry; of Ichomachus, husbandry; and of Theodorus, geometry.

At length he began himself to teach; and was so eloquent, that he could lead the mind to approve or disapprove whatever he pleased; but never used this talent for any other purpose than to conduct his fellow citizens into the path of virtue. The academy of the Lycæum, and a pleasant meadow without the city on the side of the river Ilyssus, were places where he chiefly delivered his instructions, though it seems he was never out of his way in that respect, as he made use of all times and places for that purpose.

He is represented by Xenophon as excellent in all kinds of learning, and particularly instances arithmetic, geometry, and astrology or astronomy: Plato mentions natural philosophy; Idomeneus, rhetoric; Laertius, medicine. Cicero affirms, that by the testimony of all the learned, and the judgment of all Greece, he was, as well in wisdom, acuteness, politeness, and subtlety, as in eloquence, variety, and richness, in whatever he applied himself to, without exception, the prince of all.

It has been observed by many, that Socrates little affected travel; his life being wholly spent at home, excepting when he went out upon military services. In the Peloponnesian war he was thrice personally engaged: upon which occasions it is said he outwent all the soldiers in hardiness: and if at any time, saith Alcibiades, as it often happens in war, the provisions failed, there were none who could bear the want of meat and drink like Socrates; yet, on the other hand, in times of feasting, he alone seemed to enjoy them; and though of himself he would not drink, yet being invited, he far outdrank every one, though he was never seen intoxicated.

To this great philosopher Greece was principally indebted for her glory and splendor. He formed the manners of the most celebrated persons of Greece, as Alcibiades, Xenophon, Plato, &c. But his great services and the excellent qualities of his mind could not secure him from envy, persecution, and calumny. The thirty tyrants forbad his instructing youth; and as he derided the plurality of the Pagan deities, he was accused of impiety. The day of trial being come, Socrates made his own defence, without procuring an advocate, as the custom was, to plead for him. He did not defend himself with the tone and language of a suppliant or guilty person, but, as if he were master of the judges themselves, with freedom, firmness, and some degree of contumacy. Many of his friends also spoke in his behalf; and lastly, Plato went up into the chair, and began a speech in these words: "Though I, Athenians, am the youngest of those that come up into this place"—but they stopped him, crying out, "of those that go down," which he was thereupon constrained to do; and then proceeding to vote, they condemned Socrates to death, which was effected by means of poison, when he was 70 years of age. Plato gives an affecting account of his imprisonment and death, and concludes, "This was the end of the best, the wisest, and the justest of men." And that account of it by Plato, Tully professes, he could never read without tears.

As to the person of Socrates, he is represented as very homely; he was bald, had a dark complexion, a flat nose, eyes sticking out, and a severe downcast look. But the defects of his person were amply compensated by the virtues and accomplishments of his mind. Socrates was indeed a man of all virtues; and so remarkably frugal, that how little soever he had, it was always enough. When he was amidst a great variety of rich and expensive objects, he would often say to himself, "How many things are there which I do not want!"

Socrates had two wives, one of which was the noted Xantippe; whom Aulus Gellius describes as an accursed froward woman, always chiding and scolding, by day and by night, and whom it was said he made choice of as a trial and exercise of his temper. Several instances are recorded of her impatience and his forbearance. One day, before some of his friends, she fell into the usual extravagances of her passion; when he, without answering a word, went abroad with them; but on his going out of the door, she ran up into the chamber, and threw down water upon his head; upon which, turning to his friends, "Did not I tell you

(says he), that after so much thunder we should have rain?" Another time she pulled his cloak from his shoulders in the open forum; and some of his friends advising him to beat her, "Yes (says he), that while we two fight, you may all stand by, and cry, Well done, Socrates; to him, Xantippe."

They who affirm that Socrates wrote nothing, mean only in respect to his philosophy; for it is attested and allowed, that he assisted Euripides in composing tragedies, and was the author of some pieces of poetry. Dialogues also and epistles are ascribed to him: but his philosophical disputations were committed to writing only by his scholars; and that chiefly by Plato and Xenophon. The latter set the example to the rest in doing it first, and also with the greatest punctuality; as Plato did it with the most liberty, intermixing so much of his own, that it is hardly possible to know what part belongs to each. Hence Socrates, hearing him recite his Lysis, cried out, "How many things doth this young man feign of me!" Accordingly, the greatest part of his philosophy is to be found in the writings of Plato. To Socrates is ascribed the first introduction of moral philosophy. Man having a twofold relation to things divine and human, his doctrines were with regard to the former metaphysical, to the latter moral. His metaphysical opinions were chiefly, that, There are three principles of all things, God, matter, and idea. God is the universal intellect; matter the subject of generation and corruption; idea, an incorporeal substance, the intellect of God; God the intellect of the world. God is one, perfect in himself, giving the being and well-being of every creature.—That God, not chance, made the world and all creatures, is demonstrable from the reasonable disposition of their parts, as well for use as defence; from their care to preserve themselves, and continue their species.—That he particularly regards man in his body, appears from his noble upright form, and from the gift of speech; in his soul, from the excellency of it above others.—That God takes care of all creatures, is demonstrable from the benefit he gives them of light, water, fire, and fruits of the earth in due season. That he hath a particular regard of man, from the destination of all plants and creatures for his service; from their subjection to man, though they may exceed him ever so much in strength; from the variety of man's sense, accommodated to the variety of objects, for necessity, use, and pleasure; from reason, by which he discourseth through reminiscence from sensible objects; from speech, by which he communicates all he knows, gives laws, and governs states. Finally, that God, though invisible himself, at once sees all, hears all, is every where, and orders all.

As to the other great object of metaphysical research, the soul, Socrates taught, that it is pre-existent to the body, endued with the knowledge of eternal ideas, which in its union to the body it loseth, as stupefied, until awakened by discourse from sensible objects; on which account, all its learning is only reminiscence, a recovery of its first knowledge. That the body, being compounded, is dissolved by death; but that the soul, being simple, passeth into another life, incapable of corruption. That the souls of men are divine. That the souls of the good after death are in a happy state, united to God in a blessed inaccessible place; that the bad in convenient places suffer condign punishment.

All the Grecian sects of philosophers refer their origin to the discipline of Socrates; particularly the Platonics, Peripatetics, Academics, Cyrenaics, Stoics, &c.

SOL, in Astrology, &c, signifies the sun.

SOLAR, something relating to the sun. Thus, we say Solar fire in contradistinction to culinary fire.

SOLAR *Civil Month*. See MONTH.

SOLAR *Cycle*. See CYCLE.

SOLAR *Comet*. See DISCUS.

SOLAR *Eclipse*, is a privation of the light of the sun, by the interposition of the opake body of the moon. See ECLIPSE.

SOLAR *Month*, *Rising*, *Spots*. See the substantives.

SOLAR *System*, the order and disposition of the several heavenly bodies, which revolve round the sun as the centre of their motion; viz, the planets, primary and secondary, and the comets. See SYSTEM.

SOLAR *Year*. See YEAR.

SOLID, in Physics, a body whose minute parts are connected together, so as not to give way, or slip from each other, on the smallest impression. The word is used in this sense, in contradistinction to fluid.

SOLID, in Geometry, is a magnitude extended in every possible direction, quite around. Though it is commonly said to be endued with three dimensions only, length, breadth, and depth or thickness.

Hence, as all bodies have these three dimensions, and nothing but bodies, Solid and body are often used indiscriminately.

The extremes of Solids are surfaces. That is, Solids are terminated either by one surface, as a globe, or by several, either plane or curved. And from the circumstances of these, Solids are distinguished into regular and irregular.

Regular SOLIDS, are those that are terminated by regular and equal planes. These are the tetraedron, hexaedron, or cube, octaedron, dodecaedron, and icosaedron; nor can there possibly be more than these five regular Solids or bodies, unless perhaps the sphere or globe be considered as one of an infinite number of sides. See these articles severally, also the article *Regular* BODY.

Irregular SOLIDS, are all such as do not come under the definition of regular ones: such as cylinder, cone, prism, pyramid, &c.

Similar Solids are to one another in the triplicate ratio of their like sides, or as the cubes of the same. And all sorts of prisms, as also pyramids, are to one another in the compound ratio of their bases and altitudes.

SOLID *Angle*, is that formed by three or more plane angles meeting in a point; like an angle of a die, or the point of a diamond well cut.

The sum of all the plane angles forming a Solid angle, is always less than 360°; otherwise they would constitute the plane of a circle, and not a Solid.

Atmosphere of SOLIDS. See ATMOSPHERE.

SOLID *Bastion*. See BASTION.

Cubature of SOLIDS. See CUBATURE and SOLIDITY.

Measure

Measure of a Solid. See Measure.

Solid *Foot*. See Foot.

Solid *Numbers*, are those which arise from the multiplication of a plane number, by any other number whatever. Thus, 18 is a Solid number, produced from the plane number 6 and 3, or from 9 and 2.

Solid *Place*. See Locus.

Solid *Problem*, is one which cannot be constructed geometrically; but by the intersection of a circle and a conic section, or by the intersection of two conic sections. Thus, to describe an isosceles triangle on a given base, so that either angle at the base shall be triple of that at the vertex, is a Solid problem, resolved by the intersection of a parabola and circle, and it serves to inscribe a regular heptagon in a given circle.

In like manner, to describe an isosceles triangle having its angles at the base each equal to 4 times that at the vertex, is a Solid problem, effected by the intersection of an hyperbola and a parabola, and serves to inscribe a regular nonagon in a given circle.

And such a problem as this has four solutions, and no more; because two conic sections can intersect but in 4 points.

How all such problems are constructed, is shewn by Dr. Halley, in the Philos. Trans. num. 188.

Solid *of Least Resistance*. See Resistance.

Surfaces of Solids. See Area and Superficies.

Solid *Theorem*. See Theorem.

SOLIDITY, in Physics, a property of matter or body, by which it excludes every other body from that place which is possessed by itself.

Solidity in this sense is a property common to all bodies, whether solid or fluid. It is usually called *impenetrability*; but Solidity expresses it better, as carrying with it somewhat more of positive than the other, which is a negative idea.

The idea of Solidity, Mr. Locke observes, arises from the resistance we find one body makes to the entrance of another into its own place. Solidity, he adds, seems the most extensive property of body, as being that by which we conceive it to fill space; it is distinguished from mere space, by this latter not being capable of resistance or motion.

It is distinguished from hardness, which is only a firm cohesion of the solid parts.

The difficulty of changing situation gives no more Solidity to the hardest body than to the softest; nor is the hardest diamond properly a jot more solid than water. By this we distinguish the idea of the extension of body, from that of the extension of space: that of body is the continuity or cohesion of solid, separable, moveable parts; that of space the continuity of unsolid, inseparable, immoveable parts.

The Cartesians however will, by all means, deduce Solidity, or as they call it impenetrability, from the nature of extension; they contend, that the idea of the former is contained in that of the latter; and hence they argue against a vacuum. Thus, say they, one cubic foot of extension cannot be added to another without having two cubic feet of extension; for each has in itself all that is required to constitute that magnitude. And hence they conclude, that every part of space is solid, or impenetrable, as of its own nature it excludes all others. But the conclusion is false, and the instance they give follows from this, that the parts of space are immoveable, not from their being impenetrable or solid. See Matter.

Solidity is also used for hardness, or firmness; as opposed to fluidity; viz, when body is considered either as fluid or solid, or hard or firm.

Solidity, in Geometry, denotes the quantity of space contained in a solid body, or occupied by it; called also the *solid content*, or the *cubical content*; for all solids are measured by cubes, whose sides are inches, or feet, or yards, &c; and hence the Solidity of a body is said to be so many cubic inches, feet, yards, &c, as will fill its capacity or space, or another of an equal magnitude.

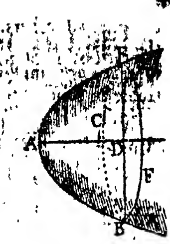
The Solidity of a cube, parallelopipedon, cylinder, or any other prismatic body, i. e. one whose parallel sections are all equal and similar throughout, is found by multiplying the base by the height or perpendicular altitude. And of any cone or other pyramid, the Solidity is equal to one-third part of the same prism, because any pyramid is equal to the 3d part of its circumscribing prism. Also, because a sphere or globe may be considered as made up of an infinite number of pyramids, whose bases form the surface of the globe, and their vertices all meet in the centre, or having their common altitude equal to the radius of the globe; therefore the solid content of it is equal to one-third part of the product of its radius and surface. For the Solidity of other figures, see each figure separately.

The foregoing rules are such as are derived from common geometry. But there are in nature numberless other forms, which require the aid of other methods and principles, as follows.

Of the Solidity *of Bodies formed by a Plane revolving about any Axis, either within or without the Body.*—Concerning such bodies, there is a remarkable property or relation between their Solidity and the path or line described by the centre of gravity of the revolving plane; viz, the Solidity of the body generated, whether by a whole revolution, or only a part of one, is always equal to the product arising from the generating plane drawn into the path or line described by its centre of gravity, during its motion in describing the body. And this rule holds true for figures generated by all sorts of motion whatever, whether rotatory, or direct or parallel, or irregularly zigzag, &c, provided the generating plane vary not, but continue the same throughout. And the same law holds true also for all surfaces any how generated by the motion of a right line. This is called the Centrobaric method. See my Mensuration, sect. 3, part 4, pa. 501, 2d edit.

Of the Solidity *of Bodies by the Method of Fluxions.*—This method applies very advantageously in all cases also in which a body is conceived to be generated by the revolution of a plane figure about an axis, or, which is much the same thing, by the parallel motion of a circle, gradually expanding and contracting itself, according to the nature of the generating plane. And this method is particularly useful for the solids generated by any curvilineal plane figures. Thus, let the plane AED revolve about the axis AD; then it will generate the solid ABFEC. But as every ordinate DE, perpendicular

pendicular to the axis AD, describes a circle BCEF in the revolution, therefore the same solid may be conceived as generated by a circle BCEF, gradually expanding itself larger and larger, and moving perpendicularly along the axis AD. Consequently the area of that circle being drawn into the fluxion of the axis, will produce the fluxion of the solid; and therefore the fluent, when taken, will give the Solidity of that body. That is, AD × circle BCF, (whose radius is DE, or diameter BE) is the fluxion of the Solidity.



Hence then, putting $AD = x$, $DE = y$, $c = 3\cdot1416$; because cy^2 is equal to the area of the circle BCF; therefore $cy^2\dot{x}$ is the fluxion of the solid. Consequently if the value of either y^2 or $\dot{x}$ be found in terms of each other, from the given equation expressing the nature of the curve, and that value be substituted for it in the fluxional expression $cy^2\dot{x}$, the fluent of the resulting quantity, being taken, will be the required Solidity of the body.

For Ex. Suppose the figure of a parabolic conoid, generated by the rotation of the common parabola ADE about its axis AD. In this case, the equation of the curve of the parabola is $px = y^2$, where p denotes the parameter of the axis. Substituting therefore px instead of y^2, in the fluxion $cy^2\dot{x}$, it becomes $cpx\dot{x}$; and the fluent of this is $\frac{1}{2}cpx^2 = \frac{1}{2}cxy^2$ for the Solidity; that is, half the product of the base of the solid drawn into its altitude; for cy^2 is the area of the circular base BCF, and x is the altitude. And so on for other such figures. See the content of each solid under its proper article.

For the Solidity *of Irregular Solids*, or such as cannot be considered as generated by some regular motion or description; they must either be considered as cut or divided into several parts of known forms, as prisms, or pyramids, or wedges, &c, and the contents of these parts found separately. Or, in the case of the smaller bodies, of forms so irregular as not to be easily divided in that way, put them into some hollow regular vessel, as a hollow cylinder or parallelopipedon, &c; then pour in water or sand so as it may fill the vessel just up to the top of the inclosed irregular body, noting the height it rises to; then take out the body, and note the height the fluid again stands at; the difference of these two heights is to be considered as the altitude of a prism of the same base and form as the hollow vessel; and consequently the product of that altitude and base will be the accurate Solidity of the immerged body, be it ever so irregular.

SOLSTICE, in Astronomy, is the time when the sun is in one of the solstitial points, that is, when he is at the greatest distance from the equator, which is now nearly 23° 28′ on either side of it. It is so called, because the sun then seems to stand still, and not to change his place, as to declination, either way.

There are two Solstices, in each year, when the sun is at the greatest distance on the north and south sides of the ecliptic; viz, the *estival* or *summer solstice*, and the *hyemal* or *winter solstice*.

The *Summer Solstice* is when the sun is in the tropic of Cancer, which is about the 21st of June, when he makes the longest day. And the [illegible]

The *Winter Solstice* is when he enters the first degree of Capricorn; which is about the 22d day of December, when he makes the shortest day.

This is to be understood, as in our northern hemisphere; for in the southern, the sun's entrance into Capricorn makes their summer Solstice, and that into Cancer the winter one. So that it is more precise and determinate, to say the northern and southern Solstice.

SOLSTITIAL *Points*, are those points of the ecliptic the sun is in at the times of the two Solstices, being the first points of Cancer and Capricorn, which are diametrically opposite to each other.

Solstitial *Colure*, is that which passes through the Solstitial points.

SOLUTION, in Mathematics, is the answering or resolving of a question or problem that is proposed. See Resolution, and Reduction *of Equations*.

Solution, in Physics, is the reduction of a solid or firm body, into a fluid state, by means of some menstruum.—Solution is often confounded with what is called dissolution, though there is a difference.

SOSIGENES, was an Egyptian mathematician, whose principal studies were chronology and the mathematics in general, and who flourished in the time of Julius Cæsar. He is represented as well versed in the mathematics and astronomy of the Ancients; particularly of those celebrated mathematicians, Thales, Archimedes, Hipparchus, Calippus, and many others, who had undertaken to determine the quantity of the solar year; which they had ascertained much nearer the truth than one can well imagine they should, with instruments so very imperfect; as may appear by reference to Ptolomy's Almagest.

It seems Sosigenes made great improvements, and gave proofs of his being able to demonstrate the certainty of his discoveries; by which means he became popular, and obtained repute with those who had a genius to understand and relish such enquiries. Hence he was sent for by Julius Cæsar, who being convinced of his capacity, employed him in reforming the calendar; and it was he who formed the Julian year which begins 45 years before the birth of Christ. His other works are lost since that period.

SOUND, in Geography, denotes a strait or inlet of the sea, between two capes or head-lands.

The Sound is used, by way of eminence, for that celebrated strait which connects the German sea to the Baltic. It is situated between the island of Zealand and the coast of Schonen. It is about 16 leagues in length, and in general about 5 in breadth, except near the castle of Cronenberg, where it is but one; so that there is no passage for vessels but under the cannon of the fortress.

Sound, in Physics, a perception of the mind, communicated by means of the ear; being an effect of the collision of bodies, and their consequent tremulous motion, communicated to the ambient fluid, and so propagated through it to the organs of hearing.

To illustrate the cause of Sound, it is to be observed, 1st, That a motion is necessary in the sonorous body for the production of sound. 2dly, That this motion exists first in the small and insensible parts of the sonorous bodies

bodies, and is excited in them by their mutual collision against each other, which produces the tremulous motion so observable in bodies that have a clear sound, as bells, musical chords, &c. 3dly, That this motion is communicated to, or produces a like motion in the air, or such parts of it as are fit to receive and propagate it. Lastly, That this motion must be communicated to those parts that are the proper and immediate instruments of hearing.

Now that motion of a sonorous body, which is the immediate cause of Sound, may be owing to two different causes; either the percussion between it and other hard bodies, as in drums, bells, chords, &c; or the beating and dashing of the sonorous body and the air immediately against each other, as in flutes, trumpets, &c.

But in both these cases, the motion, which is the consequence of the mutual action, as well as the immediate cause of the sonorous motion which the air conveys to the ear, is supposed to be an invisible, tremulous or undulating motion, in the small and insensible parts of the body. Perrault adds, that the visible motion of the grosser parts contributes no otherwise to Sound, than as it causes the invisible motion of the smaller parts, which he calls particles, to distinguish them from the sensible ones, which he calls parts, and from the smallest of all, which are called corpuscles.

The sonorous body having made its impression on the contiguous air, that impression is propagated from one particle to another, according to the laws of pneumatics.

A few particles, for instance, driven from the surface of the body, push or press their adjacent particles into a less space; and the medium, as it is thus rarefied in one place, becomes condensed in the other; but the air thus compressed in the second place, is, by its elasticity, returned back again, both to its former place and its former state; and the air contiguous to that is compressed; and the like obtains when the air less compressed, expanding itself, a new compression is generated. Therefore from each agitation of the air there arises a motion in it, analogous to the motion of a wave on the surface of the water; which is called a *wave* or *undulation* of air.

In each wave, the particles go and return back again, through very short equal spaces; the motion of each particle being analogous to the motion of a vibrating pendulum while it performs two oscillations; and most of the laws of the pendulum, with very little alteration, being applicable to the former.

Sounds are as various as are the means that concur in producing them. The chief varieties result from the figure, constitution, quantity, &c, of the sonorous body; the manner of percussion, with the velocity &c, of the consequent vibrations; the state and constitution of the medium; the disposition, distance, &c, of the organ; the obstacles between the organ and the sonorous object and the adjacent bodies. The most notable distinction of Sounds, arising from the various degrees and combinations of the conditions above mentioned, are into *loud* and *low* (or strong and weak); into *grave* and *acute* (or sharp and flat, or high and low); and into *long* and *short*. The management of which is the office of music.

Euler is of opinion, that no Sound making fewer vibrations than 30 in a second, or more than 7520, is distinguishable by the human ear. According to this doctrine, the limit of our hearing, as to acute and grave, is an interval of 8 octaves. Tentam. Nov. Theor. Mus. cap. 1, sect. 13.

The velocity of Sound is the same with that of the aerial waves, and does not vary much, whether it go with the wind or against it. By the wind indeed a certain quantity of air is carried from one place to another; and the Sound is accelerated while its waves move through that part of the air, if their direction be the same as that of the wind. But as Sound moves vastly swifter than the wind, the acceleration it will hereby receive is but inconsiderable; and the chief effect we can perceive from the wind is, that it increases and diminishes the space of the waves, so that by help of it the Sound may be heard to a greater distance than otherwise it would.

That the air is the usual medium of Sound, appears from various experiments in rarefied and condensed air. In an unexhausted receiver, a small bell may be heard to some distance; but when exhausted, it can scarce be heard at the smallest distance. When the air is condensed, the Sound is louder in proportion to the condensation, or quantity of air crowded in; of which there are many instances in Hauksbee's experiments, in Dr. Priestley's, and others.

Besides, sounding bodies communicate tremors to distant bodies; for example, the vibrating motion of a musical string puts others in motion, whose tension and quantity of matter dispose their vibrations to keep time with the pulses of air, propagated from the string that was struck. Galileo explains this phenomenon by observing, that a heavy pendulum may be put in motion by the least breath of the mouth, provided the blasts be often repeated, and keep time exactly with the vibrations of the pendulum; and also by the like art in raising a large bell.

It is not air alone that is capable of the impressions of Sound, but water also; as is manifest by striking a bell under water, the Sound of which may plainly enough be heard, only not so loud, and also a fourth deeper, according to good judges in musical notes. And Mersenne says, a Sound made under water is of the same tone or note, as if made in air, and heard under the water.

The velocity of Sound, or the space through which it is propagated in a given time, has been very differently estimated by authors who have written concerning this subject. Roberval states it at the rate of 560 feet in a second; Gassendus at 1473; Mersenne at 1474; Duhamel, in the History of the Academy of Sciences at Paris, at 1338; Newton at 968; Derham, in whose measure Flamsteed and Halley acquiesce, at 1142.

The reason of this variety is ascribed by Derham, partly to some of those gentlemen using strings and plummets instead of regular pendulums; and partly to the too small distance between the sonorous body and the place of observation; and partly to no regard being had to the winds.

But by the accounts since published by M. Cassini de Thury, in the Memoirs of the Royal Acad. of Sciences

ces at Paris, 1738, where cannon were fired at various as well as great distances, under many varieties of weather, wind, and other circumstances, and where the measures of the different places had been settled with the utmost exactness, it was found that Sound was propagated, on a medium, at the rate of 1038 French feet in a second of time. But the French foot is in proportion to the English as 15 to 16; and consequently 1038 French feet are equal to 1107 English feet. Therefore the difference of the measures of Derham and Cassini is 35 English feet, or 33 French feet, in a second. The medium velocity of Sound therefore is nearly at the rate of a mile, or 5280 feet, in $4\frac{3}{4}$ seconds, or a league in 14 seconds, or 13 miles in a minute. But sea miles are to land miles nearly as 7 to 6; and therefore Sound moves over a sea mile in $5\frac{1}{2}$ seconds nearly, or a sea league in 16 seconds.

Farther, it is a common observation, that persons in good health have about 75 pulsations, or beats of the artery at the wrist, in a minute; consequently in 75 pulsations, Sound flies about 13 land miles, or $11\frac{1}{3}$ sea miles, which is about 1 land mile in 6 pulses, or one sea mile in 7 pulses, or a league in 20 pulses.

And hence the distance of objects may be found, by knowing the time employed by Sound in moving from those objects to an observer. For Ex. On seeing the flash of a gun at sea, if 54 beats of the pulse at the wrist were counted before the report was heard; the distance of the gun will easily be found by dividing 54 by 20, which gives 2·7 leagues, or about 8 miles.

Upon the nature, production, and propagation of Sound, see the article PHONICS and ECHO; also the Memoirs of the Acad. and the Philos. Trans. in many places; Newton, Principia; Kircher, Musurgia Universalis; Mersenne; Borelli, Del Suono; Priestley, Exper. and Observ. vol. 5; Hales, Sonorum Doctrina rationalis et experimentalis; 4to 1778. See also an ingenious treatise published 1790, by Mr. Geo. Saunders, on Theatres; in which he relates many experiments made by himself, on the nature and propagation of Sound. In this work, he shews the great effect of water, and some other bodies, in conducting of Sound, probably by rendering the air more dense near them. Some of his conclusions and observations are as follow:

Earth may be supposed to have a twofold property with respect to Sound. Being very porous, it absorbs Sound, which is counteracted by its property of conducting Sound, and occasions it to pass on a plane, in an equal proportion to its progress in air, unencumbered by any body.

If a Sound be sufficiently intense to impress the earth in its tremulous quality, it will be carried to a considerable distance, as when the earth is struck with any thing hard, as by the motion of a carriage, horses feet, &c.

Plaster is proportionally better than loose earth for conducting Sound, as it is more compact.

Clothes of every kind, particularly woollen cloths, are very prejudicial to Sound: their absorption of Sound, may be compared to that of water, which they greedily imbibe.

A number of people seated before others, as in the pit or gallery of a theatre, do considerably prevent the voice reaching those behind; and hence it is, that we hear so much better in the front of the galleries, or of any situation, than behind others, though we may be nearer to the speaker. Our seats, rising so little above each other, occasion this defect, which would be remedied, could we have the seats to rise their whole height above each other, as in the ancient theatres.

Paint has generally been thought unfavourable to Sound, from its being so to musical instruments, whose effects it quite destroys.

Musical instruments mostly depend on the vibrative or tremulous property of the material, which a body of colour hardened in oil must very much alter; but we should distinguish that this regards the formation of Sound, which may not altogether be the case in the progress of it.

Water has been little noticed, with respect to its conducting Sound; but it will be found to be of the greatest consequence. I had often perceived in newly-finished houses, that while they were yet damp, they produced echoes; but that the echoing abated as they dried.

Exp. When I made the following experiment there was a gentle wind; consequently the water was proportionally agitated. I chose a quiet part of the river Thames, near Chelsea Hospital, and with two boats tried the distance the voice would reach. On the water we could distinctly hear a person read at the distance of 140 feet, on land at that of 76. It should be observed, that on land no noise intervened; but on the river some noise was occasioned by the flowing of the water against the boats; so that the difference on land and on water must be much more.

Watermen observe, that when the water is still, and the weather quite calm, if no noise intervene, a whisper may be heard across the river; and that with the current it will be carried to a much greater distance, and vice versa against the current.

Mariners well know the difference of Sound on sea and land.

When a canal of water was laid under the pit floor of the theatre of Argentino, at Rome, a surprising difference was observed; the voice has since been heard at the end very distinctly, where it was before scarce distinguishable. It is observable that, in this part, the canal is covered with a brick-arch, over which there is a quantity of earth, and the timber floor over all.

The villa Simonetta near Milan, so remarkable for its echoes, is entirely over arcades of water.

Another villa near Rouen, remarkable for its echo, is built over subterraneous cavities of water.

A reservoir of water domed over, near Stanmore, has a strong echo.

I do not remember ever being under the arches of a stone bridge that did not echo; which is not always the case with similar structures on land.

A house in Lambeth Marsh, inhabited by Mr. Tuttle, is very damp during winter, when it yields an echo which abates as the house becomes dry in summer.

Kircher observes, that echoes repeat more by night than during the day: he makes the difference to be double.

Dr. Plott says, the echo in Woodstock park repeated 17 times by day, and 20 by night. And Addison's experi-

experiment at the Villa Simonetta was in a fog, when it produced 56 repetitions.

After all these instances, I think little doubt can remain of the influence water has on Sound; and I conclude that it conducts Sound more than any other body whatever.

After water, stone may be reckoned the best conductor of Sound. To what cause it may be attributed, I leave to future enquiries: I have confined myself to speak of facts only as they appear.

Stone is sonorous, but gives a harsh disagreeable tone, unfavourable to music.

Brick, in respect to Sound, has nearly the same properties as stone. Part of the garden wall of the late W. Pitt, Esq. of Kingston in Dorsetshire, conveys a whisper to the distance of near 200 feet.

Wood is sonorous, conductive, and vibrative; of all materials it produces a tone the most agreeable and melodious; and it is therefore the fittest for musical instruments, and for lining of rooms and theatres.

The common notion that whispering at one end of a long piece of timber would be heard at the other end, I found by experiment to be erroneous. A stick of timber 65 feet long being slightly struck at one end, a sound was heard at the other, and the tremor very perceptible: which is easily accounted for, when we consider the number or length of the fibres that compose it, each of which may be compared to a string of catgut.

For the Reflection, Refraction, &c, of SOUND; see ECHO, and PHONICS.

Articulate SOUND. See ARTICULATE.

SOUND, in Music, denotes a quality in the several agitations of the air, so as to make music or harmony.

Sound is the object of music; which is nothing but the art of applying Sounds, under such circumstances of tone and time, as to raise agreeable sensations. The principal affection of Sound, by which it becomes fitted to have this end, is that by which it is distinguished into acute and grave. This difference depends on the nature of the sonorous body; the particular figure and quantity of it; and even in some cases, on the part of the body where it is struck: and it is this that constitutes what are called *different tones*.

The cause of this difference appears to be no other than the different velocities of the vibrations of the sounding body. Indeed the tone of a Sound is found, by numerous experiments, to depend on the nature of those vibrations, whose differences we can conceive no otherwise than as having different velocities: and since it is proved that the small vibrations of the same chord are all performed in equal times, and that the tone of a Sound, which continues for some time after the stroke, is the same from first to last, it follows, that the tone is necessarily connected with a certain quantity of time in making each vibration, or each wave; or that a certain number of vibrations or waves, made in a given time, constitute a certain and determinate tone. From this principle are all the phænomena of tune deduced.

If the vibrations be isochronous, or performed in the same time, the Sound is called musical, and is said to continue at the same pitch; and it is also accounted acuter, sharper, or higher than any other Sound, whose vibrations are slower, and therefore graver, flatter, or lower, than any other whose vibrations are quicker. See UNISON.

From the same principle arise what are called *concords*, &c; which result from the frequent unions and coincidences of the vibrations of two sonorous bodies, and consequently of the pulses or the waves of the air occasioned by them.

On the contrary, the result of less frequent coincidences of those vibrations, is what is called *discord*.

Another considerable distinction of musical Sounds, is that by which they are called *long* and *short*, owing to the continuation of the impulse of the efficient cause on the sonorous body for a longer or shorter time, as in the notes of a violin &c, which are made longer or shorter by strokes of different length or quickness. This continuity is properly a succession of several Sounds, or the effect of several distinct strokes, or repeated impulses, on the sonorous body, so quick, that we judge it one continued Sound, especially where it is continued in the same degree of strength; and hence arises the doctrine of *measure* and *time*.

Musical Sounds are also divided into *simple* and *compound*; and that in two different ways. In the first, a Sound is said to be compound, when a number of successive vibrations of the sonorous body, and the air, come so fast upon the ear, that we judge them the same continued Sound; like as in the phenomenon of the circle of fire, caused by putting the fired end of a stick in a quick circular motion; where supposing the end of the stick in any point of the circle, the idea we receive of it there continues till the impression is renewed by a sudden return.

A *Simple* SOUND then, with regard to this composition, should be the effect of a single vibration, or of as many vibrations as are necessary to raise in us the idea of Sound.

In the second sense of composition, a simple Sound is the product of one voice, or one instrument, &c.

A *Compound* SOUND consists of the Sounds of several distinct voices or instruments all united in the same individual time, and measure of duration, that is, all striking the ear together, whatever their other differences may be. But in this sense again, there is a twofold composition; a natural and an artificial one.

The natural composition is that proceeding from the manifold reflections of the first Sound from adjacent bodies, where the reflections are not so sudden as to occasion echoes, but are all in the same tune with the first note.

The artificial composition, which alone comes under the musician's province, is that mixture of several Sounds, which being made by art, the ingredient Sounds are separable, and distinguishable from one another. In this sense the distinct Sounds of several voices or instruments, or several notes of the same instrument, are called simple Sounds, in contradistinction to the compound ones, in which, to answer the end of

of music, the simples must have such an agreement in all relations, chiefly as to acuteness and gravity, as that the ear may receive the mixture with pleasure.

Another distinction of Sounds, with regard to music, is that by which they are said to be *smooth* or *even*, and *rough* or *harsh*, also *clear* and *hoarse*: the cause of which difference depends on the disposition and state of the sonorous body, or the circumstances of the place; but the ideas of the differences must be sought from observation.

Smooth and *Rough* Sounds depend chiefly on the sounding body; of which we have a notable instance in strings that are uneven, and not of the same dimension and constitution throughout.

As to *clear* and *hoarse* Sounds, they depend on circumstances that are accidental to the sonorous body. Thus, a voice or instrument will be hollow and hoarse if sounded within an empty hogshead, that yet is clear and bright out of it: the effect is owing to the mixture of different Sounds, raised by reflections, which corrupt and change the species of the primitive Sound.

For Sounds to be fit to obtain the end of music, they ought to be smooth and clear, especially the first; since, without this, they cannot have one certain and discernible tone, capable of being compared to others, in a certain relation of acuteness, which the ear may judge of. So that, with Malcolm, we call that an harmonic or musical Sound which, being clear and even, is agreeable to the ear, and gives a certain and discernible tune (hence called tunable Sound), which is the subject of the whole theory of harmony.

Wood has a particular vibrating quality, owing to its elasticity; and all musical instruments made of this matter, are of a thickness proportioned to the superficies of the wood, and the tone they are to produce.

Metals are sonorous and vibrative, producing a harsh tone, very serviceable to some parts of music. Most wind instruments are made of metal, which is acted upon in its elastic and tremulous quality, being capable of being reduced very thin for that purpose. Instruments of this kind are such as horns, trumpets, &c. Some instruments however depend more on the form than the material; as flutes, for instance, which, if their lengths and bore be the same, have very little difference in their Sounds, whatever the matter of them may be. See HARMONICAL.

SOUND-BOARD, the principal part of an organ, and that which makes the whole machine play. This Sound-board, or summer, is a reservoir into which the wind, drawn in by the bellows, is conducted by a portvent, and thence distributed into the pipes placed over the holes of its upper part. This wind enters them by valves, which open by pressing upon the stops or keys, after drawing the registers, which prevent the air from going into any of the other pipes beside those it is required in.

SOUND-*board* denotes also a thin broad board placed over the head of a public speaker, to enlarge and extend or strengthen his voice.

Sound-boards, in theatres, are found by experience to be of no service; their distance from the speaker being too great, to be impressed with sufficient force. But Sound-boards immediately over a pulpit have often a good effect; when the case is made of a just thickness, and according to certain principles.

SOUND-*Post*, is a post placed withinside of a violin, &c, as a prop between the back and the belly of the instrument, and nearly under the bridge.

SOUNDING, in Navigation, the act of trying the depth of the water, and the quality of the bottom, by a line and plummet, or other artifice.

At sea, there are two plummets used for this purpose, both shaped like the frustum of a cone or pyramid. One of these is called the hand-lead, weighing about 8 or 9lb; and the other the deep-sea-lead, weighing from 25 to 30lb. The former is used in shallow waters, and the latter at a great distance from the shore. The line of the hand-lead, is about 25 fathoms in length, and marked at every 2 or 3 fathoms, in this manner, viz, at 2 and 3 fathoms from the lead there are marks of black leather; at 5 fathoms a white rag, at 7 a red rag, at 10 and at 13 black leather, at 15 a white rag, and at 17 a red one.

Sounding with the hand-lead, which the seamen call heaving the lead, is generally performed by a man who stands in the main-chains to windward. Having the line all ready to run out, without interruption, he holds it nearly at the distance of a fathom from the plummet, and having swung the latter backwards and forwards three or four times, in order to acquire the greater velocity, he swings it round his head, and thence as far forward as is necessary; so that, by the lead's sinking whilst the ship advances, the line may be almost perpendicular when it reaches the bottom. The person sounding then proclaims the depth of the water in a kind of song resembling the cries of hawkers in a city; thus, if the mark of 5 be close to the surface of the water, he calls, 'by the mark 5,' and as there is no mark at 4, 6, 8, &c, he estimates those numbers, and calls, 'by the dip four, &c.' If he judges it to be a quarter or a half more than any particular number, he calls, 'and a quarter 5,' 'and a half 4' &c. If he conceives the depth to be three quarters more than a particular number, he calls it a quarter less than the next: thus, at 4 fathom $\frac{3}{4}$, he calls, 'a quarter less 5,' and so on.

The deep-sea-lead line is marked with 2 knots at 20 fathom, 3 at 30, 4 at 40, &c to the end. It is also marked with a single knot at the middle of each interval, as at 25, 35, 45 fathoms, &c. To use this lead more effectually at sea, or in deep water on the sea-coast, it is usual previously to bring-to the ship, in order to retard her course: the lead is then thrown as far as possible from the ship on the line of her drift, so that, as it sinks, the ship drives more perpendicularly over it. The pilot feeling the lead strike the bottom, readily discovers the depth of the water by the mark on the line nearest its surface. The bottom of the lead, which is a little hollowed there for the purpose, being also well rubbed over with tallow, retains the distinguishing marks of the bottom, as shells, ooze, gravel, &c, which naturally adhere to it.

The depth of the water, and the nature of the ground, which are called the Soundings, are carefully marked in the log-book, as well to determine the distance of the

the place from the shore, as to correct the observations of former pilots. Falconer.

For a machine to measure unfathomable depths of the sea, see ALTITUDE.

SOUNDING *the pump*, at sea, is done by letting fall a small line, with some weight at the end, down into the pump, to know what depth of water there is in it.

SOUTH, one of the four cardinal points of the wind, or compass, being that which is directly opposite to the north.

SOUTH *Direct Dials*. See PRIME *Verticals*.

SOUTHERN *Hemisphere, Signs, &c*, those in the south side of the equator.

SOUTHING, in Navigation, the difference of latitude made by a ship in sailing to the southward.

SPACE, denotes room, place, distance, capacity, extension, duration, &c.

When Space is considered barely in length between any two bodies, it gives the same idea as that of distance. When it is considered in length, breadth, and thickness, it is properly called capacity. And when considered between the extremities of matter, which fills the capacity of Space with something solid, tangible, and moveable, it is then called extension.

So that extension is an idea belonging to body only; but Space may be considered without it. Therefore Space, in the general signification, is the same thing with distance considered every way, whether there be any matter in it or not.

Space is usually divided into *absolute* and *relative*.

Absolute SPACE is that which is considered in its own nature, without regard to any thing external, which always remains the same, and is infinite and immoveable.

Relative SPACE is that moveable dimension, or measure of the former, which our senses define by its positions to bodies within it; and this the vulgar use for immoveable Space.

Relative Space, in magnitude and figure, is always the same with absolute; but it is not necessary it should be so numerically. Thus, when a ship is perfectly at rest, then the places of all things within her are the same both absolutely and relatively, and nothing changes its place: but, on the contrary, when the ship is under sail, or in motion, she continually passes through new parts of absolute Space; though all things on board, considered relatively, in respect to the ship, may yet be in the same places, or have the same situation and position, in regard to one another.

The Cartesians, who make extension the essence of matter, assert, that the Space any body takes up, is the same thing with the body itself; and that there is no such thing in the universe as mere Space, void of all matter; thus making Space or extension a substance. See this disproved under VACUUM.

Among those too who admit a vacuum, and consequently an essential difference between Space and matter, there are some who assert that Space is a substance. Among these we find Gravesande, Introd. ad Philos. sect. 19.

Others again put Space into the same class of beings as time and number; thus making it to be no more than a notion of the mind. So that according to these authors, absolute Space, of which the Newtonians speak, is a mere chimera. See the writings of the late bishop Berkley.

Space and time, according to Dr. Clarke, are attributes of the Deity; and the impossibility of annihilating these, even in idea, is the same with that of the necessary existence of the Deity.

SPACE, in Geometry, denotes the area of any figure; or that which fills the interval or distance between the lines that terminate or bound it. Thus,

The Parabolic Space is that included in the whole parabola. The conchoidal Space, or the cissoidal Space, is what is included within the cavity of the conchoid or cissoid. And the asymptotic Space, is what is included between an hyperbolic curve and its asymptote. By the new methods now introduced, of applying algebra to geometry, it is demonstrated that the conchoidal and cissoidal Spaces, though infinitely extended in length, are yet only finite magnitudes or Spaces.

SPACE, in Mechanics, is the line a moveable body, considered as a point, is conceived to describe by its motion.

SPANDREL, with Builders, is the space included between the curve of an arch and the straight or right lines which inclose it; as the space *a*, or *b*.

SPEAKING *Trumpet*. See *Speaking* TRUMPET.

SPECIES, in Algebra, are the letters, symbols, marks, or characters, which represent the quantities in any operation or equation.

This short and advantageous way of notation was chiefly introduced by Vieta, about the year 1590; and by means of which he made many discoveries in algebra, not before taken notice of.

The reason why Vieta gave this name of Species to the letters of the alphabet used in algebra, and hence called Arithmetica Speciosa, seems to have been in imitation of the Civilians, who call cases in law that are put abstractedly, between John a Nokes and Tom a Stiles, between A and B; supposing those letters to stand for any persons indefinitely. Such cases they call Species: whence, as the letters of the alphabet will also as well represent quantities, as persons, and that also indefinitely, one quantity as well as another, they are properly enough called Species; that is general symbols, marks, or characters. From whence the literal algebra hath since been often called Specious Arithmetic, or Algebra in Species.

SPECIES, in Optics, the image painted on the retina by the rays of light reflected from the several points of the surface of an object, received in by the pupil, and collected in their passage through the crystalline, &c.

Philosophers have been in great doubt, whether the Species of objects, which give the soul an occasion of seeing, are an effusion of the substance of the body; or a mere impression which they make on all ambient bodies, and which these all reflect, when in a proper disposition and distance; or lastly, whether they are not some other more subtile body, as light, which receives all these impressions from bodies, and is continually sent and returning from one to another, with the different impressions and figures it has taken. But the moderns have decided this point by their invention of

 artificial

artificial eyes, inwhich the Species of objects are received on a paper, in the same manner as they are received in the natural eye.

SPECIFIC, in Philosophy, that which is proper and peculiar to any thing; or that characterises it, and distinguishes it from every other thing. Thus, the attracting of iron is Specific to the loadstone, or is a Specific property of it.

A just definition should contain the Specific notion of the thing defined, or that which specifies and distinguishes it from every thing else.

Specific *Gravity*, in Hydrostatics, is the relative proportion of the weight of bodies of the same bulk. See *Specific* Gravity.

Specific *Gravity of living men*. Mr. John Robertson, late librarian to the Royal Society, in order to determine the Specific gravity of men, prepared a cistern 78 inches long, 30 inches wide, 30 inches deep; and having procured 10 men for his purpose, the height of each was taken and his weight; and afterwards they plunged successively into the cistern. A ruler or scale, graduated to inches and decimal parts, was fixed to one end of the cistern, and the height of the water shown by it was noted before each man went in, and to what height it rose when he immersed himself under its surface. The following table contains the several results of his experiments:

No. of men.	Height. Ft. In.	Weight. lbs.	Water raised. Inches.	Solidity. Feet.	Wt. of water. lbs.	Specific gravity. (Wat. 1)
1	6 2	161	1·90	2·573	160·8	1·001
2	5 10$\frac{3}{8}$	147	1·91	2·586	161·6	0·901
3	5 9$\frac{1}{2}$	156	1·85	2·505	156·6	0·991
4	5 6$\frac{3}{4}$	140	2·04	2·763	172·6	0·801
5	5 5$\frac{7}{8}$	158	2·08	2·817	176·0	0·900
6	5 5$\frac{1}{2}$	158	2·17	2·939	183·7	0·849
7	5 4$\frac{1}{8}$	140	2·01	2·722	170·1	0·823
8	5 4$\frac{1}{8}$	121	1·79	2·424	151·5	0·800
9	5 3$\frac{1}{4}$	146	1·73	2·343	146·4	0·997
10	5 3$\frac{1}{8}$	132	1·85	2·505	156·6	0·843
medium of all.	5 6$\frac{2}{3}$	146	1·933	2·618	163·6	0·891

One of the reasons, Mr. Robertson says, that induced him to make these experiments, was a desire of knowing what quantity of timber would be sufficient to keep a man afloat in water, thinking that most men were specifically heavier than river or common fresh water; but the contrary appears from the trials above recited; for, except the first, every man was lighter than an equal bulk of fresh water, and much more so than that of sea-water. So that, if persons who fall into water had presence of mind enough to avoid the fright usual on such occasions, many might be preserved from drowning; and a piece of wood not larger than an oar, would buoy a man partly above water as long as he had strength or spirits to keep his hold. Philos. Trans. vol. 50, art. 5.

From the last line of the table appears the medium of all the circumstances of height, weight, &c; particularly the mean Specific Gravity, 0·891, which is about $\frac{1}{9}$ less than common water.

SPECTACLES, an optical machine, consisting of two lenses set in a frame, and applied on the nose, to assist in defects of the organ of sight.

Old people, and all presbytæ, use Spectacles of convex lenses, to make amends for the flatness of the eye, which does not make the rays converge enough to have them meet in the retina.

Short-sighted people, or myopes, use concave lenses, to prevent the rays from converging so fast, on account of the greater roundness of the eye, or smallness of the sphere, which is such as to make them meet before they reach the retina.

F. Cherubin, a capuchin, describes a kind of Spectacle telescopes, for viewing remote objects with both eyes; and hence called *binoculi*. Though F. Rheita had mentioned the same before him, in his Oculus Enoch et Eliæ. See Binocle. The same author invented a kind of Spectacles, with three or four glasses, which performed very well.

The invention of Spectacles has been much disputed. They were certainly not known to the ancients. Francisco Redi, in a learned treatise on Spectacles, contends that they were first invented between the years 1280 and 1311, probably about 1290; and adds, that Alexander de Spina, a monk of the order of Predicants of St. Catharine, at Pisa, first communicated the secret, which was of his own invention, upon learning that another person had it as well as himself.

The author tells us, that in an old manuscript still preserved in his library, composed in 1299, Spectacles are mentioned as a thing invented about that time: and that a celebrated Jacobin, one Jourdon de Rivalto, in a treatise composed in 1305, says expressly, that it was not yet 20 years since the invention of Spectacles. He likewise quotes Bernard Gordon in his Lilium Medicinæ, written the same year, where he speaks of a collyrium, good to enable an old man to read without Spectacles.

Musschenbroek observes, (Introd. vol. 2, pa. 786) that it is inscribed on the tomb of Salvinus Armatus, a nobleman of Florence, who died in 1317, that he was the inventor of Spectacles.

Du-Cange, however, carries the invention of Spectacles farther back; assuring us, that there is a Greek poem in manuscript in the French king's library, which shews that Spectacles were in use in the year 1150; however the dictionary of the Academy Della Crusca, under the word *occhiale*, inclines to Redi's side; and quotes a passage from Jourdon's sermons, which says that Spectacles had not been 20 years in use; and Salvati has observed that those sermons were composed between the years 1330 and 1336.

It is probable that the first hint of the construction and use of Spectacles, was derived from the writings either of Alhazen, who lived in the 12th century, or of our own countryman Roger Bacon, who was born in 1214, and died in 1292, or 1294. The following remarkable passage occurs in Bacon's Opus Majus by Jebb, p. 352. Si vero homo aspiciat literas et alias res minutas per medium crystalli, vel vitri, vel alterius perspicui suppositi literis, et sit portio minor sphere, cujus convexitas sit versus oculum et oculus sit in aere, longe

longe melius videbit literas, et apparebunt ei majores.—Et ideo hoc instrumentum est utile senibus et habentibus oculos debiles: nam literam quantumcunque parvam possunt videre in sufficienti magnitudine. Hence, and from other passages in his writings, much to the same purpose, Molyneux, Plott, and others, have attributed to him the invention of reading-glasses. Dr. Smith indeed, observing that there are some mistakes in his reasoning on this subject, has disputed his claim. See Molyneux's Dioptr. p. 256. Smith's Optics, Rem. 86—89.

SPECULATIVE *Geometry*, *Mathematics*, *Music*, and *Philosophy*. See the SUBSTANTIVES.

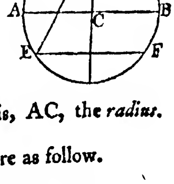
SPECULUM, or *Mirror*, in Optics, any polished body, impervious to the rays of light: such as polished metals, and glasses lined with quicksilver, or any other opake matter, popularly called Looking-glasses; or even the surface of mercury or of water, &c.

For the several kinds and forms of Specula, plane, concave, and convex, with their theory and phenomena, see MIRROR. And for their laws and effects, see REFLECTION and BURNING-*Glass*.

As for the Specula of reflecting telescopes, it may here be observed, that the perfection of the metal of which they should be made, consists in its hardness, whiteness, and compactness; for upon these properties the reflective powers and durability of the Specula depend. There are various compositions recommended for these Specula, in Smith's Optics, book 3, ch. 2, sect. 787; also by Mr. Mudge in the Philos. Trans. vol. 67; and in various other places, as by Mr. Edwards, in the Naut. Alm. for 1787, whose metal is the whitest and best of any that I have seen.—For the method of grinding, see GRINDING.

Mr. Hearne's method of cleaning a tarnished Speculum was this: Get a little of the strongest soap ley from the soap-makers, and having laid the Speculum on a table with its face upwards, put on as much of the ley as it will hold, and let it remain about an hour: then rub it softly with a silk or muslin, till the ley is all gone; then put on some spirit of wine, and rub it dry with another part of the silk or muslin. If the Speculum will not perform well after this, it must be new polished. A few faint spots of tarnish may be rubbed off with spirit of wine only, without the ley. Smith's Optics, Rem. p. 107.

SPHERE, in Geometry, a solid body contained under one single uniform surface, every point of which is equally distant from a certain point in the middle called its centre.



The Sphere may be supposed to be generated by the revolution of a semicircle ABD about its diameter AB, which is also called the *axis* of the Sphere, and the extreme points of the axis, A and B, the *poles* of the Sphere; also the middle of the axis C is the *centre*, and half the axis, AC, the *radius*.

Properties of the SPHERE, are as follow.

1. A Sphere may be considered as made up of an infinite number of pyramids, whose common altitude is equal to the radius of the Sphere, and all their bases form the surface of the Sphere. And therefore the solid content of the Sphere is equal to that of a pyramid whose altitude is the radius, and its base is equal to the surface of the Sphere, that is, the solid content is equal to $\frac{1}{3}$ of the product of its radius and surface.

2. A Sphere is equal to $\frac{2}{3}$ of its circumscribing cylinder, or of the cylinder of the same height and diameter, and therefore equal to the cube of the diameter multiplied by ·5236, or $\frac{2}{3}$ of ·7854; or equal to double a cone of the same base and height. Hence also different Spheres are to one another as the cubes of their diameters. And their surfaces as the squares of the same diameters.

3. The surface or superficies of any Sphere, is equal to 4 times the area of its great circle, or of a circle of the same diameter as the Sphere. Or

4. The surface of the whole Sphere is equal to the area of a circle whose radius is equal to the diameter of the Sphere. And, in like manner, the curve surface of any segment EDF, whether greater or less than a hemisphere, is equal to a circle whose radius is the chord line DE, drawn from the vertex D of the segment to the circumference of its base, or the chord of half its arc.

5. The curve surface of any segment or zone of a Sphere, is also equal to the curve surface of a cylinder of the same height with that portion, and of the same diameter with the Sphere. Also the surface of the whole Sphere, or of an hemisphere, is equal to the curve surface of its circumscribing cylinder. And the curve surfaces of their corresponding parts are equal, that are contained between any two places parallel to the base. And consequently the surface of any segment or zone of a Sphere, is as its height or altitude.

Most of these properties are contained in Archimedes's treatise on the Sphere and cylinder. And many other rules for the surfaces and solidities of Spheres, their segments, zones, frustums, &c, may be seen in my Mensuration, part 3, sect. 1, prob. 10, &c.

Hence, if d denote the diameter or axis of a Sphere, s its curve surface, c its solid content, and a = ·7854 the area of a circle whose diam. is 1; then we shall, from the foregoing properties, have these following general values or equations, viz,

$$s = 4ad^2 = \frac{6c}{d} = 6\sqrt[3]{\tfrac{2}{3}ac^2}.$$

$$c = \tfrac{1}{6}ds = \tfrac{2}{3}ad^3 = \tfrac{1}{12}\sqrt{\frac{s^3}{a}}.$$

$$d = \frac{6c}{s} = \sqrt{\frac{s}{4a}} = \sqrt[3]{\frac{3c}{2a}}.$$

Doctrine of the SPHERE. See SPHERICS.

Projection of the SPHERE. See PROJECTION.

SPHERE *of Activity*, of any body, is that determinate space or extent all around it, to which, and no farther, the effluvia or the virtue of that body reaches, and in which it operates according to the nature of the body. See ACTIVITY.

SPHERE, in Astronomy, that concave orb or expanse which invests our globe, and in which the heavenly

venly bodies, the ſun, moon, ſtars, planets, and comets, appear to be fixed at an equal diſtance from the eye. This is alſo called the Sphere of the world; and it is the ſubject of ſpherical aſtronomy.

This Sphere, as it includes the fixed ſtars, from whence it is ſometimes called the *Sphere of the fixed ſtars*, is immenſely great. So much ſo, that the diameter of the earth's orbit is vaſtly ſmall in reſpect of it; and conſequently the centre of the Sphere is not ſenſibly changed by any alteration of the ſpectator's place in the ſeveral parts of the orbit: but ſtill in all points of the earth's ſurface, and at all times, the inhabitants have the ſame appearance of the Sphere; that is, the fixed ſtars ſeem to poſſeſs the ſame points in the ſurface of the Sphere. For, our way of judging of the places &c of the ſtars, is to conceive right lines drawn from the eye, or from the centre of the earth, through the centres of the ſtars, and thence continued till they cut the Sphere; and the points where theſe lines ſo meet the Sphere, are the apparent places of thoſe ſtars.

The better to determine the places of the heavenly bodies in the Sphere, ſeveral circles are conceived to be drawn in the ſurface of it, which are called circles of the Sphere.

SPHERE, in Geography, &c, denotes a certain diſpoſition of the circles on the ſurface of the earth, with regard to one another, which varies in the different parts of it.

The circles originally conceived on the ſurface of the Sphere of the world, are almoſt all transferred, by analogy, to the ſurface of the earth, where they are conceived to be drawn directly underneath thoſe of the Sphere, or in the ſame poſitions with them; ſo that, if the planes of theſe of the earth were continued to the Sphere of the ſtars, they would coincide with the reſpective circles on it. Thus, we have an horizon, meridian, equator, &c, on the earth. And as the equinoctial, or equator, in the heavens, divides the Sphere into two equal parts, the one north and the other ſouth, ſo does the equator on the ſurface of the earth divide its globe in the ſame manner. And as the meridians in the heavens paſs through the poles of the equinoctial, ſo do thoſe on the earth, &c. With regard then to the poſition of ſome of theſe circles in reſpect of others, we have a *right*, an *oblique*, and a *parallel* Sphere.

A Right or Direct SPHERE, (fig. 4, plate 26), is that which has the poles of the world PS in its horizon, and the equator EQ in the zenith and nadir. The inhabitants of this Sphere live exactly at the equator of the earth, or under the line. They have therefore no latitude, nor no elevation of the pole. They can ſee both poles of the world; all the ſtars do riſe, culminate, and ſet to them; and the ſun always riſes at right-angles to their horizon, making their days and nights always of equal length, becauſe the horizon biſects the circle of the diurnal revolution.

An Oblique SPHERE, (fig. 5, plate 26), is that in which the equator EQ, as alſo the axis PS, cuts the horizon HO obliquely. In this Sphere, one pole P is above the horizon, and the other below it; and therefore the inhabitants of it ſee always the former pole, but never the latter; the ſun and ſtars &c all riſe and ſet obliquely; and the days and nights are always varying, and growing alternately longer and ſhorter.

A Parallel SPHERE, (fig. 6, plate 26), is that which has the equator in or parallel to the horizon, as well as all the ſun's parallels of declination. Hence, the poles are in the zenith and nadir; the ſun and ſtars move always quite around parallel to the horizon, the inhabitants, if any, being juſt at the two poles, having 6 months continual day, and 6 months night, in each year; and the greateſt height to which the ſun riſes to them, is 23° 28′, or equal to his greateſt declination.

Armillary or Artificial SPHERE, is an aſtronomical inſtrument, repreſenting the ſeveral circles of the Sphere in their natural order; ſerving to give an idea of the office and poſition of each of them, and to reſolve various problems relating to them.

It is thus called, as conſiſting of a number of rings of braſs, or other matter, called by the Latins *armillæ*, from their reſembling of bracelets or rings for the arm.

By this, it is diſtinguiſhed from the globe, which, though it has all the circles of the Sphere on its ſurface; yet is not cut into armillæ or rings, to repreſent the circles ſimply and alone; but exhibits alſo the intermediate ſpaces between the circles.

Armillary Spheres are of different kinds, with regard to the poſition of the earth in them; whence they become diſtinguiſhed into Ptolomaic and Copernican Spheres: in the firſt of which, the earth is in the centre, and in the latter near the circumference, according to the poſition which that planet obtains in thoſe ſyſtems.

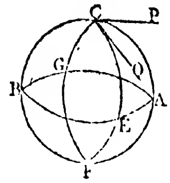
The Ptolomaic SPHERE, is that commonly in uſe, and is repreſented in fig. 6, plate 2, vol. 1, with the names of the ſeveral circles, lines, &c of the Sphere inſcribed upon it. In the middle, upon the axis of the Sphere, is a ball T, repreſenting the earth, on the ſurface of which are the circles &c of the earth. The Sphere is made to revolve about the ſaid axis, which remains at reſt; by which means the ſun's diurnal and annual courſes about the earth are repreſented according to the Ptolomaic hypotheſis: and even by means of this, all problems relating to the phenomena of the ſun and earth are reſolved, as upon the celeſtial globe, and after the ſame manner; which ſee deſcribed under GLOBE.

Copernican SPHERE, fig. 7, plate 26, is very different from the Ptolomaic, both in its conſtitution and uſe; and is more intricate in both. Indeed the inſtrument is in the hands of ſo few people, and its uſe ſo inconſiderable, except what we have in the other more common inſtruments, particularly the globe and the Ptolomaic Sphere, that any farther account of it is unneceſſary.

Dr. Long had an Armillary Sphere of glaſs, of a very large ſize, which is deſcribed and repreſented in his Aſtronomy. And Mr. Ferguſon conſtructed a ſimilar one of braſs, which is exhibited in his Lectures, p. 194 &c.

SPHERICAL, ſomething relating to the ſphere. As,

SPHERICAL *Angle*, is the angle formed on the ſurface of a Sphere or globe by the circumferences of two



two great circles. This angle, formed by the circumferences, is equal to that formed by the planes of the ſame circles, or equal to the inclination of thoſe two planes; or equal to the angle made by their tangents at the angular point. Thus, the inclination of the two planes CAF, CEF, forms the Spherical Angle ACE, equal to the tangential angle PCQ.

The meaſure of a Spherical Angle, ACE, is an arc of a great circle AE, deſcribed from the vertex C, as from a pole, and intercepted between the legs CA and CE.

Hence, 1ſt, Since the inclination of the plane CEF to the plane CAF, is every where the ſame, the angles in the oppoſite interſections, C and F, are equal.—2d, Hence the meaſure of a Spherical Angle ACE, is an arc deſcribed at the interval of a quadrant CA or CE, from the vertex C between the legs CA, CE.—3d, If a circle of the ſphere CEFG cut another AEBG, the adjacent angles AEC and BEC are together equal to two right angles; and the vertical angles AEC, BEF are equal to one another. Alſo all the angles formed at the ſame point, on the ſame ſide of a circle, are equal to two right angles, and all thoſe quite around any point equal to four right angles.

Spherical *Triangle*, is a triangle formed upon the ſurface of a ſphere, by the interſecting arcs of three great circles; as the triangle ACE.

Spherical Triangles are either *right-angled*, *oblique*, *equilateral*, *iſoſceles*, or *ſcalene*, in the ſame manner as plane triangles. They are alſo ſaid to be *quadrantal*, when they have one ſide a quadrant. Two ſides or two angles are ſaid to be of the *ſame affection*, when they are at the ſame time either both greater, or both leſs than a quadrant or a right angle or 90°; and of *different affections*, when one is greater and the other leſs than 90 degrees.

Properties of Spherical *Triangles.*

1. Spherical Triangles have many properties in common with plane ones: Such as, That, in a triangle, equal ſides ſubtend equal angles, and equal angles are ſubtended by equal ſides: That the greater angles are ſubtended by the greater ſides, and the leſs angles by the leſs ſides.

2. In every Spherical Triangle, each ſide is leſs than a ſemicircle: any two ſides taken together are greater than the third ſide: and all the three ſides taken together are leſs than the whole circumference of a circle.

3. In every Spherical Triangle, any angle is leſs than 2 right angles; and the ſum of all the three angles taken together, is greater than 2, but leſs than 6, right angles.

4. In an oblique Spherical Triangle, if the angles at the baſe be of the ſame affection, the perpendicular from the other angle falls within the triangle; but if they be of different affections, the perpendicular falls without the triangle.

Dr. Maſkelyne's remarks on the properties of Spherical Triangles, are as follow: (See the Introd. to my Logs. pa. 160, 2d edition.)

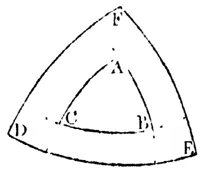
5. "A Spherical Triangle is equilateral, iſoſcelar, or ſcalene, according as it has its three angles all equal, or two of them equal, or all three unequal; and vice verſa.

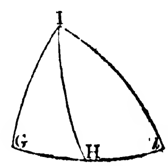
6. The greateſt ſide is always oppoſite the greateſt angle, and the ſmalleſt ſide oppoſite the ſmalleſt angle.

7. Any two ſides taken together are greater than the third.

8. If the three angles are all acute, or all right, or all obtuſe; the three ſides will be, accordingly, all leſs than 90°, or equal to 90°, or greater than 90°; and vice verſa.

9. If from the three angles A, B, C, of a triangle ABC, as poles, there be deſcribed, upon the ſurface of the ſphere, three arches of a great circle DE, DF, FE, forming by their interſections a new Spherical Triangle DEF; each ſide of the new triangle will be the ſupplement of the angle at its pole; and each angle of the ſame triangle, will be the ſupplement of the ſide oppoſite to it in the triangle ABC.





10. In any triangle GHI or GhI, right angled in G, 1ſt, The angles at the hypotenuſe are always of the ſame kind as their oppoſite ſides; 2dly, The hypotenuſe is leſs or greater than a quadrant, according as the ſides including the right angle, are of the ſame or different kinds; that is to ſay, according as theſe ſame ſides are either both acute, or both obtuſe, or as one is acute and the other obtuſe. And, vice verſa, 1ſt, The ſides including the right angle, are always of the ſame kind as their oppoſite angles; 2dly, The ſides including the right angle will be of the ſame or different kinds, according as the hypotenuſe is leſs or more than 90°; but one at leaſt of them will be of 90°, if the hypotenuſe is ſo."

Of the Area of a Spherical *Triangle.* The menſuration of Spherical Triangles and polygons was firſt found out by Albert Girard, about the year 1600, and is given at large in his *Invention Nouvelle en l'Algebre*, pa. 50, &c; 4to, Amſt. 1629. In any Spherical Triangle, the area, or ſurface incloſed by its three ſides upon the ſurface of the globe, will be found by this proportion:

As 8 right angles or 720°,
Is to the whole ſurface of the ſphere;
Or, as 2 right angles or 180°,
To one great circle of the ſphere;
So is the exceſs of the 3 angles above 2 right angles,
To the area of the Spherical Triangle.

Hence, if a denote $\cdot 7854$,
$d =$ diam. of the globe, and
$s =$ ſum of the 3 angles of the triangle;

then

then $add \times \frac{s-180}{180}$ = area of the Spherical Triangle.

Hence alſo, if r denote the radius of the ſphere, and c its circumference;

then the area of the triangle will thus be variouſly expreſſed; viz, Area =

$$ad^2 \times \frac{s-180}{180} = cd \times \frac{s-180}{720} = cr \times \frac{s-180}{360};$$

or barely $= r \times \overline{s-180^\circ}$, in ſquare degrees, when the radius r is eſtimated in degrees; for then the circumference c is $= 360^\circ$.

Farther, becauſe the radius r, of any circle, when eſtimated in degrees, is, $= \frac{180}{3\cdot14159 \text{ \&c.}} = 57\cdot2957795$, the laſt rule $r \times \overline{s-180}$, for expreſſing the area A of the Spherical Triangle, in ſquare degrees, will be barely

$$A = 57\cdot2957795\, s - 10313\cdot24 =$$
$$= 57\tfrac{3}{10}s - 10313\tfrac{1}{4} \text{ very nearly.}$$

Hence may be found the ſums of the three angles in any Spherical Triangle, having its area A known; for the laſt equation gives the ſum

$$s = \frac{A}{r} + 180 = \frac{A}{57\cdot29 \text{ \&c.}} + 180 = \frac{169A}{9683} + 180.$$

So that, for a Triangle on the ſurface of the earth, whoſe three ſides are known; if it be but ſmall, as of a few miles extent, its area may be found from the known lengths of its ſides, conſidering it as a plane Triangle, which gives the value of the quantity A; and then the laſt rule above will give the value of s, the ſum of the three angles; which will ſerve to prove whether thoſe angles are nearly exact, that have been taken with a very nice inſtrument, as in large and extenſive meaſurements on the ſurface of the earth.

Reſolution of SPHERICAL *Triangles.* See TRIANGLE, and TRIGONOMETRY.

SPHERICAL *Polygon,* is a figure of more than three ſides, formed on the ſurface of a globe by the interſecting arcs of great circles,

The area of any Spherical Polygon will be found by the following proportion; viz,

As 8 right-angles or 720°,
To the whole ſurface of the ſphere;
Or, as 2 right angles or 180°,
To a great circle of the ſphere;
So is the exceſs of all the angles above the product of 180 and 2 leſs than the number of angles,
To the area of the ſpherical polygon.

That is, putting n = the number of angles,
s = ſum of all the angles,
d = diam. of the ſphere,
a = ·78539 &c;

Then $A = ad^2 \times \frac{s-(n-2)180}{180}$ = the area of the Spherical Polygon.

Hence other rules might be found, ſimilar to thoſe for the area of the Spherical Triangle.

Hence alſo, the ſum s of all the angles of any Spherical Polygon, is always leſs than $180n$, but greater than $180(n-2)$, that is leſs than n times 2 right angles, but greater than $n-2$ times 2 right angles.

SPHERICAL *Aſtronomy,* that part of aſtronomy which conſiders the univerſe ſuch as it appears to the eye. See ASTRONOMY.

Under Spherical Aſtronomy, then, come all the phenomena and appearances of the heavens and heavenly bodies, ſuch as we perceive them, without any enquiry into the reaſon, the theory, or truth of them. By which it is diſtinguiſhed from theorical aſtronomy, which conſiders the real ſtructure of the univerſe, and the cauſes of thoſe phenomena.

In the Spherical Aſtronomy, the world is conceived to be a concave Spherical ſurface, in whoſe centre is the earth, or rather the eye, about which the viſible frame revolves, with ſtars and planets fixed in the circumference of it. And on this ſuppoſition all the other phenomena are determined.

The theorical aſtronomy teaches us, from the laws of optics, &c, to correct this Scheme and reduce the whole to a juſter ſyſtem.

SPHERICAL *Compaſſes.* See COMPASSES.

SPHERICAL *Geometry,* the doctrine of the ſphere; particularly of the circles deſcribed on its ſurface, with the method of projecting the ſame on a plane; and meaſuring their arches and angles when projected.

SPHERICAL *Numbers.* See CIRCULAR *Numbers.*

SPHERICAL *Trigonometry.* See *Spherical* TRIGONOMETRY.

SPHERICITY, the quality of a ſphere; or that by which a thing becomes ſpherical or round.

SPHERICS, the Doctrine of the ſphere, particularly of the ſeveral circles deſcribed on its ſurface; with the method of projecting the ſame on a plane. See PROJECTION *of the Sphere.*

A circle of the ſphere is that which is made by a plane cutting it. If the plane paſs through the centre, it is a *great* circle: if not, it is a *little* circle.

The *pole* of a circle, is a point on the ſurface of the ſphere equidiſtant from every point of the circumference of the circle. Hence every circle has two poles, which are diametrically oppoſite to each other; and all circles that are parallel to each other have the ſame poles.

Properties of the Circles of the Sphere.

1. If a ſphere be cut in any manner by a plane, the ſection will be a circle. And a great circle when the ſection paſſes through the centre, otherwiſe it is a *little* circle. Hence, all great circles are equal to each other: and the line of ſection of two great circles of the ſphere, is a diameter of the ſphere: and therefore two great circles interſect each other in points diametrically oppoſite; and make equal angles at thoſe points; and divide each other into two equal parts; alſo any great circle divides the whole ſphere into two equal parts.

2. If a great circle be perpendicular to any other circle, it paſſes through its poles. And if a great circle paſs

pass through the pole of any other circle, it cuts it at right angles, and into two equal parts.

3. The distance between the poles of two circles, is equal to the angle of their inclination.

4. Two great circles passing through the poles of another great circle, cut all the parallels to this latter into similar arcs. Hence, an angle made by two great circles of the sphere, is equal to the angle of inclination of the planes of these great circles. And hence also the lengths of those parallels are to one another as the sines of their distances from their common pole, or as the cosines of their distances from their parallel great circle. Consequently, as radius is to the cosine of the latitude of any point on the globe, so is the length of a degree at the equator, to the length of a degree in that latitude.

5. If a great circle pass through the poles of another; this latter also passes through the poles of the former; and the two cut each other perpendicularly.

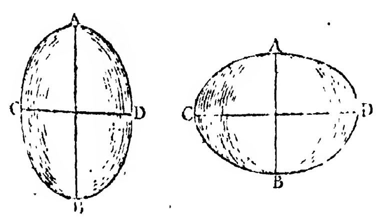
6. If two or more great circles intersect each other in the poles of another great circle; this latter will pass through the poles of all the former.

7. All circles of the sphere that are equally distant from the centre, are equal; and the farther they are distant from the centre, the less they are.

8. The shortest distance on the surface of a sphere, between any two points on that surface, is the arc of a great circle passing through those points. And the smaller the circle is that passes through the same points, the longer is the arc of distance between them. Hence the proper measure, or distance, of two places on the surface of the globe, is an arc of a great circle intercepted between the same. See Theodosius and other writers on Spherics.

SPHEROID, a solid body approaching to the figure of a sphere, though not exactly round, but having one of its diameters longer than the other.

This solid is usually considered as generated by the rotation of an oval plane figure about one of its axes. If that be the longer or transverse axis, the solid so generated is called an *oblong* Spheroid, and sometimes *prolate*, which resembles an egg, or a lemon; but if the oval revolve about its shorter axis, the solid will be an *oblate* Spheroid, which resembles an orange, and in this shape also is the figure of the earth, and the other planets.



The axis about which the oval revolves, is called the *fixed* axis, as AB; and the other CD is the *revolving* axis: whichever of them happens to be the longer.

When the revolving oval is a perfect ellipse, the solid generated by the revolution is properly called an *ellipsoid*, as distinguished from the Spheroid, which is generated from the revolution of any oval whatever, whether it be an ellipse or not. But generally speaking, in common acceptation, the term Spheroid is used for an ellipsoid; and therefore, in what follows, they are considered as one and the same thing.

Any section of a Spheroid, by a plane, is an ellipse (except the sections perpendicular to the fixed axe, which are circles); and all parallel sections are similar ellipses, or having their transverse and conjugate axes in the same constant ratio; and the sections parallel to the fixed axe are similar to the ellipse from which the solid was generated. See my Mensuration pa. 267 &c, 2d edit.

For the Surface of a Spheroid, whether it be oblong or oblate. Let f denote the fixed axe,

r the revolving axe,

$$a = \cdot 7854, \text{ and } q = \frac{ff \backsim rr}{ff};$$

then will the surface s be expressed by the following series, using the upper signs for the oblong spheroid, and the under signs for the oblate one; viz,

$$s = 4arf \times \left(1 \mp \frac{1}{2.3}q - \frac{1}{2.4.5}q^2 \mp \frac{3}{2.4.6.7}q^3 \text{ \&c};\right.$$

where the signs of the terms, after the first, are all negative for the oblong Spheroid, but alternately positive and negative for the oblate one.

Hence, because the factor $4arf$ is equal to 4 times the area of the generating ellipse, it appears that the surface of the oblong Spheroid is less than 4 times the generating ellipse, but the surface of the oblate Spheroid is greater than 4 times the same: while the surface of the sphere falls in between the two, being just equal to 4 times its generating circle.

Huygens, in his Horolog. Oscillat. prop. 9, has given two elegant constructions for describing a circle equal to the superficies of an oblong and an oblate Spheroid, which he says he found out towards the latter end of the year 1657. As he gave no demonstrations of these, I have demonstrated them, and also rendered them more general, by extending and adapting them to the surface of any segment or zone of the Spheroid. See my Mensuration, pa. 308 &c, 2d ed. where also are several other rules and constructions for the surfaces of Spheroids, besides those of their segments, and frustums.

Of the Solidity of a Spheroid. Every Spheroid, whether oblong or oblate, is, like a sphere, exactly equal to two-thirds of its circumscribing cylinder. So that, if f denote the fixed axe, r the revolving axe, and $a = \cdot 7854$; then $\frac{2}{3}afr^2$ denotes the solid content of either Spheroid. Or, which comes to the same thing, if t denote the transverse, and c the conjugate axe of the generating ellipse;

then $\frac{2}{3}ac^2t$ is the content of the oblong Spheroid,
and $\frac{2}{3}act^2$ is the content of the oblate Spheroid.

Consequently, the proportion of the former solid to the latter, is as c to t, or as the less axis to the greater.

Farther, if about the two axes of an ellipse be generated

nerated two ſpheres and two ſpheroids, the four ſolids will be continued proportionals, and the common ratio will be that of the two axes of the ellipſe; that is, as the greater ſphere, or the ſphere upon the greater axe, is to the oblate Spheroid, ſo is the oblate Spheroid to the oblong Spheroid, and ſo is the oblong Spheroid to the leſs ſphere, and ſo is the tranſverſe axis to the conjugate. See my Menſuration, pa. 327 &c, 2d ed. where may be ſeen many other rules for the ſolid contents of Spheroids, and their various parts. See alſo Archimedes on Spheroids and Conoids.

Dr. Halley has demonſtrated, that in a ſphere, Mercator's nautical meridian line is a ſcale of logarithmic tangents of the half complements of the latitudes. But as it has been found that the ſhape of the earth is ſpheroidal, this figure will make ſome alteration in the numbers reſulting from Dr. Halley's theorem. Maclaurin has therefore given a rule, by which the meridional parts to any Spheroid may be found with the ſame exactneſs as in a ſphere. There is alſo an ingenious tract by Mr. Murdoch on the ſame ſubject. See Philoſ. Tranſ. No. 219. Mr. Cotes has alſo demonſtrated the ſame propoſition, Harm. Menſ. pa. 20, 21. See MERIDIONAL *Parts*.

Univerſal SPHEROID, a name given to the ſolid generated by the rotation of an ellipſe about ſome other diameter, which is neither the tranſverſe nor conjugate axis. This produces a figure reſembling a heart. See my Menſuration, pa. 352, 2d ed.

SPINDLE, in Geometry, a ſolid body generated by the revolution of ſome curve line about its baſe or double ordinate AB; in oppoſition to a conoid, which is generated by the rotation of the curve about its axis or abſciſs, perpendicular to its ordinate.

The Spindle is denominated circular, elliptic, hyperbolic, or parabolic, &c, according to the figure of its generating curve. See my Menſur. in ſeveral places.

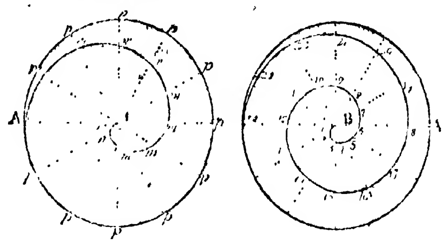
SPINDLE, in Mechanics, ſometimes denotes the axis of a wheel, or roller, &c; and its ends are the pivots. See alſo *Double* CONE.

SPIRAL, in Geometry, a curve line of the circular kind, which, in its progreſs, recedes always more and more from a point within, called its centre; as in winding from the vertex of a cone down to its baſe.

The firſt treatiſe on a Spiral is by Archimedes, who thus deſcribes it: Divide the circumference of a circle A*pp* &c into any number of equal parts, by a continual biſection at the points *pp* &c. Divide alſo the radius AC into the ſame number of equal parts, and make C*m*, C*m*, C*m*, &c, equal to 1, 2, 3, &c of theſe equal parts; then a line drawn, with a ſteady hand, drawn through all the points *m*, *m*, *m*, &c, will trace out the Spiral.

This is more particularly called the *firſt* Spiral, when it has made one complete revolution to the point A; and the ſpace included between the Spiral and the radius CA, is the *Spiral ſpace*.

The firſt Spiral may be continued to a *ſecond*, by deſcribing another circle with double the radius of the firſt; and the ſecond may be continued to a *third*, by a third circle; and ſo on.



Hence it follows, that the parts of the circumference A*p* are as the parts of the radii C*m*; or A*p* is to the whole circumference, as C*m* is to the whole radius. Conſequently, if *c* denote the circumference, *r* the radius, $x = Cm$, and $y = Ap$; then there ariſes this proportion $r : c :: x : y$, which gives $ry = cx$ for the equation of this Spiral; and which therefore it has in common with the quadratrix of Dinoſtrates, and that of Tſchirnhauſen: ſo that $r^n y^m = c^n x^m$ will ſerve for infinite Spirals and quadratrices. See QUADRATRIX.

The Spiral may alſo be conceived to be thus generated, by a continued uniform motion. If a right line, as AB (*laſt fig. above*) having one end moveable about a fixed point at B, be uniformly turned round, ſo as the other end A may deſcribe the circumference of a circle; and at the ſame time a point be conceived to move uniformly forward from B towards A, in the right line or radius AB, ſo that the point may deſcribe that line, while the line generates the circle; then will the point, with its two motions, deſcribe the curve B, 1, 2, 3, 4, 5, &c, of the ſame Spiral as before.

Again, if the point B be conceived to move twice as ſlow as the line AB, ſo that it ſhall get but half way along BA, when that line ſhall have formed the circle; and if then you imagine a new revolution to be made of the line carrying the point, ſo that they ſhall end their motion at laſt together, there will be formed a *double* Spiral line, as in the laſt figure. From the manner of this deſcription may eaſily be drawn theſe corollaries:

1. That the lines B12, B11, B10, &c, making equal angles with the firſt and ſecond Spiral (as alſo B12, B10, B8), &c, are in arithmetical progreſſion.

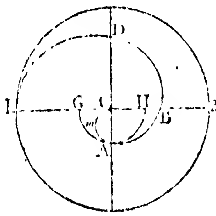
2. The lines B7, B10, &c, drawn any how to the firſt Spiral, are to one another as the arcs of the circle intercepted between BA and thoſe lines; becauſe whatever parts of the circumference the point A deſcribes, as ſuppoſe 7, the point B will alſo have run over 7 parts of the line AB.

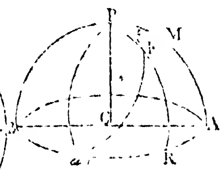
3. Any lines drawn from B to the ſecond Spiral, as B18, B22, &c, are to each other as the aforeſaid arcs, together with the whole circumference added on both ſides: for at the ſame time that the point A runs over 12, or the whole circumference, or perhaps 7 parts more, ſhall the point B have run over 12, and 7 parts of the line AB, which is now ſuppoſed to be divided into 24 equal parts.

4. The

4. The first Spiral line is equal to half the circumference of the first circle; for the radii of the sectors, and consequently of the arcs, are in a simple arithmetic progression, while the circumference of the circle contains as many arcs equal to the greatest; therefore the circumference is in proportion to all those Spiral arcs, as 2 to 1.

5. The first Spiral space is equal to $\frac{1}{3}$ of the first or circumscribing circle. That is, the area CABDE of the Spiral, is equal to $\frac{1}{3}$ part of the circle described with the radius CE. In like manner, the whole Spiral area, generated by the ray drawn from the point C to the curve, when it makes two revolutions, is $\frac{7}{3}$ of the circle described with the radius 2CE.





And, generally, the whole area generated by the ray from the beginning of the motion, till after any number n of revolutions, is equal to $\frac{n}{3}$ of the circle whose radius is $n \times$ CE, that is equal to the 3d part of the space which is the same multiple of the circle described with the greatest ray, as the number of revolutions is of unity.

In like manner also, any sector or portion of the area of the Spiral, terminated by the curve CmA and the right line CA, is equal to $\frac{1}{3}$ of the circular sector CAG terminated by the right lines CA and CG, this latter being the situation of the revolving ray when the point that describes the curve sets out from C. See Maclaurin's Flux. Introd. pa. 30, 31. See also QUADRATURE of the Spiral of Archimedes.

SPIRAL, *Logistic*, or *Logarithmic*. See LOGISTIC and QUADRATURE.

SPIRAL *of Pappus*, a Spiral formed on the surface of a sphere, by a motion similar to that by which the Spiral of Archimedes is described on a plane. This Spiral is so called from its inventor Pappus. Collect. Mathem. lib. 4 prop. 30. Thus, if C be the centre of the sphere, ARBA a great circle, P its pole; and while the quadrant PMA revolves about the pole P with an uniform motion, if a point proceeding from P move with a given velocity along the quadrant, it will trace upon the spherical surface the Spiral PZFa.

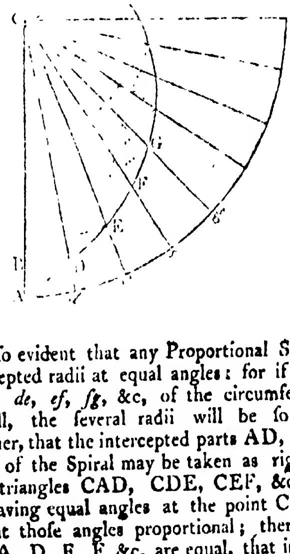
Now if we suppose the quadrant PMA to make a complete revolution in the same time that the point, which traces the Spiral on the surface of the sphere, describes the quadrant, which is the case considered by Pappus; then the portion of the spherical surface terminated by the whole Spiral, and the circle ARBA, and the quadrant PMA, will be equal to the square of the diameter AB. In any other case, the area PMAaFZP is to the square of that diameter AB, as the arc Aa is to the whole circumference ARBA. And this area is always to the spherical triangle PAa, as a square is to its circumscribing circle, or as the diameter of a circle is to half its circumference, or as 2 is to 3·14159 &c. See Maclaurin's Fluxions, Introd. pa. 31—33.

The portion of the spherical surface, terminated by the quadrant PMA, with the arches AR, FR, and the spiral PZF, admits of a perfect quadrature, when the ratio of the arch Aa to the whole circumference can be assigned. See Maclaurin, ibid. pa. 33.

Parabolic SPIRAL. See HELICOID.

Proportional SPIRAL, is generated by supposing the radius to revolve uniformly, and a point from the circumference to move towards the centre with a motion decreasing in geometrical progression. See LOGISTIC.

From the nature of a decreasing geometrical progression, it is easy to conceive that the radius CA may be continually divided; and although each successive division becomes shorter than the next preceding one, yet there must be an infinite number of divisions or terms before the last of them become of no finite magnitude. Whence it follows, that this Spiral winds continually round the centre, without ever falling into it in any finite number of revolutions.



It is also evident that any Proportional Spiral cuts the intercepted radii at equal angles: for if the divisions Ad, de, ef, fg, &c, of the circumference be very small, the several radii will be so close to one another, that the intercepted parts AD, DE, EF, FG, &c, of the Spiral may be taken as right lines; and the triangles CAD, CDE, CEF, &c, will be similar, having equal angles at the point C, and the sides about those angles proportional; therefore the angles at A, D, E, F, &c, are equal, that is, the spiral cuts the radii at equal angles. Robertson's Elem. of Navig. book 2, pa. 87.

Proportional Spirals are such Spiral lines as the rhumb lines on the terraqueous globe; which, because they make equal angles with every meridian, must also make equal angles with the meridians in the stereographic projection on the plane of the equator, and therefore will be, as Dr. Halley observes, Proportional Spirals about the polar point. From whence he demonstrates, that the meridian line is a scale of log. tangents of

of the half complements of the latitudes. See RHUMB, LOXODROMY, and MERIDIONAL *Parts*.

SPIRAL *Pump*. See *Archimedes*'s SCREW.

SPIRAL, in Architecture and Sculpture, denotes a curve that ascends, winding about a cone, or spire, so that all the points of it continually approach the axis.

By this it is distinguished from the Helix, which winds in the same manner about a cylinder.

SPORADES, in Astronomy, a name by which the ancients distinguished such stars as were not included in any constellation. These the moderns more usually call *unformed*, or *extraconstellary* stars.

Many of the Sporades of the ancients have been since formed into new constellations: thus, of those between Ursa Major and Leo, Hevelius has formed a constellation named Leo Minor; and of those between Ursa Minor and Auriga, he also formed the Lynx; and of those under the tail of Ursa Minor, another called Canis Venaticus; &c.

SPOTS, in Astronomy, are dark places observed on the disks or faces of the sun, moon, and planets.

The Spots on the sun are seldom if ever visible, except through a telescope. I have indeed met with persons whose eyes were so good that they have declared they could distinguish the solar Spots; and it is mentioned in Josephus à Costa's Natural and Moral History of the West Indies, book 1, ch. 2, before the use of telescopes, that in Peru there are Spots to be seen in the sun, which are not to be seen in Europe. See a memoir by Dr. Zach, in the Astronomical Ephemeris of the Acad. of Berlin for 1788, relating to the discoveries and unpublished papers of Thomas Harriot the celebrated algebraist. In that memoir it is shewn, for the first time, that Harriot was also an excellent astronomer, both theoretical and practical; that he made innumerable observations with telescopes from the year 1610, and, amongst them, 199 observations of the solar Spots, with their drawings, calculations, and the determinations of the sun's revolution round his axis. These Spots were also discovered near about the same time by Galileo and Scheiner. See Joh. Fabricius Phrysius De Maculis in Sole observatis & apparente eorum cum sole conversione narratio, 1611; also Galileo's Istoria e Demonstrazioni interne alle Machie Solare e loro accidenti, 1613.

Some distinguish the Spots into Maculæ, or dark Spots; and Faculæ, or bright Spots; but there seems but little foundation for any such division. They are very changeable as to number, form, &c; and are sometimes in a multitude, and sometimes none at all. Some imagine they may become so numerous, as to hide the whole face of the Sun, or at least the greater part of it; and to this they ascribe what Plutarch mentions, viz, that in the first year of the reign of Augustus, the sun's light was so faint and obscure, that one might look steadily at it with the naked eye. To which Kepler adds, that in 1547, the Sun appeared reddish, as when viewed through a thick mist; and hence he conjectures that the Spots in the sun are a kind of dark smoke, or clouds, floating on his surface.

Some again will have them stars, or planets, passing over the body of the sun: but others, with more probability, think they are opake bodies, in manner of crusts, formed like the scums on the surface of liquors.

Dr. Derham, from a variety of particulars, which he has recited, concerning the solar Spots, and their congruity to what we observe in our own globe, infers, that they are caused by the eruption of some new volcano in the sun, which pouring out at first a prodigious quantity of smoke and other opake matter, causeth the Spots: and as that fuliginous matter decays and spends itself, and the volcano at last becomes more torrid and flaming, so the Spots decay and become umbræ, and at last faculæ: which faculæ he supposes to be no other than more flaming lighter parts than any other parts of the sun. Philos. Trans. vol. 23, p. 1504, or Abr. vol. 4, p 235.

Dr. Franklin (in his Exper. and Observ. p. 266.) suggests a conjecture, that the parts of the Sun's sulphur separated by fire, rise into the atmosphere, and there being freed from the immediate action of the fire, they collect into cloudy masses, and gradually becoming too heavy to be longer supported, they descend to the sun, and are burnt over again. Hence, he says, the Spots appearing on his face, which are observed to diminish daily in size, their consuming edges being of particular brightness.

For another solution of these phenomena, see MACULÆ. Various other accounts and hypotheses of these Spots may be seen in many of the other volumes of the Philos. Trans. In one of these, viz, vol. 57, pa. 398, Dr. Horsley attempts to determine the height of the sun's atmosphere from the height of the solar Spots above his surface.

By means of the observations of these Spots, has been determined the period of the sun's rotation about his axis, viz, by observing their periodical return.

The lunar Spots are fixed: and astronomers reckon about 48 of them on the moon's face; to each of which they have given names. The 21st, called *Tycho*, is one of the most considerable.

Circular SPOTS, in Electricity. See CIRCULAR Spots and COLOURS.

Lucid SPOTS, *in the heavens*, are several little whitish Spots, that appear magnified, and more luminous when seen through telescopes; and yet without any stars in them. One of these is in Andromeda's girdle, and was first observed in 1612, by Simon Marius: it has some whitish rays near its middle, is liable to several changes, and is sometimes invisible. Another is near the ecliptic, between the head and bow of Sagittarius; it is small, but very luminous. A third is in the back of the Centaur, which is too far south to be seen in Britain. A fourth, of a smaller size, is before Antinous's right foot, having a star in it, which makes it appear more bright. A fifth is in the constellation Hercules, between the stars ζ and η, which is visible to the naked eye, though it is but small, when the sky is clear and the moon absent. It is probable that with more powerful telescopes these lucid Spots will be found to be congeries of very minute fixed stars.

Planetary SPOTS, are those of the planets. Astronomers find that the planets are not without their spots. Jupiter, Mars, and Venus, when viewed through a telescope, shew several very remarkable ones: and it is by

by the motion of these Spots, that the rotation of the planets about their axes is concluded, in the same manner as that of the sun is deduced from the apparent motion of his maculæ.

SPOUT, or *Water* SPOUT, an extraordinary meteor, or appearance, consisting of a moving column or pillar of water; called by the Latins *typho*, and *sypho*; and by the French *trompe*, from its shape, which resembles a speaking trumpet, the widest end uppermost.

Its first appearance is in form of a deep cloud, the upper part of which is white, and the lower black. From the lower part of this cloud there hangs, or rather falls down, what is properly called the Spout, in manner of a conical tube, largest at top. Under this tube is always a great boiling and flying up of the water of the sea, as in a jet d'eau. For some yards above the surface of the sea, the water stands as a column, or pillar; from the extremity of which it spreads, and goes off, as in a kind of smoke. Frequently the cone descends so low as to the middle of this column, and continues for some time contiguous to it; though sometimes it only points to it at some distance, either in a perpendicular, or in an oblique line.

Frequently it can scarce be distinguished, whether the cone or the column appear the first, both appearing all of a sudden against each other. But sometimes the water boils up from the sea to a great height, without any appearance of a Spout pointing to it, either perpendicularly or obliquely. Indeed, generally, the boiling or flying up of the water has the priority, this always preceding its being formed into a column. For the most part the cone does not appear hollow till towards the end, when the sea water is violently thrown up along its middle, as smoke up a chimney: soon after this, the Spout or canal breaks and disappears; the boiling up of the water, and even the pillar, continuing to the last, and for some time afterwards; sometimes till the Spout form itself again, and appear anew, which it will do several times in a quarter of an hour. See a description of several Water-Spouts by Mr. Gordon, and by Dr. Stuart, in Phil. Transf. Abr. vol. iv, pa. 103 &c.

M. de la Pryme, from a near observation of two or three Spouts in Yorkshire, described in the Philosophical Transactions, num. 281, or Abr. vol. iv, pa. 106, concludes, that the Water Spout is nothing but a gyration of clouds by contrary winds meeting in a point, or centre; and there, where the greatest condensation and gravitation is, falling down into a pipe, or great tube, somewhat like Archimedes's spiral screw; and, in its working and whirling motion, absorbing and raising the water, in the same manner as the spiral screw does; and thus destroying ships &c.

Thus, June the 21st, he observed the clouds mightily agitated above, and driven together; upon which they became very black, and were hurried round; whence proceeded a most audible whirling noise like that usually heard in a mill. Soon after there issued a long tube, or Spout, from the centre of the congregated clouds, in which he observed a spiral motion, like that of a screw, by which the water was raised up.

Again, August 15, 1687, the wind blowing at the same time out of the several quarters, created a great vortex and whirling among the clouds, the centre of which every now and then dropt down, in shape of a long thin black pipe, in which he could distinctly behold a motion like that of a screw, continually drawing upwards, and screwing up, as it were, wherever it touched.

In its progress it moved slowly over a grove of trees, which bent under it like wands, in a circular motion. Proceeding, it tore off the thatch from a barn, bent a huge oak tree, broke one of its greatest limbs, and threw it to a great distance. He adds, that whereas it is commonly said, the water works and rises in a column, before the tube comes to touch it, this is doubtless a mistake, owing to the fineness and transparency of the tubes, which do most certainly touch the surface of the sea, before any considerable motion can be raised in it; but which do not become opake and visible, till after they have imbibed a considerable quantity of water.

The dissolution of Water-Spouts he ascribes to the great quantity of water they have glutted: which, by its weight, impeding their motion, upon which their force, and even existence depends, they break, and let go their contents; which use to prove fatal to whatever is found underneath.

A notable instance of this may be seen in the Philosophical Transactions (num. 363, or Abr. vol iv. pa 108), related by Dr. Richardson. A Spout, in 1718, breaking on Emmotmoor, nigh Coln, in Lancashire, the country was immediately overflowed; a brook, in a few minutes, rose six feet perpendicularly high; and the ground upon which the Spout fell, which was 66 feet over, was torn up to the very rock, which was no less than 7 feet deep; and a deep gulf was made for above half a mile, the earth being raised in vast heaps on each side. See a description and figure of a Water-Spout, with an attempt to account for it in Franklin's Exp. and Obs. pa. 226, &c.

Signor Beccaria has taken pains to show that Water-Spouts have an electrical origin. To make this more evident, he first describes the circumstances attending their appearance, which are the following.

They generally appear in calm weather. The sea seems to boil, and to send up a smoke under them, rising in a hill towards the Spout. At the same time, persons who have been near them have heard a rumbling noise. The form of a Water-Spout is that of a speaking trumpet, the wider end being in the clouds, and the narrower end towards the sea.

The size is various, even in the same Spout. The colour is sometimes inclining to white, and sometimes to black. Their position is sometimes perpendicular to the sea, sometimes oblique; and sometimes the Spout itself is in the form of a curve. Their continuance is very various, some disappearing as soon as formed, and some continuing a considerable time. One that he had heard of continued a whole hour. But they often vanish, and presently appear again in the same place. The very same things that Water-Spouts are at sea, are some kinds of whirlwinds and hurricanes by land. They have been known to tear up trees, to throw down buildings, and make caverns in the earth; and in all these cases, to scatter earth, bricks, stones, timber, &c, to

to a great distance in every direction. Great quantities of water have been left, or raised by them, so as to make a kind of deluge; and they have always been attended by a prodigious rumbling noise.

That these phenomena depend upon electricity cannot but appear very probable from the nature of several of them; but the conjecture is made more probable from the following additional circumstances. They generally appear in months peculiarly subject to thunder-storms, and are commonly preceded, accompanied, or followed by lightning, rain, or hail, the previous state of the air being similar. Whitish or yellowish flashes of light have sometimes been seen moving with prodigious swiftness about them. And lastly, the manner in which they terminate exactly resembles what might be expected from the prolongation of one of the uniform protuberances of electrified clouds, mentioned before, towards the sea; the water and the cloud mutually attracting one another: for they suddenly contract themselves, and disperse almost at once; the cloud rising, and the water of the sea under it falling to its level. But the most remarkable circumstance, and the most favourable to the supposition of their depending on electricity, is, that they have been dispersed by presenting to them sharp pointed knives or swords. This, at least, is the constant practice of mariners, in many parts of the world, where these Water-Spouts abound, and he was assured by several of them, that the method has often been undoubtedly effectual.

The analogy between the phenomena of Water Spouts and electricity, he says, may be made visible, by hanging a drop of water to a wire communicating with the prime conductor, and placing a vessel of water under it. In these circumstances, the drop assumes all the various appearances of a Water Spout, both in its rise, form, and manner of disappearing. Nothing is wanting but the smoke, which may require a great force of electricity to become visible.

Mr. Wilcke also considers the Water-Spout as a kind of great electrical cone, raised between the cloud strongly electrified, and the sea or the earth, and he relates a very remarkable appearance which occurred to himself, and which strongly confirms his supposition. On the 20th of July 1758, at three o'clock in the afternoon, he observed a great quantity of dust rising from the ground, and covering a field, and part of the town in which he then was. There was no wind, and the dust moved gently towards the east, where appeared a great black cloud, which, when it was near its zenith, electrified his apparatus positively, and to as great a degree as ever he had observed it to be done by natural electricity. This cloud passed his zenith, and went gradually towards the west, the dust then following it, and continuing to rise higher and higher till it composed a thick pillar, in the form of a sugar-loaf, and at length seemed to be in contact with the cloud. At some distance from this, there came, in the same path, another great cloud, together with a long stream of smaller clouds, moving faster than the preceding. These clouds electrified his apparatus negatively, and when they came near the positive cloud, a flash of lightning was seen to dart through the cloud of dust, the positive cloud, the large negative cloud, and, as far as the eye could distinguish, the whole train of smaller negative clouds which followed it. Upon this, the negative clouds spread very much, and dissolved in rain, and the air was presently clear of all the dust. The whole appearance lasted not above half an hour. See Priestley's Electr. vol. 1, pa. 438, &c.

This theory of Water-Spouts has been farther confirmed by the account which Mr. Forster gives of one of them, in his Voyage Round the World, vol. 1, pa. 191, &c. On the coast of New Zealand he had an opportunity of seeing several, one of which he has particularly described. The water, he says, in a space of fifty or sixty fathoms, moved towards the centre, and there rising into vapour, by the force of the whirling motion, ascended in a spiral form towards the clouds. Directly over the whirlpool, or agitated spot in the sea, a cloud gradually tapered into a long slender tube, which seemed to descend to meet the rising spiral, and soon united with it into a straight column of a cylindrical form. The water was whirled upwards with the greatest violence in a spiral, and appeared to leave a hollow space in the centre; so that the water seemed to form a hollow tube, instead of a solid column; and that this was the case, was rendered still more probable by the colour, which was exactly like that of a hollow glass tube. After some time, this last column was incurvated, and broke like the others; and the appearance of a flash of lightning which attended its disjunction, as well as the hail stones which fell at the time, seemed plainly to indicate, that Water-Spouts either owe their formation to the electric matter, or, at least, that they have some connection with it.

In Pliny's time, the seamen used to pour vinegar into the sea, to assuage and lay the Spout when it approached them: our modern seamen think to keep it off, by making a noise with filing and scratching violently on the deck; or by discharging great guns to disperse it.

See the figure of a Water-Spout, fig. 1, plate 27.

SPRING, in Natural History, a fountain or source of water, rising out of the ground.

The most general and probable opinion among philosophers, on the formation of Springs, is, that they are owing to rain. The rain-water penetrates the earth till such time as it meets a clayey soil, or stratum; which proving a bottom sufficiently solid to sustain and stop its descent, it glides along it that way to which the earth declines, till, meeting with a place or aperture on the surface, through which it may escape, it forms a Spring, and perhaps the head of a stream or brook.

Now, that the rain is sufficient for this effect, appears from hence, that upon calculating the quantity of rain and snow which falls yearly on the tract of ground that is to furnish, for instance, the water of the Seine, it is found that this river does not take up above one-sixth part of it.

Springs commonly rise at the bottom of mountains; the reason is, that mountains collect the most waters, and give them the greatest descent the same way. And if we sometimes see Springs on high grounds, and even on the tops of mountains, they must come from other remoter places, considerably higher, along beds of clay, or clayey ground, as in their natural channels. So that if there happen to be a valley between a mountain on whose top is a Spring, and the mountain which is to furnish

furnish it with water, the Spring must be considered as water conducted from a reservoir of a certain height, through a subterraneous channel, to make a jet of an almost equal height.

As to the manner in which this water is collected, so as to form reservoirs for the different kinds of Springs, it seems to be this: the tops of mountains usually abound with cavities and subterraneous caverns, formed by nature to serve as reservoirs; and their pointed summits, which seem to pierce the clouds, stop those vapours which float in the atmosphere; which being thus condensed, they precipitate in water, and by their gravity and fluidity easily penetrate through beds of sand and the lighter earth, till they become stopped in their descent by the denser strata, such as beds of clay, stone, &c, where they form a bason or cavern, and working a passage horizontally, or a little declining, they issue out at the sides of the mountains. Many of these Springs discharge water, which running down between the ridges of hills, unite their streams, and form rivulets or brooks, and many of these uniting again on the plain, become a river.

The perpetuity of divers Springs, always yielding the same quantity of water, equally when the least rain or vapour is afforded as when they are the greatest, furnish, in the opinion of some, considerable objections to the universality or sufficiency of the theory above. Dr. Derham mentions a Spring in his own parish of Upminster, which he could never perceive by his eye was diminished in the greatest droughts, even when all the ponds in the country, as well as an adjoining brook, had been dry for several months together; nor ever to be increased in the most rainy seasons, excepting perhaps for a few hours, or at most for a day, from sudden and violent rains. Had this Spring, he thought, derived its origin from rain or vapours, there would be found an increase and decrease of its water corresponding to those of its causes; as we actually find in such temporary Springs, as have undoubtedly their rise from rain and vapour.

Some naturalists therefore have recourse to the sea, and derive the origin of Springs immediately from thence. But how the sea-water should be raised up to the surface of the earth, and even to the tops of the mountains, is a difficulty, in the solution of which they cannot agree. Some fancy a kind of hollow subterranean rocks to receive the watery vapours raised from channels communicating with the sea, by means of an internal fire, and to act the part of alembics, in freeing them from their saline particles, as well as condensing and converting them into water. This kind of subterranean laboratory, serving for the distillation of sea-water, was the invention of Des Cartes: see his Princip. part 4, § 64. Others, as De la Hire &c (Mem. de l'Acad. 1703) set aside the alembics, and think it enough that there be large subterranean reservoirs of water at the height of the sea, from whence the warmth of the bottom of the earth, &c, may raise vapours; which pervade not only the intervals and fissures of the strata, but the bodies of the strata themselves, and at length arrive near the surface; where, being condensed by the cold, they glide along on the first bed of clay they meet with, till they issue forth by some aperture in the ground. De la Hire adds, that the salts of stones and minerals may contribute to the detaining and fixing the vapours, and converting them into water. Farther, it is urged by some, that there is a still more natural and easy way of exhibiting the rise of the sea-water up into mountains &c, viz, by putting a little heap of sand, or ashes, or the like, into a bason of water; in which case the sand &c will represent the dry land, or an island; and the bason of water, the sea about it. Here, say they, the water in the bason will rise to the top of the heap, or nearly so, in the same manner, and from the same principle, as the waters of the sea, lakes, &c, rise in the hills. The principle of ascent in both is accordingly supposed to be the same with that of the ascent of liquids in capillary tubes, or between contiguous planes, or in a tube filled with ashes; all which are now generally accounted for by the doctrine of attraction.

Against this last theory, Perrault and others have urged several unanswerable objections. It supposes a variety of subterranean passages and caverns, communicating with the sea, and a complicated apparatus of alembics, with heat and cold, &c, of the existence of all which we have no sort of proof. Besides, the water that is supposed to ascend from the depths of the sea, or from subterranean canals proceeding from it, through the porous parts of the earth, as it rises in capillary tubes, ascends to no great height, and in much too small a quantity to furnish springs with water, as Perrault has sufficiently shewn. And though the sand and earth through which the water ascends may acquire some saline particles from it, they are nevertheless incapable of rendering it so fresh as the water of our fountains is generally found to be. Not to add, that in process of time the saline particles of which the water is deprived, either by subterranean distillation or filtration, must clog and obstruct those canals and alembics, by which it is supposed to be conveyed to our Springs, and the sea must likewise gradually lose a considerable quantity of its salt.

Different sorts of SPRINGS. Springs are either such as run continually, called perennial; or such as run only for a time, and at certain seasons of the year, and therefore called *temporary* Springs. Others again are called *intermitting* Springs, because they flow and then stop, aud flow and stop again; and *reciprocating* Springs, whose waters rise and fall, or flow and ebb, by regular intervals.

In order to account for these differences in Springs, let ABCDE (fig. 2, pl. 27) represent the declivity of a hill, along which the rain descends; passing through the fissures or channels BF, CG, DH, and LK, into the cavity or reservoir FGHKMI; from this cavity let there be a narrow drain or duct KE, which discharges the water at E. As the capacity of the reservoir is supposed to be large in proportion to that of the drain, it will furnish a constant supply of water to the spring at E. But if the reservoir FGHKMI be small, and the drain large, the water contained in the former, unless it is supplied by rain, will be wholly discharged by the latter, and the Spring will become dry: and so it will continue, even though it rains, till the water has had time to penetrate through the earth, or to pass through the channels into the reservoir; and the time necessary for furnishing a new supply to the drain KE will depend on the size of the fissures, the nature

ture of the soil, and the depth of the cavity with which it communicates. Hence it may happen, that the Spring at E may remain dry for a considerable time, and even while it rains; but when the water has found its way into the cavity of the hill, the Spring will begin to run. Springs of this kind, it is evident, may be dry in wet weather, especially if the cleft KE be not exactly level with the bottom of the cavity in the hill, and discharge water in dry weather; and the intermissions of the Spring may continue several days. But if we suppose XOP to represent another cavity, supplied with water by the channel NO, as well as by fissures and clefts in the rock, and by the draining of the adjacent earth; and another channel STV, communicating with the bottom of it at S, ascending to T, and terminating on the surface at V, in the form of a siphon; this disposition of the internal cavities of the earth, which we may reasonably suppose that nature has formed in a variety of places, will serve to explain the principle of reciprocating Springs; for it is plain, that the cavity XOP must be supplied with water to the height QPT, before it can pass over the bend of the channel at T, and then it will flow through the longer leg of the siphon TV, and be discharged at the end V, which is lower than S. Now if the channel STV be considerably larger than NO, by which the water is principally conveyed into the reservoir XOP, the reservoir will be emptied of its water by the siphon; and when the water descends below its orifice S, the air will drive the remaining water out of the channel STV, and the Spring will cease to flow. But in time the water in the reservoir will again rise to the height QPT, and be discharged at V as before. It is easy to conceive, that the diameters of the channels NO and STV may be so proportioned to one another, as to afford an intermission and renewal of the Spring V at regular intervals. Thus, if NO communicates with a well supplied by the tide, during the time of flow, the quantity of water conveyed by it into the cavity XOP may be sufficient to fill it up to QPT; and STV may be of such a size as to empty it, during the time of ebb. It is easy to apply this reasoning to more complicated cases, where several reservoirs and siphons communicating with each other, may supply Springs with circumstances of greater variety. See Musschenbroek's Introd. ad Phil. Nat. tom. ii. pa. 1010. Desagu. Exp Phil. vol. ii, pa. 173, &c.

We shall here observe, that Desaguliers calls those *reciprocating* Springs which flow constantly, but with a stream subject to increase and decrease; and thus he distinguishes them from *intermitting* Springs, which flow or stop alternately.

It is said that in the diocese of Paderborn, in Westphalia, there is a Spring which disappears after twenty-four hours, and always returns at the end of six hours with a great noise, and with so much force, as to turn three mills, not far from its source. It is called the Bolderborn, or boisterous Spring. Phil. Transf. num. 7, pa. 127.

There are many Springs of an extraordinary nature in our own country, which it is needless to recite, as they are explicable by the general principles already illustrated.

SPRING, *Ver*, in Astronomy and Cosmography, denotes one of the seasons of the year; commencing, in the northern parts of the earth, on the day the sun enters the first degree of Aries, which is about the 21st day of March, and ending when the sun enters Cancer, at the summer solstice, about the 21st of June; Spring ending when the summer begins.

Or, more strictly and generally, for any part of the earth, or on either side of the equator, the Spring season begins when the meridian altitude of the sun, being on the increase, is at a medium between the greatest and least; and ends when the meridian altitude is at the greatest. Or the Spring is the season, or time, from the moment of the sun's crossing the equator till he rise to the greatest height above it.

Elater SPRING, in Physics, denotes a natural faculty, or endeavour, of certain bodies, to return to their first state, after having been violently put out of the same by compressing, or bending them, or the like.

This faculty is usually called by philosophers, *elastic force*, or *elasticity*.

SPRING, in Mechanics, is used to signify a body of any shape, perfectly elastic.

Elasticity of a SPRING. See ELASTICITY.

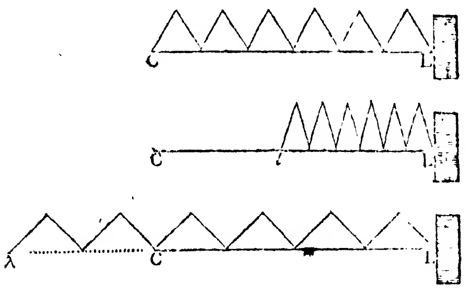
Length of a SPRING, may, from its etymology, signify the length of any elastic body; but it is particularly used by Dr Jurin to signify the greatest length to which a Spring can be forced inwards, or drawn outwards, without prejudice to its elasticity. He observes, this would be the whole length, were the Spring considered as a mathematical line; but in a material Spring, it is the difference between the whole length, when the Spring is in its natural situation, or the situation it will rest in when not disturbed by any external force, and the length or space it takes up when wholly compressed and closed, or when drawn out.

Strength or Force of a SPRING, is used for the force or weight which, when the Spring is wholly compressed or closed, will just prevent it from unbending itself. Also the Force of a Spring partly bent or closed, is the force or weight which is just sufficient to keep the Spring in that state, by preventing it from unbending itself any farther.

The theory of Springs is founded on this principle, *ut intensio, sic vis*; that is, the intensity is as the compressing force; or if a Spring be any way forced or put out of its natural situation, its resistance is proportional to the space by which it is removed from that situation. This principle has been verified by the experiments of Dr. Hook, and since him by those of others, particularly by the accurate hand of Mr. George Graham. Lectures De Potentia Restitutiva, 1678.

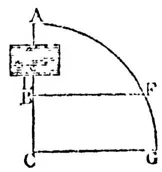
For elucidating this principle, on which the whole theory of Springs depends, suppose a Spring CL, resting at L against any immoveable support, but otherwise lying in its natural situation, and at full liberty. Then if this Spring be pressed inwards by any force p, or from C towards L, through the space of one inch, and can be there detained by that force p, the resistance of the Spring, and the force p, exactly counterbalancing each other; then will the double force $2p$ bend the Spring through the space of 2 inches, and the triple force $3p$ through 3 inches, and the quadruple force $4p$ through 4 inches, and so on. The space CL through which the Spring is bent, or by which its end C is removed from its natural situation, being always

ways proportional to the force which will bend it fo far, and will juft detain it when fo bent. On the other hand, if the end C be drawn outwards to any place λ, and be there detained from returning back by any force p, the fpace Cλ, through which it is fo drawn outwards, will be alfo proportional to the force p, which is juft able to retain it in that fituation.



It may here be obferved, that the Spring of the air, or its elaftic force, is a power of a different nature, and governed by different laws, from that of a palpable rigid Spring. For fuppofing the line LC to reprefent a cylindrical volume of air, which by compreffion is reduced to Ll, or by dilatation is extended to Lλ, its elaftic force will be reciprocally as Ll or Lλ; whereas the force or refiftance of a Spring is directly as Cl or Cλ.

This principle being premifed, Dr. Jurin lays down a general theorem concerning the action of a body ftriking on one end of a Spring, while the other end is fuppofed to reft againft an immoveable fupport.



Thus, if a Spring of the ftrength P, and the length CL, lying at full liberty upon an horizontal plane, reft with one end L againft an immoveable fupport; and a body of the weight M, moving with the velocity V, in the direction of the axis of the Spring, ftrike directly on the other end C, and fo force the Spring inwards, or bend it through any fpace CB; and if a mean proportional CG be taken between $\frac{M}{P} \times CL$ and $2a$, where a denotes the height to which a body would afcend in vacuo with the velocity V; and farther, if upon the radius R = CG be defcribed the quadrant of a circle GFA: then,

1. When the Spring is bent through the right fine CB of any arc GF, the velocity v of the body M is to the original velocity V, as the cofine BF is to the radius CG; that is $v : V :: BF : CG$, or $v = \frac{BF}{R} \times V$.

2. The time t of bending the Spring through the fame fine CB, is to T, the time of a heavy body's afcending in vacuo with the velocity V, as the correfponding arc is to $2a$; that is $t : T :: GF : 2a$, or $t = \frac{GF}{2a} \times T$.

The doctor gives a demonftration of this theorem, and deduces a great many curious corollaries from it. Thefe he divides into three claffes. The firft contains fuch corollaries as are of more particular ufe when the Spring is wholly clofed before the motion of the body ceafes: the fecond comprehends thofe relating to the cafe, when the motion of the body ceafes before the Spring is wholly clofed: and the third when the motion of the body ceafes at the inftant that the Spring is wholly clofed.

We fhall here mention fome of the laft clafs, as being the moft fimple; having firft premifed, that P = the ftrength of the Spring, L = its length, V = the initial velocity of the body clofing the Spring, M = its mafs, t = time fpent by the body in clofing the Spring, A = height from which a heavy body will fall in vacuo in a fecond of time, a = the height to which a body would afcend in vacuo with the velocity V, C = the velocity gained by the fall, m = the circumference of a circle, whofe diameter is 1. Then, the motion of the ftriking body ceafing when the Spring is wholly clofed, it will be,

1. $V = C\sqrt{\frac{PL}{2MA}}$.

2. $Vt = \frac{mCL}{4A} \times 1''$.

3. $MV = C\sqrt{\frac{PLM}{2A}}$ the firft momentum.

4. If a quantity of motion MV bend a Spring through its whole length, and be deftroyed by it; no other quantity of motion equal to the former, as $nM \times \frac{V}{n}$, will clofe the fame Spring, and be wholly deftroyed by it.

5. But a quantity of motion, greater or lefs than MV, in any given ratio, may clofe the fame Spring, and be wholly deftroyed in clofing it; [illegible] the time fpent in clofing the Spring will be refpectively greater or lefs, in the fame given ratio.

6. The initial vis viva, or MV^2 is $= \frac{C^2PL}{2A}$; and $2aM = PL$; alfo the initial vis viva is as the rectangle under the length and ftrength of the Spring, that is, MV^2 is as PL.

7. If the vis viva MV^2 bend a Spring through its whole length, and be deftroyed in clofing it; any other vis viva, equal to the former, as $n^2M \times \frac{V^2}{n^2}$, will clofe the fame Spring, and be deftroyed by it.

8. But the time of clofing the Spring by the vis viva $n^2M \times \frac{V^2}{n^2}$, will be to the time of clofing it by the vis viva MV^2, as n to 1.

9. If the vis viva MV^2 be wholly confumed in clofing a Spring, of the length L, and ftrength P; then the vis

vis viva n^2MV^2 will be sufficient to close, 1st, Either a Spring of the length L and strength n^2P. 2d, Or a Spring of the length nL and strength nP. 3d, Or of the length n^2L and strength P. 4th, Or, if n be a whole number, the number n^2 of Springs, each of the length L and strength P.—It may be added, that it appears from hence, that the number of similar and equal Springs a given body in motion can wholly close, is always proportional to the squares of the velocity of that body. And it is from this principle that the chief argument, to prove that the force of a body in motion is as the square of its velocity, is deduced. See Force.

The theorem given above, and its corollaries, will equally hold good, if the Spring be supposed to have been at first bent through a certain space, and by unbending itself to press upon a body at rest, and thus to drive that body before it, during the time of its expansion: only V, instead of being the initial velocity with which the body struck the Spring, will now be the final velocity with which the body parts from the Spring when totally expanded.

It may also be observed, that the theorem, &c, will equally hold good, if the Spring, instead of being pressed inward, be drawn outward by the action of the body. The like may be said, if the Spring be supposed to have been already drawn outward to a certain length, and in restoring itself draw the body after it. And lastly, the theorem extends to a Spring of any form whatever, provided L be the greatest length it can be extended to from its natural situation, and P the force which will confine it to that length. See Philos. Trans. num. 472, sect. 10, or vol. 43, art. 10.

Spring is more particularly used, in the Mechanic Arts, for a piece of tempered steel, put into various machines to give them motion, by the endeavour it makes to unbend itself.

In watches, it is a fine piece of well-beaten steel, coiled up in a cylindrical case, or frame; which by stretching itself forth, gives motion to the wheels, &c.

Spring *Arbor*, in a Watch, is that part in the middle of the spring-box, about which the Spring is wound or turned, and to which it is hooked at one end.

Spring *Box*, in a Watch, is the cylindrical case, or frame, containing within it the Spring of the watch.

Spring-*Compasses*. See Compasses.

Spring *of the Air*, or its elastic force. See Air, and Elasticity.

Spring-*Tides*, are the higher tides, about the times of the new and full moon. See Tide.

Springy, or *Elastic Body*. See Elastic *Body*.

SQUARE, in Geometry, a quadrilateral figure, whose angles are right, and sides equal. Or it is an equilateral rectangle. Or an equilateral rectangular parallelogram.

A Square, and indeed any other parallelogram, is bisected by its diagonal. And the side of a Square is incommensurable to its diagonal, being in the ratio of 1 to $\sqrt{2}$.

To find the Area of a Square. Multiply the side by itself, and the product is the area. So, if the side be 10, the area is 100; and if the side be 12, the area is 144.

Square *Foot*, is a Square each side of which is equal to a foot, or 12 inches; and the area, or Square foot is equal to 144 square inches.

Geometrical Square, a compartment often added on the face of a quadrant, called also *Line of* Shadows, and Quadrant.

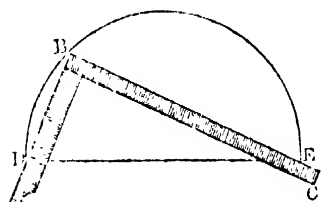
Gunner's Square. See Quadrant.

Magic Square. See Magic *Square*.

Square *Measures*, the Squares of the lineal measures; as in the following Table of Square Measures:

Squa. Inches.	Sq Feet.	Sq Yards.	Sq. Poles.	Sq. Chs	Acres.	Sq. Miles.
144	1					
1296	9	1				
39204	272¼	30¼	1			
627264	4356	484	16	1		
6272640	43560	4840	160	1	1	
4014489600	27878400	3097600	102400	6400	640	1

Normal Square, is an instrument, made of wood or metal, serving to describe and measure right angles;



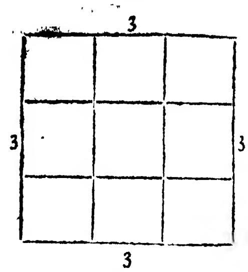
such is ABC. It consists of two rulers or branches fastened together perpendicularly. When the two legs are moveable on a joint, it is called a bevel.

To examine whether the Square is exact or not. Describe a semicircle DBE, with any radius at pleasure; in the circumference of which apply the angle of the Square to any point as B, and the edge of one leg to one end of the diameter as D, then if the other leg pass just by the other extremity at E, the Square is true; otherwise not.

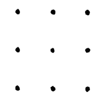
Square *Number*, is the product arising from a number multiplied by itself. Thus, 4 is the Square of 2, and 16 the Square of 4.

The series of Square integers, is 1, 4, 9, 16, 25, 36, &c;
which are the Squares of - - 1, 2, 3, 4, 5, 6, &c.
Or the Square fractions - - $\frac{1}{4}$, $\frac{4}{9}$, $\frac{9}{16}$, $\frac{16}{25}$, $\frac{25}{36}$, $\frac{36}{49}$, &c,
which are the Squares of - - $\frac{1}{2}$, $\frac{2}{3}$, $\frac{3}{4}$, $\frac{4}{5}$, $\frac{5}{6}$, $\frac{6}{7}$, &c.

A Square number is so called, either because it denotes the area of a Square, whose side is expressed by the root of the Square number; as in the annexed Square, which



which consists of 9 little squares, the side being equal to 3; or else, which is much the same thing, because the points in the number may be ranged in the form of a Square, by making the root, or factor, the side of the Square.



Some properties of Squares are as follow: 1. Of the

Natural series of Squares,	1^2, 2^2, 3^2, 4^2, &c,
which are equal to	1, 4, 9, 16, &c;

The mean proportional mn between any two of these Squares m^2 and n^2, is equal to the less square *plus* its root multiplied by the difference of the roots; or also equal to the greater square *minus* its root multiplied by the said difference of the roots. That is,

$$mn = m^2 + dm = n^2 - dn;$$

where $d = n - m$ is the difference of their roots.

2. An arithmetical mean between any two Squares m^2 and n^2, exceeds their geometrical mean, by half the Square of the difference of their roots.

That is $\frac{1}{2}m^2 + \frac{1}{2}n^2 = mn + \frac{1}{2}d^2$.

3. Of three equidistant Squares in the Series, the geometrical mean between the extremes, is less than the middle Square by the Square of their common distance in the Series, or of the common difference of their roots.

That is, $mp = n^2 - d^2$;

where m, n, p, are in arithmetical progression, the common difference being d.

4. The difference between the two adjacent Squares m^2, and n^2, is $n^2 - m^2 = 2m + 1$; in like manner, $p^2 - n^2 = 2n + 1$, the difference between the next two adjacent Squares n^2 and p^2; and so on, for the next following Squares. Hence the difference of these differences, or the second difference of the Squares, is $2n - 2m = 2 \times \overline{n - m} = 2$ only, because $n - m = 1$; that is, the second differences of the Squares are each the same constant number 2: therefore the first differences will be found by the continual addition of the number 2; and then the Squares themselves will be found by the continual addition of the first differences; and thus the whole series of Squares is constructed by addition only, as here below:

2d Diff.		2	2	2	2	2	2	&c.
1st Diff.	1	3	5	7	9	11	13	&c.
Squares.	1	4	9	16	25	36	49	&c.

And this method of constructing the table of Square numbers I find first noticed by Peletarius, in his Algebra.

5. Another curious property, also noted by the same author, is, that the sum of any number of the cubes of the natural series 1, 2, 3, 4, &c, taken from the beginning, always makes a Square number; and that the series of Squares, so formed, have for their roots the numbers 1, 3, 6, 10, 15, 21, &c, the diffs. of which are 1, 2, 3, 4, 5, 6, &c, viz, $1^3 = 1^2$,

$$1^3 + 2^3 = 3^2,$$

$$1^3 + 2^3 + 3^3 = 6^2,$$

$1^3 + 2^3 + 3^3 + 4^3 = 10^2$; and in general

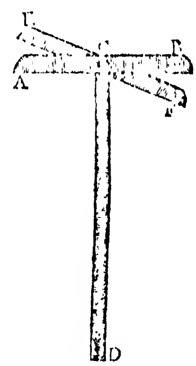
$$1^3 + 2^3 + 3^3 + n^3 = (1 + 2 + 3 + n)^2 = \tfrac{1}{2}n\cdot\overline{n+1};$$

where n is the number of the terms or cubes.

SQUARE *Root*, a number considered as the root of a second power or Square number: or a number which multiplied by itself, produces the given number. See EXTRACTION *of Roots*, and also the article ROOT, where tables of Squares and roots are inserted.

T. SQUARE, or *Tee* SQUARE, an instrument used in drawing, so called from its resemblance to the capital letter T.

This instrument consists of two straight rulers AB and CD, fixed at right angles to each other. To which is sometimes added a third EF, moveable about the pin C, to set it to make any angle with CD.—It is very useful for drawing parallel and perpendicular lines, on the face of a smooth drawing-board.



SQUARED *square*, SQUARED *cube*, &c. See POWER.

SQUARING. See QUADRATURE.

SQUARING *the Circle*, is the making or finding a Square whose area shall be equal to the area of a given circle.

The best mathematicians have not yet been able to resolve this problem accurately, and perhaps never will. But they can easily come to any proposed degree of approximation whatever; for instance, so near as not to err so much in the area, as a grain of sand would cover, in a circle whose diameter is equal to that of the orbit of Saturn. The following proportion is near enough the truth for any real use, viz, as 1 is to ·88622692, so is the diameter of any circle, to the side of the square of an equal area. Therefore, if the diameter of the circle be called d, and the side of the equal square s;

then is $s = \cdot 88622692d = \frac{8}{9}d$ nearly,

and $d = \dfrac{s}{\cdot 88622692} = \frac{9}{8}s$ nearly.

See CIRCLE, DIAMETER, and QUADRATURE.

 STADIUM,

STADIUM, an ancient Greek long measure, containing 125 geometrical paces, or 625 Roman feet; corresponding to our furlong.

Eight Stadia make a geometrical or Roman mile; and 20, according to Dacier, a French league: but according to others, 800 Stadia make $41\frac{2}{3}$ leagues.

Cuilletiere observes, that the Stadium was only 600 Athenian feet, which amount to 625 Roman, or 566 French, or 604 English feet: so that the Stadium should have been only 113 geometrical paces. It must be observed however, that the Stadium was different at different times and places.

STAFF, *Almucantar's, Augural, Back, Cross, Fore, Offset, &c.* See these several articles.

STAR, STELLA, in Astronomy, a general name for all the heavenly bodies.

The Stars are distinguished, from the phenomena, &c, into *fixed* and *erratic* or *wandering*.

Erratic or *Wandering* STARS, are those which are continually changing their places and distances, with regard to each other. These are what are properly called *planets*. Though to the same class may likewise be referred comets or blazing Stars.

Fixed STARS, called also barely *Stars*, by way of eminence, are those which have usually been observed to keep the same distance, with regard to each other.

The chief circumstances observable in the fixed Stars, are their *distance, magnitude, number, nature,* and *motion*. Of each of which in their order.

Distance of the Fixed STARS. The fixed Stars are so extremely remote from us, that we have no distances in the planetary system to compare to them. Their immense distance appears from hence, that they have no sensible parallax; that is, that the diameter of the earth's annual orbit, which is nearly 190 millions of miles, bears no sensible proportion to their distance.

Mr. Huygens (Cosmotheor. lib. 4) attempts to determine the distance of the Stars, by making the aperture of a telescope so small, as that the sun through it appears no larger than Sirius; which he found to be only as 1 to 27664 of his diameter, when seen with the naked eye. So that, were the sun's distance 27664 times as much as it is, it would then be seen of the same diameter with Sirius. And hence, supposing Sirius to be a sun of the same magnitude with our sun, the distance of Sirius will be found to be 27664 times the distance of the sun, or 345 million times the earth's diameter.

Dr. David Gregory investigated the distance of Sirius, by supposing it of the same magnitude with the sun, and of the same apparent diameter with Jupiter in opposition: as may be seen at large in his Astronomy, lib. 3, prop. 47.

Cassini (Mem. Acad. 1717), by comparing Jupiter and Sirius, when viewed through the same telescope, inferred, that the diameter of that planet was 10 times as great as that of the Star; and the diameter of Jupiter being 50″, he concluded that the diameter of Sirius was about 5″; supposing then that the real magnitude of Sirius is equal to that of the sun, and the distance of the sun from us 12000 diameters of the earth, and the apparent diameter of Sirius being to that of the sun as 1 to 384, the distance of Sirius becomes equal to 4608000 diameters of the earth.

These methods of Huygens, Gregory, and Cassini, are conjectural and precarious; both because the sun and Sirius are supposed of equal magnitude, and also because it is supposed the diameter of Sirius is determined with sufficient exactness.

Mr. Michell has proposed an enquiry into the probable parallax and magnitude of the fixed Stars, from the quantity of light which they afford us, and the peculiar circumstances of their situation. With this view he supposes, that they are, on a medium, equal in magnitude and natural brightness to the sun; and then proceeds to inquire, what would be the parallax of the sun, if he were to be removed so far from us, as to make the quantity of the light, which we should then receive from him, no more than equal to that of the fixed Stars. Accordingly, he assumes Saturn in opposition, as equal, or nearly equal in light to the brightest fixed Star. As the mean distance of Saturn from the sun is equal to about 2082 of the sun's semidiameters, the density of the sun's light at Saturn will consequently be less than at his own surface, in the ratio of the square of 2082 or 4334724 to 1: If Saturn therefore reflected all the light that falls upon him, he would be less luminous in that same proportion. And besides, his apparent diameter, in the opposition, being but about the 105th part of that of the sun, the quantity of light which we receive from him must be again diminished in the ratio of the square of 105 or 11025 to 1. Consequently, by multiplying these two numbers together, we shall have the whole of the light of the sun to that of Saturn, as the square nearly of 220,000 or 48,400,000,000 to 1. Hence, removing the sun to 220,000 times his present distance, he would still appear at least as bright as Saturn, and his whole parallax up to the diameter of the earth's orbit would be less than 2 seconds: and this must be assumed for the parallax of the brightest of the fixed Stars, upon the supposition that their light does not exceed that of Saturn.

By a like computation it may be found, that the distance, at which the sun would afford us as much light as we receive from Jupiter, is not less than 46,000 times his present distance, and his whole parallax in that case, upon the diameter of the earth's orbit, would not be more than 9 seconds; the light of Jupiter and Saturn, as seen from the earth, being in the ratio of about 22 to 1, when they are both in opposition, and supposing them to reflect equally in proportion to the whole of the light that falls upon them. But if Jupiter and Saturn, instead of reflecting the whole of the light that falls upon them, should really reflect only a part of it, as a 4th, or a 6th, which may be the case, the above distances must be increased in the ratio of 2 or $2\frac{1}{2}$ to 1, to make the sun's light no more than equal to theirs; and his parallax would be less in the same proportion. Supposing then that the fixed Stars are of the same magnitude and brightness with the sun, it is no wonder that their parallax should hitherto have escaped observation; since in this case it could hardly amount to 2 seconds, and probably not more than one in Sirius himself, though he had been placed in the pole of the ecliptic; and in those that appear much less luminous, as γ Draconis, which is only of the 3d magnitude, it could hardly be expected to be sensible with such instruments as have hitherto been used. However, Mr. Michell

schell suggests, that it is not impracticable to construct instruments capable of distinguishing even to the 20th part of a second, provided the air will admit of that degree of exactness. This ingenious writer apprehends that the quantity of light which we receive from Sirius, does not exceed the light we receive from the least fixed Star of the 6th magnitude, in a greater ratio than that of 1000 to 1, nor less than that of 400 to 1; and the smaller Stars of the 2d magnitude seem to be about a mean proportional between the other two. Hence the whole parallax of the least fixed Stars of the 6th magnitude, supposing them of the same size and native brightness with the sun, should be from about 2''' to 3''', and their distance from about 8 to 12 million times that of the sun: and the parallax of the smaller Stars of the 2d magnitude, upon the same supposition, should be about 12''', and their distance about 2 million times that of the sun.

This author farther suggests, that, from the apparent situation of the Stars in the heavens, there is the greatest probability that the Stars are collected together in clusters in some places, where they form a kind of systems, whilst in others there are either few or none of them; whether this disposition be owing to their mutual gravitation, or to some other law or appointment of the Creator. Hence it may be inferred, that such double Stars, &c. as appear to consist of two or more Stars placed very near together, do really consist of Stars placed near together, and under the influence of some general law: and he proceeds to inquire whether, if the Stars be collected into systems, the sun does not likewise make one of some system, and which fixed Stars those are that belong to the same system with him.

Those Stars, he apprehends, which are found in clusters, and surrounded by many others at a small distance from them, belong probably to other systems, and not to ours. And those Stars, which are surrounded with nebulæ, are probably only very large Stars which, on account of their superior magnitude, are singly visible, while the others, which compose the remaining parts of the same system, are so small as to escape our sight. And those nebulæ in which we can discover either none or only a few Stars, even with the assistance of the best telescopes, are probably systems that are still more distant than the rest. For other particulars of this inquiry, see Philos. Trans. vol. 57, pa. 234 &c.

As the distance of the fixed Stars is best determined by their parallax, various methods have been pursued, though hitherto without success, for investigating it; the result of the most accurate observations having given us little more than a distant approximation; from which however we may conclude, that the nearest of the fixed Stars cannot be less than 40 thousand diameters of the whole annual orbit of the earth distant from us.

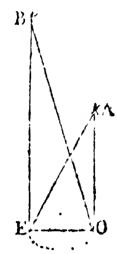
The method pointed out by Galileo, and attempted by Hook, Flamsteed, Molyneux, and Bradley, of taking the distances of such Stars from the zenith as pass very near it, has given us a much juster idea of the immense distance of the Stars, and furnished an approximation to their parallax, much nearer the truth, than any we had before.

Dr. Bradley assures us (Philos. Trans. num. 406, or Abr. vol. 6, pa. 162), that had the parallax amounted to a single second, or two at most, he should have perceived it in the great number of observations which he made, especially upon γ Draconis; and that it seemed to him very probable, that the annual parallax of this Star does not amount to a single second, and consequently that it is above 400 thousand times farther from us than the sun.

But Dr. Herschel, to whose industry and ingenuity, in exploring the heavens, astronomy is already much indebted, remarks that the instrument used on this occasion, being the same with the present zenith sectors, can hardly be allowed capable of shewing an angle of one or even two seconds, with accuracy: and besides, the Star on which the observations were made, is only a bright Star of the 3d magnitude, or a small Star of the 2d; and that therefore its parallax is probably much less than that of a Star of the first magnitude. So that we are not warranted in inferring, that the parallax of the Stars in general does not exceed 1'', whereas those of the first magnitude may have, notwithstanding the result of Dr. Bradley's observations, a parallax of several seconds.

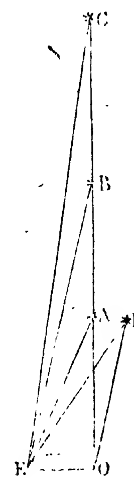
As to the method of zenith distances, it is liable to considerable errors, on account of refraction, the change of position of the earth's axis, arising from nutation, precession of the equinoxes, or other causes, and the aberration of light.

Dr. Herschel has proposed another method, by means of double Stars, which is free from these errors, and of such a nature, that the annual parallax, even if it should not exceed the 10th part of a second, may still become visible, and be ascertained at least much nearer than heretofore. This method, which was first proposed in an imperfect manner by Galileo, and has been also mentioned by other authors, is capable of every improvement which the telescope and mechanism of micrometers can furnish. To give a general idea of it, let O and E be two opposite points of the annual orbit, taken in the same plane with two stars A, B, of unequal magnitudes. Let the angle AOB be observed when the earth is at O, and AEB be observed when the earth is at E. From the difference of these angles, when there is any, the parallax of the Stars may be computed, according to the theory subjoined. These two Stars ought to be as near as possible to each other, and also to differ as much in magnitude as we can find them.



This theory of the annual parallax of double Stars, with the method of computing from thence what is usually called the parallax of the fixed Stars, or of single Stars of the first magnitude, such as are nearest to us, supposes 1st, that the Stars are all about the size of the sun; and 2dly, that the difference in their apparent magnitudes, is owing to their different distances, so as that a Star of the 2d, 3d, or 4th magnitude, is 2, 3, or 4 times as far off as one of the first. These principles, which Dr. Herschel premises as postulata, have so great a probability in their favour, that they will scarcely

fcarcely be objected to by thofe who are in the leaft acquainted with the doctrine of chances. See Mr. Michell's Inquiry, &c. already cited. And Philof. Tranf. vol. 57, pa. 234 - - - - 240. Alfo Dr. Halley, on the Number, Order, and Light of the fixed Stars, in the Philof. Tranf. vol. 31, or Abr. vol. 6, pa. 148.



Therefore, let EO be the whole diameter of the earth's annual orbit; and let A, B, C be three Stars fituated in the ecliptic, in fuch a manner, that they may appear all in one line OABC when the earth is at O. Now if OA, AB, BC be equal to each other, A will be a Star of the firft magnitude, B of the fecond, and C of the third. Let us next fuppofe the angle OAE, or parallax of the whole orbit of the earth, to be 1″ of a degree; then, becaufe very fmall angles, having the fame fubtenfe EO, may be taken to be in the inverfe ratio of the lines OA, OB, OC, &c, we fhall have EBO = $\frac{1}{2}$″, and ECO = $\frac{1}{3}$″, &c, alfo becaufe EA = AB nearly, the angle AEB = ABE = $\frac{1}{2}$″; and becaufe BC = $\frac{1}{2}$ BO = $\frac{1}{2}$ BE nearly, the angle BEC = $\frac{1}{2}$ BCE = $\frac{1}{6}$″, and hence AEC = $\frac{1}{2} + \frac{1}{6} = \frac{2}{3}$″; from all which it follows that, when the earth is at E,
the Stars A and B appear at $\frac{1}{2}$″ diftant from one another,
the Stars A and C at $\frac{2}{3}$″ diftant, and
the Stars B and C only $\frac{1}{6}$″ diftant. In like manner may be deduced a general expreffion for the parallax that will become vifible in the change of diftance between the two Stars, by the removal of the earth from one extreme of her orbit to the other. Let P denote the total parallax of a fixed Star of the magnitude of the M order, and m the number of the order of a fmaller Star, p denoting the partial parallax to be obferved by the change in the diftance of a double Star;

then is $p = \frac{m-M}{mM}P$, or $P = \frac{mMp}{m-M}$, which gives P, when p is found by obfervation.

For Ex. Suppofe a Star of the 1ft magnitude fhould have a fmall Star of the 12th magnitude near it; then will the partial parallax we are to expect to fee be $\frac{12-1}{12\times 1}P = \frac{11}{12}P$, or $\frac{11}{12}$ of the total parallax of the larger Star; and if we fhould, by obfervation, find the partial parallax between two fuch Stars to amount to 1″, then will the total parallax $P = \frac{12}{11}p = 1''\frac{1}{11}$. Again, if the Stars be of the 3d and 24th magnitude, the total parallax will be $P = \frac{24\times 3}{24-3}p = \frac{72}{21}p = \frac{24}{7}p$; fo that if by obfervation p be found to be $\frac{1}{10}$ of a fecond, the whole parallax P will come out $\frac{24}{70}'' = 0{\cdot}3428''$.

Farther, the Stars being ftill in the ecliptic, fuppofe they fhould appear in one line, when the earth is in fome other part of her orbit between E and O; then will the parallax be ftill expreffed by the fame algebraic formula, and one of the maxima will ftill lie at E, the other at O; but the whole effect will be divided into two parts, which will be in proportion to each other, as radius — fine to radius + fine of the Star's diftance from the neareft conjunction or oppofition.

When the Stars are any where out of the ecliptic, fituated fo as to appear in one line OABC perpendicular to EO, the maximum of parallax will ftill be expreffed by $\frac{m-M}{mM}P$; but there will arife another additional parallax in the conjunction and oppofition, which will be to that which is found 90° before or after the fun, as the fine (s) of the latitude of the Stars feen at O, is to radius (1); and the effect of this parallax will be divided into two parts; half of it lying on one fide of the large Star, the other half on the other fide of it. This latter parallax will alfo be compounded with the former, fo that the diftance of the Stars in the conjunction and oppofition will then be reprefented by the diagonal of a parallelogram, whofe fides are the two femiparallaxes; a general expreffion for which will be

$$\frac{m-M}{2mM}P\sqrt{1+s^2} \text{ or } \tfrac{1}{2}p\sqrt{1+s^2}.$$

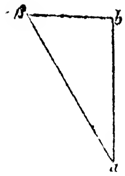
When the Stars are in the pole of the ecliptic, s will be = 1, and the laft formula becomes $\frac{1}{2}p\sqrt{2} = {\cdot}7071p$.

Again, let the Stars be at fome diftance, as 5″, from each other, and let them be both in the ecliptic. This cafe is refolvable into the firft; for imagine the Star A to ftand at I; then the angle AEI may be accounted equal to AOI; and as the foregoing formula, $p = \frac{m-M}{mM}P$, gives us the angles AEB, AEC, we are to add AEI or 5″ to AEB, which will give IEB. In general, let the diftance of the Stars be d, and let the obferved diftance at E be D; then will $D = d + p$, and therefore the whole parallax of the annual orbit will be expreffed by $\frac{D-d}{m-M}Dd = P$.

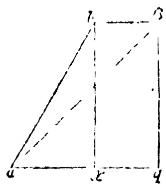
Suppofe now the Stars to differ only in latitude, one being in the ecliptic, the other at fome diftance as 5″ north, when feen at O. This cafe may alfo be refolved by the former; for imagine the Stars B and C to be elevated at right angles above the plane of the figure, fo that AOB, or AOC, may make an angle of 5″ at O; then inftead of the lines OABC, EA, EB, EC, imagine them all to be planes at right angles to the figure; and it will appear that the parallax of the Stars in longitude, muft be the fame as if the fmall Star had been without latitude. And fince the Stars B, C, by the motion of the earth from O to E, will not change their latitude, we fhall have the following conftruction for finding the diftance of the Stars AB and AC at E, and from thence the parallax P.

Let

Let the triangle $ab\beta$ repreſent the ſituation of the Stars; ab is the ſubtenſe of 5″, the angle under which they are ſuppoſed to be ſeen at O. The quantity $b\beta$ by the former theorem is found $= \frac{m-M}{mM}P$, which is the partial parallax, that would have been ſeen by the earth's moving from O to E, if both Stars had been in the ecliptic; but, on account of the difference in latitude, it will now be repreſented by $a\beta$, the hypotenuſe of the triangle $ab\beta$: therefore in general, putting $ab = d$, $a\beta = D$, we have $\frac{mM}{m-M}\sqrt{D^2 - d^2} = P$. Hence, D being found by obſervation, and the three d, m, M given, the total parallax is obtained.



When the Stars differ in longitude as well as latitude, this caſe may be reſolved in the following manner. Let the triangle $ab\beta$ repreſent the ſituation of the Stars, $ab = d$ being their diſtance ſeen at O, $a\beta = D$ their diſtance ſeen at E. That the change $b\beta$, which is produced by the earth's motion, will be truly expreſſed by $\frac{m-M}{mM}P$, may be proved as before, by ſuppoſing the Star a to have been placed at α.



Now let the angle of poſition $ba\alpha$ be taken by a micrometer, or by any other method ſufficiently exact; then, by reſolving the triangle $ab\alpha$, we obtain the longitudinal and latitudinal differences $a\alpha$ and $b\alpha$ of the two ſtars. Put $a\alpha = x$, $b\alpha = y$, and it will be $x + b\beta = aq$, whence

$$D = \sqrt{\left(x + \frac{m-M}{mM}P\right)^2 + y^2}; \text{ and } P = \frac{\sqrt{D^2 - y^2} - x}{m-M} mM.$$

If neither of the Stars ſhould be in the ecliptic, nor have the ſame longitude or latitude, the laſt theorem will ſtill ſerve to calculate the total parallax, whoſe maximum will lie in E. There will alſo ariſe another parallax, whoſe maximum will be in the conjunction and oppoſition, which will be divided, and lie on different ſides of the large Star; but as the whole parallax is extremely ſmall, it is not neceſſary to inveſtigate every particular caſe of this kind; for by reaſon of the diviſion of the parallax, which renders obſervations taken at any other time, except where it is greateſt, very unfavourable, the formulæ would be of little uſe.

Dr. Herſchel cloſes his account of this theory, with a general obſervation on the time and place where the maxima of parallax will happen. Thus, when two unequal Stars are both in the ecliptic, or, not being in the ecliptic, have equal latitudes, north or ſouth, and the larger Star has moſt longitude, the maximum of the apparent diſtance will be when the ſun's longitude is 90° more than the Star's, or when obſerved in the morning: and the minimum, when the longitude of the ſun is 90° leſs than that of the Star, or when obſerved in the evening. But when the ſmall Star has moſt longitude, the maximum and minimum, as well as the time of obſervation, will be the reverſe of the former. And when the Stars differ in latitude, this makes no alteration in the place of the maximum or minimum, nor in the time of obſervation; that is, it is immaterial which of the two Stars has the greater latitude. Philoſ. Tranſ. vol. 72, art. 11.

The diſtance of the Star γ Draconis appears, by Bradley's obſervations, already recited, to be at leaſt 400,000 times that of the ſun, and the diſtance of the neareſt fixed Star, not leſs than 40,000 diameters of the earth's annual orbit: that is, the diſtance from the earth, of the former at leaſt 38,000,000,000,000 miles, and the latter not leſs than 7,600,000,000,000 miles.

As theſe diſtances are immenſely great, it may both be amuſing, and help to a clearer and more familiar idea, to compare them with the velocity of ſome moving body, by which they may be meaſured.

The ſwifteſt motion we know of, is that of light, which paſſes from the ſun to the earth in about 8 minutes; and yet this would be above 6 years traverſing the firſt ſpace, and near a year and a quarter in paſſing from the neareſt fixed Star to the earth. But a cannon ball, moving on a medium at the rate of about 20 miles in a minute, would be 3 million 8 hundred thouſand years in paſſing from γ Draconis to the earth, and 760 thouſand years paſſing from the neareſt fixed Star. Sound, which moves at the rate of about 13 miles in a minute, would be 5 million 600 thouſand years traverſing the former diſtance, and 1 million 128 thouſand, in paſſing through the latter.

The celebrated Huygens purſued ſpeculations of this kind ſo far, as to believe it not impoſſible, that there may be Stars at ſuch inconceivable diſtances, that their light has not yet reached the earth ſince its creation.

Dr. Halley has alſo advanced, what he ſays ſeems to be a metaphyſical paradox (Philoſ. Tranſ. number 364, or Abr. vol. 6, pa. 148), viz, that the number of fixed Stars muſt be more than finite, and ſome of them more than at a finite diſtance from others: and Addiſon has juſtly obſerved, that this thought is far from being extravagant, when we conſider that the univerſe is the work of infinite power, prompted by infinite goodneſs, and having an infinite ſpace to exert itſelf in; ſo that our imagination can ſet no bounds to it.

Magnitude of the fixed STARS. The magnitudes of the Stars appear to be very different from one another; which difference may probably ariſe, partly from a diverſity in their real magnitude, but principally from their diſtances, which are different.

To the bare eye, the Stars appear of ſome ſenſible magnitude, owing to the glare of light ariſing from the numberleſs reflections from the aerial particles &c about the eye: this makes us imagine the Stars to be much larger than they would appear, if we ſaw them only by the few rays which come directly from them, ſo as to enter our eyes without being intermixed with others.

Any perſon may be ſenſible of this, by looking at a Star of the firſt magnitude through a long narrow tube; which, though it takes in as much of the ſky as would hold a thouſand ſuch ſtars, ſcarce renders that one viſible.

The

The Stars, on account of their apparently various sizes, have been distributed into several classes, called *magnitudes*. The 1st class, or Stars of the first magnitude, are those that appear largest, and may probably be nearest to us. Next to these, are those of the 2d magnitude; and so on to the 6th, which comprehends the smallest Stars visible to the naked eye. All beyond these, that can be perceived by the help of telescopes, are called *telescopic* stars. Not that all the Stars of each class appear justly of the same magnitude; there being great latitude in this respect; and those of the first magnitude appearing almost all different in lustre and size. There are also other Stars, of intermediate magnitudes, which astronomers cannot refer to one class rather than another, and therefore they place them between the two. Procyon, for instance, which Ptolomy makes of the first magnitude, and Tycho of the 2d, Flamsteed lays down as between the 1st and 2d. So that, instead of 6 magnitudes, we may say there are almost as many orders of Stars, as there are Stars; so great variations being observable in the magnitude, colour, and brightness of them.

There seems to be little chance of discovering with certainty the real size of any of the fixed Stars; we must therefore be content with an approximation, deduced from their parallax, if this should ever be found; and the quantity of light they afford us, compared with that of the sun. And to this purpose, Dr. Herschel informs us, that with a magnifying power of 6450, and by means of his new micrometer, he found the apparent diameter of α Lyræ to be $0''\cdot355$.

The Stars are also distinguished, with regard to their situation, into *asterisms*, or *constellations*; which are nothing but assemblages of several neighbouring Stars, considered as constituting some determinate figure, as of an animal, &c, from which it is therefore denominated: a division as ancient as the book of Job, in which mention is made of Orion, the Pleiades, &c.

Besides the Stars thus distinguished into magnitudes and constellations, there are others not reduced to either. Those not reduced into constellations, are called *informes*, or *unformed* Stars; of which kind several, so left at large by the ancients, have since been formed into new constellations by the modern astronomers, and especially by Hevelius.

Those not reduced to classes or magnitudes, are called nebulous Stars; but such as only appear faintly in clusters, in form of little lucid spots, nebulæ, or clouds.

Ptolomy sets down five of such nebulæ, viz, one at the extremity of the right hand of Perseus, which appears through the telescope, thick set with Stars; one in the middle of the crab, called *Præsepe*, or the Manger, in which Galileo counted above 40 Stars; one unformed near the sting of the Scorpion; another in the eye of Sagittarius, in which two Stars may be seen in a clear sky with the naked eye, and several more with the telescope; and the fifth in the head of Orion, in which Galileo counted 21 Stars.

Flamsteed observed a cloudy Star before the bow of Sagittarius, which consists of a great number of small Stars; and the Star *d* above the right shoulder of this constellation is encompassed with several more. Flamsteed and Cassini also discovered one between the great and little dog, which is very full of Stars, that are visible only by the telescope.

But the most remarkable of all the cloudy Stars, is that in the middle of Orion's sword, in which Huygens and Dr. Long observed 12 Stars, 7 of which (3 of them, now known to be 4, being very close together) seem to shine through a cloud, very lucid near the middle, but faint and ill defined about the edges. But the greatest discoveries of nebulæ and clusters of Stars, we owe to the powerful telescopes of Dr. Herschel, who has given accounts of some thousands of such nebulæ, in many of which the Stars seem to be innumerable, like grains of sand. See Philos. Trans. 1784, 1785, 1786, 1789. See GALAXY, and MAGELLANIC *clouds*, and *lucid* SPOTS.

Cassini is of opinion, that the brightness of these proceeds from Stars so minute, as not to be distinguished by the best glasses: and this opinion is fully confirmed by the observations of Dr. Herschel, whose powerful telescopes shew those lucid specks to be composed entirely of masses of small Stars, like heaps of sand.

There are also many Stars which, though they appear single to the naked eye, are yet discovered by the telescope to be double, triple, &c. Of these, several have been observed by Cassini, Hooke, Long, Maskelyne, Hornsby, Pigott, Mayer, &c; but Dr. Herschel has been much the most successful in observations of this kind; and his success has been chiefly owing to the very extraordinary magnifying powers of the Newtonian 7 feet reflector which he has used, and the advantage of an excellent micrometer of his own construction. The powers which he has used, have been 146, 227, 278, 460, 754, 932, 1159, 1536, 2010, 3168, and even 6450. He has already formed a catalogue, containing 269 double Stars, 227 of which, as far as he knows, have not been noticed by any other person. Among these there are also some Stars that are treble, double-double, quadruple, double-treble, and multiple. His catalogue comprehends the names of the Stars, and the number in Flamsteed's catalogue, or such a description of those that are not contained in it, as will be found sufficient to distinguish them; also the comparative size of the Stars; their colours as they appeared to his view; their distances determined in several different ways; their angle of position with regard to the parallel of declination; and the dates when he first perceived the Stars to be double, treble, &c. His observations appear to commence with the year 1776, but almost all of them were made in the years 1779, 1780, 1781.

Dr. Herschel has distributed the double Stars contained in his catalogue, into 6 different classes. In the first he has placed all those which require a very superior telescope, with the utmost clearness of air, and every other favourable circumstance, to be seen at all, or well enough to judge of them; and there are 24 of these. To the 2d class belong all those double Stars that are proper for estimations by the eye, and very delicate measures by the micrometer; the number being 38. The 3d class comprehends all those double Stars, that are between 5″ and 15″ asunder; the number of them being 46. The 4th, 5th, and 6th classes contain

double

double Stars that are from 15″ to 30″, and from 30″ to 1′, and from 1′ to 2′ or more asunder; of which there are 44 in the 4th class, 51 in the 5th class, and 66 in the 6th class: the last of this class is α Tauri, number 87 of Flamsteed, whose apparent diameter, upon the meridian measured with a power of 460 at a mean of two observations 1″ 46‴, and with a power of 932 at a mean of two observations 1″ 12‴. See the list at large, Philosoph. Transf. vol. 72, art. 12.

The Stars are also distinguished, in each constellation, by numbers, or by the letters of the alphabet. This sort of distinction was introduced by John Bayer, in his Uranometria, 1654; where he denotes the Stars, in each constellation, by the letters of the Greek alphabet, α, β, γ, δ, ε, &c, viz, the most remarkable Star of each by α, the 2d by β, the 3d by γ, &c; and when there are more Stars in a constellation than the characters in the Greek alphabet, he denotes the rest, in their order, by the Roman letters A, b, c, d, &c. But as the number of the Stars, that have been observed and registered in catalogues, since Bayer's time, is greatly increased, as by Flamsteed and others, the additional ones have been marked by the ordinal numbers 1, 2, 3, 4, 5, &c.

The *Number of* STARS. The number of the Stars appears to be immensely great, almost infinite; yet have astronomers long since ascertained the number of such as are visible to the eye, which are much fewer than at first sight could be imagined. See CATALOGUE *of the Stars*.

Of the 3000 contained in Flamsteed's catalogue, there are many that are only visible through a telescope; and a good eye scarce ever sees more than a thousand at the same time in the clearest heaven; the appearance of innumerable more, that are frequent in clear winter nights, arising from our sight's being deceived by their twinkling, and from our viewing them confusedly, and not reducing them to any order. But nevertheless we cannot but think the Stars are almost, if not altogether, infinite. See Halley, on the number, order, and light of the fixed Stars, Philof. Tranf. number 364, or Abr. vol. 6, pa. 148.

Riccioli, in his New Almagest, affirms, that a man who shall say there are above 20 thousand times 20 thousand, would say nothing improbable. For a good telescope, directed indifferently to almost any point of the heavens, discovers multitudes that are lost to the naked eye; particularly in the milky way, which some take to be an assemblage of Stars, too remote to be seen singly, but so closely disposed as to give a luminous appearance to that part of the heavens where they are. And this fact has been confirmed by Herschel's observations: though it is disputed by others, who contend that the milky way must be owing to some other cause.

In the single constellation of the Pleiades, instead of 6, 7, or 8 Stars seen by the best eye; Dr. Hook, with a telescope 12 feet long, told 78, and with larger glasses many more, of different magnitudes. And F. de Rheita affirms, that he has observed above 2000 Stars in the single constellation of Orion. The same author found above 188 in the Pleiades. And Huygens, looking at the Star in the middle of Orion's sword, instead of one, found it to be 12. Galileo found 80 in the space of the belt of Orion's sword, 21 in the nebulous Star of his head, and above 500 in another part of him, within the compass of one or two degrees space, and more than 40 in the nebulous Star Præsepe.

The Changes that have happened in the STARS are very considerable. The first change that is upon record, was about 120 years before Christ; when Hipparchus, discovering a new Star to appear, was first induced to make a catalogue of the Stars, that posterity might perceive any future changes of the like nature.

In the year 1572, Cornelius Gemma and Tycho Brahe observed another new Star in the constellation Cassiopeia, which was likewise the occasion of Tycho's making a new catalogue. At first its magnitude and brightness exceeded the largest of the Stars, Sirius and Lyra; and even equalled the planet Venus when nearest the earth, and was seen in fair day-light. It continued 16 months; towards the latter end of which it began to dwindle, and at length, in March 1574, it totally disappeared, without any change of place in all that time.

Leovicius tells us of another Star appearing in the same constellation, about the year 945, which resembled that of 1572; and he quotes another ancient observation, by which it appears that a new Star was seen about the same place in 1264. Dr. Keil thinks these were all the same Star; and indeed the periodical intervals, or distance of time between these appearances, were nearly equal, being from 318 to 319 years; and if so, its next appearance may be expected about 1890.

Fabricius, in 1596, discovered another new Star, called the *stella mira*, or *wonderful Star*, in the neck of the whale, which has since been found to appear and disappear periodically, 7 times in 6 years, continuing in its greatest lustre for 15 days together; and is never quite extinguished. Its course and motion are described by Bulliald, in a treatise printed at Paris in 1667. Dr. Herschel has lately, viz, in the years 1777, 1778, 1779, and 1780, made several observations on this Star, an account of which may be seen in the Philof. Tranf. vol. 70, art. 21.

In the year 1600, William Jansen discovered a changeable Star in the neck of the Swan, which gradually decreased till it became so small as to be thought to disappear entirely, till the years 1657, 1658, and 1659, when it regained its former lustre and magnitude; but soon decayed again, and is now of the smallest size.

In the year 1604, a new Star was seen by Kepler, and several of his friends, near the heel of the right foot of Serpentarius, which was particularly bright and sparkling; and it was observed to be every moment changing into some of the colours of the rainbow, except when it is near the horizon, at which time it was generally white. It surpassed Jupiter in magnitude, but was easily distinguished from him, by the steady light of the planet. It disappeared about the end of the year 1605, and has not been seen since that time.

Simon Marius discovered another in Andromeda's girdle,

girdle, in 1612 and 1613; though Bulliald says it had been seen before, in the 15th century.

In July 1670, Hevelius discovered a second changeable Star in the Swan, which was so diminished in October as to be scarce perceptible. In April following it regained its former lustre, but wholly disappeared in August. In March 1672 it was seen again, but appeared very small, and has not been visible since.

In 1686 a third changeable Star was discovered by Kirchius in the Swan, viz, the Star χ of that constellation, which returned periodically in about 405 days.

In 1672 Cassini saw a Star in the neck of the Bull, which he thought was not visible in Tycho's time, nor when Bayer made his figures.

It is certain, from the old catalogues, that many of the ancient Stars are not now visible. This has been particularly remarked with regard to the Pleiades.

M. Montanari, in his letter to the Royal Society in 1670, observes that there are now wanting in the heavens two Stars of the 2d magnitude, in the stern of the ship Argo, and its yard, which had been seen till the year 1664. When they first disappeared is not known; but he assures us there was not the least glimpse of them in 1668. He adds, he has observed many more changes in the fixed Stars, even to the number of a hundred. And many other changes of the Stars have been noticed by Cassini, Maraldi, and other observers. See Gregory's Astron. lib. 2, prop. 30.

But the greatest numbers of variable Stars have been observed of late years, and the most accurate observations made on their periods, &c, by Herschel, Goodricke, Pigott, &c, in the late volumes of the Philos. Trans. particularly in the vol. for 1786, where the last of these gentlemen has given a catalogue of all that have been hitherto observed, with accounts of the observations that have been made upon them.

Various hypotheses have been devised to account for such changes and appearances in the Stars. It is not probable they could be comets, as they had no parallax, even when largest and brightest. It has been supposed that the periodical Stars have vast dark spots, or dark sides, and very slow rotations on their axes, by which means they must disappear when the darker side is turned towards us. And as for those which break out suddenly with such lustre, these may perhaps be suns whose fuel is almost spent, and again supplied by some of their comets falling upon them, and occasioning an uncommon blaze and splendor for some time; which it is conjectured may be one use of the cometary part of our system.

Maupertuis, in his Dissertation on the figures of the Celestial Bodies (pa. 61—63), is of opinion that some Stars, by their prodigious swift rotation on their axes, may not only assume the figures of oblate spheroids, but that by the great centrifugal force arising from such rotations, they may become of the figures of mill-stones, or be reduced to flat circular planes, so thin as to be quite invisible when their edges are turned towards us, as Saturn's ring is in such position. But when very eccentric planets or comets go round any flat Star in orbits much inclined to its equator, the attraction of the planets or comets in their perihelions must alter the inclination of the axis of that Star; on which account it will appear more or less large and luminous, as its broad side is more or less turned towards us. And thus he imagines we may account for the apparent changes of magnitude and lustre of those Stars, and also for their appearing and disappearing.

Hevelius apprehends (Cometograph. pa. 380), that the Sun and Stars are surrounded with atmospheres, and that by whirling round their axes with great rapidity, they throw off great quantities of matter into those atmospheres, and so cause great changes in them; and that thus it may come to pass that a Star, which, when its atmosphere is clear, shines out with great lustre, may at another time, when it is full of clouds and thick vapours, appear greatly diminished in brightness and magnitude, or even become quite invisible.

Nature of the fixed STARS. The immense distance of the Stars leaves us greatly at a loss about the nature of them. What we can gather for certain from their phenomena, is as follows:

1st, That the fixed Stars are greater than our earth: because if that was not the case, they could not be visible at such an immense distance.

2nd, The fixed Stars are farther distant from the earth than the farthest of the planets. For we frequently find the fixed Stars hid behind the body of the planets: and besides, they have no parallax, which the planets have.

3rd, The fixed Stars shine with their own light; for they are much farther from the Sun than Saturn, and appear much smaller than Saturn; but since, notwithstanding this, they are found to shine much brighter than that planet, it is evident they cannot borrow their light from the same source as Saturn does, viz, the Sun; but since we know of no other luminous body beside the Sun, whence they might derive their light, it follows that they shine with their own native light.

Besides, it is known, that the more a telescope magnifies, the less is the aperture through which the Star is seen; and consequently, the fewer rays it admits into the eye. Now since the Stars appear less in a telescope which magnifies two hundred times, than they do to the naked eye, insomuch that they seem to be only indivisible points, it proves at once that the Stars are at immense distances from us, and that they shine by their own proper light. If they shone by borrowed light, they would be as invisible without telescopes as the satellites of Jupiter are; for the satellites appear larger when viewed with a good telescope than the largest fixed Stars do.

Hence,

1. We deduce, that the fixed Stars are so many suns; for they have all the characters of suns.

2. That in all probability the Stars are not smaller than our sun.

3. That it is highly probable each Star is the centre of a system, and has planets or earths revolving round it, in the same manner as round our sun, i. e. it has opake bodies illuminated, warmed, and cherished by its light and heat. As we have incomparably more light from the moon than from all the Stars together, it is absurd to imagine that the Stars were made for no other purpose than to cast a faint light upon the earth; especially

especially since many more require the assistance of a good telescope to find them out, than are visible without that instrument. Our sun is surrounded by a system of planets and comets, all which would be invisible from the nearest fixed Star; and from what we already know of the immense distance of the Stars, it is easy to prove, that the sun, seen from such a distance, would appear no larger than a Star of the first magnitude.

From all this it is highly probable, that each Star is a sun to a system of worlds moving round it, though unseen by us; especially as the doctrine of a plurality of worlds is rational, and greatly manifests the power, the wisdom, and the goodness of the great creator.

How immense, then, does the universe appear! Indeed, it must either be infinite, or infinitely near it.

Kepler, it is true, denies that each Star can have its system of planets as ours has; and takes them all to be fixed in the same surface or sphere; urging, that were one twice or thrice as remote as another, it would be twice or thrice as small, supposing their real magnitudes equal; whereas there is no difference in their apparent magnitudes, justly observed, at all. But to this it is opposed, that Huygens has not only shewn, that fires and flames are visible at distances where other bodies, comprehended under equal angles, disappear; but it should likewise seem, that the optic theorem about the apparent diameters of objects, being reciprocally proportional to their distances from the eye, does only hold while the object has some sensible ratio to its distance.

As for periodical Stars, &c. see CHANGES, *&c. of Stars*, supra.

Motion of the STARS. The fixed Stars have two kinds of apparent motion; one called the *first*, *common*, or *diurnal motion*, arising from the earth's motion round its axis: by this they seem to be carried along with the sphere or firmament, in which they appear fixed, round the earth, from east to west, in the space of 24 hours.

The other, called the *second*, or *proper motion*, is that by which they appear to go backwards from west to east, round the poles of the ecliptic, with an exceeding slow motion, as describing a degree of their circle only in the space of 71½ years, or 50⅓ seconds in a year. This apparent motion is owing to the recession of the equinoctial points, which is 50⅓ seconds of a degree in a year backward, or contrary to the order of the signs of the zodiac.

In consequence of this second motion, the longitude of the Stars will be always increasing. Thus, for example, the longitude of Cor Leonis was found at different periods, to be as follows: viz,

	Year.		*Long.*
By Ptolomy, in - - -	138	to be	2° 30′
By the Persians, in -	1115	- - -	17 30
By Alphonsus, in - -	1364	- - -	20 40
By Prince of Hesse, in	1586	- - -	24 11
By Tycho, in - - -	1601	- - -	24 17
By Flamsteed, in - -	1690	- - -	25 31½

Whence the proper motion of the Stars, according to the order of the signs, in circles parallel to the ecliptic, is easily inferred.

It was Hipparchus who first suspected this motion, upon comparing his own observations with those of Timocharis and Aristyllus. Ptolomy, who lived three centuries after Hipparchus, demonstrated the same by undeniable arguments.

The increase of longitude in a century, as stated by different astronomers, is as follows:

By Tycho Brahe - - - -	1°	25′	0″
Copernicus - - - - -	1	23	40½
Flamsteed and Riccioli	1	23	20
Bulliald - - - - - - -	1	24	54
Hevelius - - - - - -	1	24	46⅚
Dr. Bradley, &c. - -	1	23	55

which is at the rate of 50⅓ seconds per year.

From these data, the increase in the longitude of a Star for any given time, is easily had, and thence its longitude at any time: ex. gr. the longitude of Sirius, in Flamsteed's tables, for the year 1690, being 9° 49′ 1″, its longitude for the year 1800, is found by multiplying the interval of time, viz, 110 years, by 50⅓, the product 5537″, or 1° 32′ 17″, added to the given longitude - - - - 9 49 1

gives the longitude - - 11 21 18 for the year 1800.

The chief phenomena of the fixed Stars, arising from their common and proper motion, besides their longitude, are their altitudes, right ascensions, declinations, occultations, culminations, risings, and settings.

Some have supposed that the latitudes of the Stars are invariable. But this supposition is founded on two assumptions, which are both controverted among astronomers. The one of these is, that the orbit of the earth continues unalterably in the same plane, and consequently that the ecliptic is invariable; the contrary of which is now very generally allowed.

The other assumption is, that the Stars are so fixed as to keep their places immoveably. Ptolomy, Tycho, and others, comparing their observations with those of the ancient astronomers, have adopted this opinion. But from the result of the comparison of our best modern observations, with such as were formerly made with any tolerable degree of exactness, there appears to have been a real change in the position of some of the fixed Stars, with respect to each other; and several Stars of the first magnitude have already been observed, and others suspected to have a proper motion of their own.

Dr. Halley (Philos. Trans. number 355, or Abr. vol. 4, p. 225) has observed, that the three following Stars, the Bull's eye, Sirius, and Arcturus, are now found to be above half a degree more southerly than the ancients reckoned them: that this difference cannot arise from the errors of the transcribers, because the declinations of the Stars, set down by Ptolomy, as observed by Timocharis, Hipparchus, and himself, shew their latitudes given by him are such as those authors intended: and it is scarce to be believed that those three observers could be deceived in so plain a matter. To this he adds, that the bright Star in the shoulder of Orion has, in Ptolomy, almost a whole degree more southerly latitude than at present: that an ancient observation, made at Athens in the year 509, as Bulliald supposes, of an appulse of the moon to the Bull's eye, shews that Star to have had less latitude at that time than it now has: that as to Sirius, it appears by Tycho's observations, that he found him 4½′ more northerly than

than he is at this time. All these obfervations, compared together, feem to favour an opinion, that fome of the Stars have a proper motion of their own, which changes their places in the fphere of heaven: this change of place, as Dr. Halley obferves, may fhew itfelf in fo long a time as 1800 years, though it be entirely imperceptible in the fpace of one fingle century; and it is likely to be fooneft difcovered in fuch Stars as thofe juft now mentioned; becaufe they are all of the firft magnitude, and may, therefore, probably be fome of the neareft to our folar Syftem. Arcturus, in particular, affords a ftrong proof of this: for if its prefent declination be compared with its place, as determined either by Tycho or Flamfteed, the difference will be found to be much greater than what can be fufpected to arife from the uncertainty of their obfervations. See ARCTURUS, and Mr. Hornfby's enquiry into the quantity and direction of the proper motion of Arcturus, Phil. Tranf. vol. 63, part 1, pa. 93, &c.

For an account of Dr. Bradley's obfervations, fee the fequel of this article.

Dr. Herfchel has alfo lately obferved, that the diftance of the two Stars forming the double Star γ Draconis, is 54″ 48‴, and their pofition 44° 19′ N. preceding. Whereas, from the right afcenfion and declination of thefe Stars in Flamfteed's catalogue, their diftance, in his time, appears to have been 1′ 11″ ·418, and their pofition 44° 23′ N. preceding. Hence he infers, that as the difference in the diftance of thefe two Stars is fo confiderable, we can hardly account for it, otherwife than by admitting a proper motion in one or the other of the Stars, or in our folar fyftem: moft probably he fays, neither of the three is at reft. He alfo fufpects a proper motion in one of the double Stars, in Cauda Lyncis Media, and in o Ceti. Phil. Tranf. vol. 72, part 1, p. 117, 143, 150.

It is reafonable to expect, that other inftances of the like kind muft alfo occur among the great number of vifible Stars, becaufe their relative pofitions may be altered by various means. For if our own folar fyftem be conceived to change its place with refpect to abfolute fpace, this might, in procefs of time, occafion an apparent change in the angular diftances of the fixed Stars; and in fuch a cafe, the places of the neareft Stars being more affected than of thofe that are very remote, their relative pofition might feem to alter, though the Stars themfelves were really immoveable; and vice verfa, we may furmife, from the obferved motion of the Stars, that our fun, with all its planets and comets, may have a motion towards fome particular part of the heavens, on account of a greater quantity of matter collected in a number of Stars and their furrounding planets there fituated, which may perhaps occafion a gravitation of our whole folar fyftem towards it. If this furmife fhould have any foundation, as Dr. Herfchel obferves, ubi fupra, p. 103, it will fhew itfelf in a feries of fome years; fince from that motion there will arife another kind of hitherto unknown parallax (fuggefted by Mr. Michell, Philof. Tranf. vol. 57, p. 252), the inveftigation of which may account for fome part of the motions already obferved in fome of the principal Stars; and for the purpofe of determining the direction and quantity of fuch a motion, accurate obfervations of the diftance of Stars, that are near enough to be meafured with a micrometer, and a very high power of telefcopes, may be of confiderable ufe, as they will undoubtedly give us the relative places of thofe Stars to a much greater degree of accuracy than they can be had by inftruments or fectors, and thereby much fooner enable us to difcover any apparent change in their fituation, occafioned by this new kind of fecular or fyftematical parallax, if we may fo exprefs the change arifing from the motion of the whole folar fyftem.

And, on the other hand, if our fyftem be at reft, and any of the Stars really in motion, this might likewife vary their apparent pofitions; and the more fo, the nearer they are to us, or the fwifter their motions are; or the more proper the direction of the motion is to be rendered perceptible by us. Since then the relative places of the Stars may be changed from fuch a variety of caufes, confidering the amazing diftance at which it is certain fome of them are placed, it may require the obfervations of many ages to determine the laws of the apparent changes, even of a fingle Star; much more difficult, therefore, muft it be to fettle the laws relating to all the moft remarkable Stars.

When the caufes which affect the places of all the Stars in general are known; fuch as the preceffion, aberration, and nutation, it may be of fingular ufe to examine nicely the relative fituations of particular Stars, and efpecially of thofe of the greateft luftre, which, it may be prefumed, lie neareft to us, and may therefore be fubject to more fenfible changes, either from their own motion, or from that of our fyftem. And if, at the fame time the brighter Stars are compared with each other, we likewife determine the relative pofitions of fome of the fmalleft that appear near them, whofe places can be afcertained with fufficient exactnefs, we may perhaps be able to judge to what caufe the change, if any be obfervable, is owing. The uncertainty that we are at prefent under, with refpect to the degree of accuracy with which former aftronomers could obferve, makes us unable to determine feveral things relating to this fubject; but the improvements, which have of late years been made in the methods of taking the places of the heavenly bodies, are fo great, that a few years may hereafter be fufficient to fettle fome points, which cannot now be fettled; by comparing even the earlieft obfervations with thofe of the prefent age

Dr. Hook communicated feveral obfervations on the apparent motions of the fixed Stars; and as this was a matter of great importance in aftronomy, feveral of the learned were defirous of verifying and confirming his obfervations. An inftrument was accordingly contrived by Mr. George Graham, and executed with furprifing exactnefs.

With this inftrument the Star γ, in the conftellation Draco, was frequently obferved by Meffrs. Molyneux, Bradley, and Graham, in the years 1725, 1726; and the obfervations were afterwards repeated by Dr. Bradley with an inftrument contrived by the fame ingenious perfon, Mr. Graham, and fo exact, that it might be depended on to half a fecond. The refult of thefe obfervations was, that the Star did not always appear in the fame place, but that its diftance from the zenith varied, and that the difference of the apparent places amounted to 21 or 22 feconds. Similar obfervations were made on other Stars, and a like apparent motion was

was found in them, proportional to the latitude of the Star. This motion was by no means such as was to have been expected, as the effect of a parallax, and it was some time before any way could be found of accounting for this new phenomenon. At length Dr. Bradley resolved all its variety, in a satisfactory manner, by the motion of light and the motion of the earth compounded together. See Light, and Phil. Transf. No. 406, p. 364, or Abr. vol. vi, p. 149, &c.

Our excellent astronomer, Dr. Bradley, had no sooner discovered the cause, and settled the laws of aberration of the fixed Stars, than his attention was again excited by another new phenomenon, viz, an annual change of declination in some of the fixed Stars, which appeared to be sensibly greater than a precession of the equinoctial points of 50″ in a year, the mean quantity now usually allowed by astronomers, would have occasioned.

This apparent change of declination was observed in the Stars near the equinoctial colure, and there appearing at the same time an effect of a quite contrary nature, in some Stars near the solstitial colure, which seemed to alter their declination less than a precession of 50″ required, Dr. Bradley was thereby convinced, that all the phenomena in the different Stars could not be accounted for merely by supposing that he had assumed a wrong quantity for the precession of the equinoctial points. He had also, after many trials, sufficient reason to conclude, that these second unexpected deviations of the Stars were not owing to any imperfection of his instruments. At length, from repeated observations he began to guess at the real cause of these phenomena.

It appeared from the Doctor's observations, during his residence at Wansted, from the year 1727 to 1732, that some of the Stars near the solstitial colure had changed their declinations 9″ or 10″ less than a precession of 50″ would have produced; and, at the same time, that others near the equinoctial colure had altered theirs about the same quantity more than a like precession would have occasioned: the north pole of the equator seeming to have approached the Stars, which come to the meridian with the sun about the vernal equinox, and the winter solstice; and to have receded from those, which come to the meridian with the sun about the autumnal equinox and the summer solstice.

From the consideration of these circumstances, and the situation of the ascending node of the moon's orbit when he first began to make his observations, he suspected that the moon's action upon the equatorial parts of the earth might produce these effects.

For if the precession of the equinox be, according to Sir Isaac Newton's principles, caused by the actions of the sun and moon upon those parts; the plane of the moon's orbit being, at one time, above 10 degrees more inclined to the plane of the equator than at another, it was reasonable to conclude, that the part of the whole annual precession, which arises from her action, would, in different years, be varied in its quantity; whereas the plane of the ecliptic, in which the sun appears, keeping always nearly the same inclination to the equator, that part of the precession, which is owing to the sun's action, may be the same every year; and from hence, it would follow, that although the mean annual precession, proceeding from the joint actions of the sun and moon, were 50″; yet the apparent annual precession might sometimes exceed, and sometimes fall short of that mean quantity, according to the various situations of the nodes of the moon's orbit.

In the year 1727, the moon's ascending node was near the beginning of Aries, and consequently her orbit was as much inclined to the equator as it can at any time be; and then the apparent annual precession was found, by the Doctor's first year's observations, to be greater than the mean; which proved, that the Stars near the equinoctial colure, whose declinations are most of all affected by the precession, had changed theirs, above a tenth part more than a precession of 50″ would have caused. The succeeding year's observations proved the same thing; and, in three or four years' time, the difference became so considerable as to leave no room to suspect it was owing to any imperfection either of the instrument or observation.

But some of the Stars, that were near the solstitial colure, having appeared to move, during the same time, in a manner contrary to what they ought to have done, by an increase of the precession; and the deviations in them being as remarkable as in the others, it was evident that something more than a mere change in the quantity of the precession would be requisite to solve this part of the phenomenon. Upon comparing the observations of Stars near the solstitial colure, that were almost opposite to each other in right ascension, they were found to be equally affected by this cause. For whilst γ Draconis appeared to have moved northward, the small Star, which is the 35th Camelopardali Hevelii, in the British catalogue, seemed to have gone as much towards the south; which shewed, that this apparent motion in both those Stars might proceed from a nutation of the earth's axis; whereas the comparison of the Doctor's observations of the same Stars formerly enabled him to draw a different conclusion, with respect to the cause of the annual aberrations arising from the motion of light. For the apparent alteration in γ Draconis, from that cause, being as large again as in the other small Star, proved, that that did not proceed from a nutation of the earth's axis; as, on the contrary, this may.

Upon making the like comparison between the observations of other Stars, that lie nearly opposite in right ascension, whatever their situations were with respect to the cardinal points of the equator, it appeared, that their change of declination was nearly equal, but contrary; and such as a nutation or motion of the earth's axis would effect.

The moon's ascending node being got back towards the beginning of Capricorn in the year 1732, the Stars near the equinoctial colure appeared about that time to change their declinations no more than a precession of 50″ required; whilst some of those near the solstitial colure altered theirs above 2″ in a year less than they ought. Soon after the annual change of declination of the former was perceived to be diminished, so as to become less than 50″ of precession would cause; and it continued to diminish till the year 1736, when the moon's ascending node was about the beginning of Libra, and her orbit had the least inclination to the equator. But by this time, some of the Stars near the solstitial colure had altered their declinations 18″ less

lefs fince the year 1727, than they ought to have done from a preceffion of 50″. For γ Draconis, which in thofe 9 years would have gone about 8″ more foutherly, was obferved, in 1736, to appear 10″ more northerly than it did in the year 1727.

As this appearance in γ Draconis indicated a diminution of the inclination of the earth's axis to the plane of the ecliptic, and as feveral aftronomers have fuppofed that inclination to diminifh regularly; if this phenomenon depend upon fuch a caufe and amounted to 18″ in 9 years, the obliquity of the ecliptic would, at that rate, alter a whole minute in 30 years; which is much fafter than any obfervations before made would allow. The Doctor had therefore reafon to think, that fome part of this motion at leaft, if not the whole, was owing to the moon's action on the equatorial parts of the earth, which he conceived might caufe a libratory motion of the earth's axis. But as he was unable to judge, from only 9 years obfervation, whether the axis would entirely recover the fame pofition that it had in the year 1727, he found it neceffary to continue his obfervations through a whole period of the moon's nodes; at the end of which he had the fatisfaction to fee, that the Stars returned into the fame pofitions again, as if there had been no alteration at all in the inclination of the earth's axis; which fully convinced him, that he had gueffed rightly as to the caufe of the phenomenon. This circumftance proves likewife, that if there be a gradual diminution of the obliquity of the ecliptic, it does not arife only from an alteration in the pofition of the earth's axis, but rather from fome change in the plane of the ecliptic itfelf; becaufe the Stars, at the end of the period of the moon's nodes, appeared in the fame places, with refpect to the equator, as they ought to have done if the earth's axis had retained the fame inclination to an invariable plane.

The Doctor having communicated thefe obfervations, and his fufpicion of their caufe, to the late Mr. Machin, that excellent geometrician foon after fent him a table, containing the quantity of the annual preceffion in the various pofitions of the moon's nodes, as alfo the correfponding nutations of the earth's axis; which was computed upon the fuppofition that the mean annual preceffion is 50″, and that the whole is governed by the pole of the moon's orbit only; and therefore Mr. Machin imagined, that the numbers in the table would be too large, as, in fact, they were found to be. But it appeared that the changes which Dr. Bradley had obferved, both in the annual preceffion and nutation, kept the fame law, as to increafing and decreafing, with the numbers of Mr. Machin's table. Thofe were calculated on the fuppofition, that the pole of the equator, during a period of the moon's nodes, moved round in the periphery of a little circle, whofe centre was 23° 29′ diftant from the pole of the ecliptic; having itfelf alfo an angular motion of 50″ in a year about the fame pole. The north pole of the equator was conceived to be in that part of the fmall circle which is fartheft from the north pole of the ecliptic at the fame time when the moon's afcending node is in the beginning of Aries; and in the oppofite point of it, when the fame node is in Libra.

If the diameter of the little circle, in which the pole of the equator moves, be fuppofed equal to 18″, which is the whole quantity of the nutation, as collected from Dr. Bradley's obfervations of the Star γ Draconis, then all the phenomena of the feveral Stars which he obferved will be very nearly folved by this hypothefis. But for the particulars of his folution, and the application of his theory to the practice of aftronomy, we muft refer to the excellent author himfelf; our intention being only to give the hiftory of the invention.

The corrections arifing from the aberration of light, and from the nutation of the earth's axis, muft not be neglected in aftronomical obfervations; fince fuch neglects might produce errors of near a minute in the polar diftance of fome Stars.

As to the allowance to be made for the aberration of light, Dr. Bradley affures us, that having again examined thofe of his own obfervations, which were moft proper to determine the tranfverfe axis of the ellipfis, which each Star feems to defcribe, he found it to be neareft to 40″; and this is the number he makes ufe of in his computations relating to the nutation.

Dr. Bradley fays, in general, that experience has taught him, that the obfervations of fuch Stars as lie neareft the zenith, generally agree beft with one another, and are therefore fitteft to prove the truth of any hypothefis. Phil. Tranf. N°. 485, vol. 45, p. 1, &c.

Monfieur d'Alembert has publifhed a treatife, entitled, Recherches fur la Preceffion des Equinoxes, et fur la Nutation de la Terre dans le Syfteme Newtonien, 4to. Paris, 1749. The calculations of this learned gentleman agree in general with Dr. Bradley's obfervations. But Monfieur d'Alembert finds, that the pole of the equator defcribes an ellipfis in the heavens, the ratio of whofe axes is that of 4 to 3; whereas, according to Dr. Bradley, the curve defcribed is either a circle or an ellipfis, the ratio of whofe axes is as 9 to 8.

The following two catalogues of Stars are taken from Dr. Zach's Tabulæ Motuum Solis &c, and are adapted to the beginning of the year 1800. The former contains 381 Stars, fhewing their names and Bayer's mark, their magnitude, declination, and right afcenfion, both in time and in arcs or degrees of a great circle, with the annual variations of the fame. And the latter contains 162 principal Stars, fhewing their declinations to feconds of a degree, with their annual variations. The explanations are fufficiently clear from the titles of the columns.

A Catalogue *of the most remarkable* **Fixed Stars,** *with their Magnitudes, Right Ascensions, Declinations and Annual Variations, for the Beginning of the Year* 1800.

STAR, in Electricity, denotes the appearance of the electric matter on a point into which it enters. Beccaria supposes that the Star is occasioned by the difficulty with which the electric fluid is extricated from the air, which is an electric substance. See BRUSH.

STAR, in Fortification, denotes a small fort, having 5 or more points, or saliant and re-entering angles, flanking one another, and their faces 90 or 100 feet long.

STAR, in Pyrotechny, a composition of combustible matters; which being borne, or thrown aloft into the air, exhibits the appearance of a real Star.—Stars are chiefly used as appendages to rockets, a number of them being usually inclosed in a conical cap, or cover, at the head of the rocket, and carried up with it to its utmost height, where the Stars, taking fire, are spread around, and exhibit an agreeable spectacle.

To make Stars.—Mix 3lbs of saltpetre, 11 ounces of sulphur, one of antimony, and 3 of gunpowder dust: or, 12 ounces of sulphur, 6 of saltpetre, $5\frac{1}{2}$ of gunpowder dust, 4 of olibanum, one of mastic, camphor, sublimate of mercury, and half an ounce of antimony and orpiment. Moisten the mass with gumwater, and make it into little balls, of the size of a chesnut; which dry either in the sun, or in the oven. These being set on fire in the air, will represent Stars.

STAR-*Board* denotes the right hand side of a ship, when a person on board stands with the face looking forward towards the head or fore part of the ship. In contradistinction from *Larboard*, which denotes the left hand side of the ship in the same circumstances.—They say, *Starboard the helm*, or *helm a Starboard*, when the man at the helm should put the helm to the right hand side of the ship.

Falling STAR, or *Shooting* STAR, a luminous meteor darting rapidly through the air, and resembling a Star falling.—The explication of this phenomenon has puzzled all philosophers, till the modern discoveries in electricity have led to the most probable account of it. Signior Beccaria makes it pretty evident, that it is an electrical appearance, and recites the following fact in proof of it. About an hour after sunset, he and some friends that were with him, observed a falling Star directing its course towards them, and apparently growing larger and larger, but it disappeared not far from them; when it left their faces, hands, and clothes, with the earth, and all the neighbouring objects, suddenly illuminated with a diffused and lambent light, not attended with any noise at all. During their surprize at this appearance, a servant informed them that he had seen a light shine suddenly in the garden, and especially upon the streams which he was throwing to water it. All these appearances were evidently electrical; and Beccaria was confirmed in his conjecture, that electricity was the cause of them, by the quantity of electric matter which he had seen gradually advancing towards his kite, which had very much the appearance of a falling Star. Sometimes also he saw a kind of glory round the kite, which followed it when it changed its place, but left some light, for a small space of time, in the place it had quitted. Priestley's Elect. vol. 1, pa. 434, 8vo. See IGNIS *Fatuus*.

STAR-*fort*, or *Redoubt*, in Fortification. See STAR, REDOUBT, and FORT.

STARLINGS, or STERLINGS, or *Jettees*, a kind of case made about a pier of stilts, &c, to secure it. See STILTS.

STATICS, a branch of mathematics which considers weight or gravity, and the motion of bodies resulting from it.

Those who define mechanics, the science of motion, make Statics a part of it; viz, that part which considers the motion of bodies arising from gravity.

Others make them two distinct doctrines; restraining mechanics to the doctrine of motion and weight, as depending on, or connected with, the power of machines; and Statics to the doctrine of motion, considered merely as arising from the weight of bodies, without any immediate respect to machines. In this way, Statics should be the doctrine or theory of motion; and mechanics, the application of it to machines.

For the laws of Statics, see GRAVITY, DESCENT, &c.

STATION, or STATIONARY, in Astronomy, the position or appearance of a planet in the same point of the zodiac, for several days. This happens from the observer being situated on the earth, which is far out of the centre of their orbits, by which they seem to proceed irregularly; being sometimes seen to go forwards, or from west to east, which is their natural *direction*; sometimes to go backwards, or from east to west, which is their *retrogradation*; and between these two states there must be an intermediate one, where the planet appears neither to go forwards nor backwards, but to stand still, and keep the same place in the heavens, which is called her *Station*, and the planet is then said to be *Stationary*.

Apollonius Pergæus has shewn how to find the Stationary point of a planet, according to the old theory of the planets, which supposes them to move in epicycles; which was followed by Ptolomy in his Almag. lib. 12, cap. 1, and others, till the time of Copernicus. Concerning this, see Regiomontanus in Epitome Almagesti, lib. 12, prop. 1; Copernicus's Revolutiones Cœlest. lib. 5, cap. 35 and 36; Kepler in Tabulis Rudolphinis, cap. 24; Riccioli's Almag. lib. 7, sect. 5, cap. 2: Harman in Miscellan. Berolinens, pa. 197. Dr. Halley, Mr. Facio, Mr. De Moivre, Dr. Keil, and others have treated on this subject. See also the articles RETROGRADE and STATIONARY in this Dictionary.

STATION, in Practical Geometry &c, is a place pitched upon to make an observation, or take an angle, or such like, as in surveying, measuring heights and distances, levelling, &c.

An accessible height is taken from one Station; but an inaccessible height or distance is only to be taken by making two Stations, from two places whose distance asunder is known. In making maps of counties, provinces, &c, Stations are fixed upon certain eminencies &c of the country, and angles taken from thence to the several towns, villages, &c.—In surveying, the instrument is to be adjusted by the needle, or otherwise, to answer the points of the horizon at every Station; the distance from hence to the last Station is to be measured, and an angle is to be taken to the next Station; which process repeated includes the chief practice of surveying.

surveying.—In levelling, the instrument is rectified, or placed level at each Station, and observations made forwards and backwards.

There is a method of measuring distances at one Station, in the Philos. Trans. numb. 7, by means of a telescope. I have heard of another, by Mr. Ramsden; and have seen a third ingenious way by Mr. Green of Deptford, not yet published; this consists of a permanent scale of divisions, placed at any point whose distance is required; then the number of divisions seen through the telescope, gives the distance sought.

STATION-*Line*, in Surveying, and *Line of Station*, in Perspective. See LINE.

STATIONARY, in Astronomy, the state of a planet when, to an observer on the earth, it appears for some time to stand still, or remain immoveable in the same place in the heavens. For as the planets, to such an observer, have sometimes a progressive motion, and sometimes a retrograde one, there must be some point between the two where they must appear Stationary. Now a planet will be seen Stationary, when the line that joins the centres of the earth and planet is constantly directed to the same point in the heavens, which is when it keeps parallel to itself. For all right lines drawn from any point of the earth's orbit, parallel to one another, do all point to the same star; the distance of these lines being insensible, in comparison of that of the fixed stars.

The planet Herschel is seen Stationary at the distance of from the sun; Saturn at somewhat more than 90°; Jupiter at the distance of 52°; and Mars at a much greater distance; Venus at 47°, and Mercury at 28°.

Herschel is Stationary days, Saturn 8, Jupiter 4, Mars 2, Venus $1\frac{1}{2}$, and Mercury $\frac{1}{2}$ a day: though the several stations are not always equal; because the orbits of the planets are not circles which have the sun in their centre.

STEAM, the smoke or vapour arising from water, or any other liquid or moist body, when considerably heated. Subterranean Steams often affect the surface of the earth in a remarkable manner, and promote or prevent vegetation more than any thing else. It has been imagined that Steams may be the generative cause of both minerals and metals, and of all the peculiarities of springs. See Philos. Trans. vol. 5, pa. 1154, or Abr. vol. 2, pa. 833.—Of the use of the air to elevate the Steams of bodies, see pa. 2048 and 297 ib.—Concerning the warm and fertilizing temperature and Steams of the earth, see Phil. Trans. vol. 10, pa. 307 and 357. See also Dr. Hamilton "On the Ascent of Vapours."

The Steam raised from hot water is an elastic fluid, which, like elastic air, has its elasticity proportional to its density when the heat is the same, or proportional to the heat when the density is the same. The Steam raised with the ordinary heat of boiling water, is almost 3000 times rarer than water, or about $3\frac{1}{2}$ times rarer than air, and has its elasticity about equal to that of the common air of the atmosphere. And by great heat it has been found that the Steam may be expanded into 14000 times the space of water, or may be made about 5 times stronger than the atmosphere. But from some accidents that have happened, it appears that Steam, suddenly raised from water, or moist substances, by the immediate application of strong heat, is vastly stronger than the atmosphere, or even than gunpowder itself. Witness the accident that happened to a foundery of cannon at Moorfields, when upon the hot metal first running into the mould in the earth, some small quantity of water in the bottom of it was suddenly changed into Steam, which by its explosion, blew the foundery all to pieces. I remember another such accident at a foundery at Newcastle; the founder having purchased, among some old brass, a hollow brass ball that had been used for many years as a valve in a pump, withinside of which it would seem some water had got insinuated; and having put it into his fire to melt, when it had become very hot, it suddenly burst with a prodigious noise, and blew the adjacent parts of the furnace in pieces.

Steam may be applied to many purposes useful in life, but one of its chief uses is in the Steam-engine described in the following article.

STEAM *Engine*, an engine for raising water by the force of Steam produced from boiling water; and often called the *Fire-engine*, on account of the fire employed in boiling the water to produce the Steam. This is one of the most curious and useful machines, which modern art can boast, for raising water from ponds, wells, or pits, for draining mines, &c. Were it not for the use of this most important invention, it is probable we should not now have the benefit of coal fires in England; as our forefathers had, before the present century, excavated all the mines of coal as deep as it could be worked, without the benefit of this engine to draw the water from greater depths.

This engine is commonly a forcing pump, having its rod fixed to one end of a lever, which is worked by the weight or pressure of the atmosphere upon a piston, at the other end, a temporary vacuum being made below it, by suddenly condensing the Steam, that had been let into the cylinder in which this piston works, by a jet of cold water thrown into it. A partial vacuum being thus made, the weight of the atmosphere presses down the piston, and raises the other end of the straight lever with the water from the well &c. Then immediately a hole is uncovered in the bottom of the cylinder, by which a fresh fill of hot Steam rushes in from a boiler of water below it, which proves a counterbalance for the atmosphere above the piston, upon which the weight of the pump rods at the other end of the lever carries that end down, and raises the piston of the Steam cylinder. Immediately the Steam hole is shut, and the cock opened for injecting the cold water into the cylinder of Steam, which condenses it to water again, and thus making another vacuum below the piston, the atmosphere above it presses it down, and raises the pump rods with another lift of water; and so on continually. This is the common principle: but there are also other modes of applying the force of the Steam, as we shall see in the following short history of this invention and its various improvements.

The earliest account to be met with of the invention of this engine, is in the marquis of Worcester's small book intitled a Century of Inventions (being a description of 100 notable discoveries), published in the year 1663, where he proposed the raising of great quantities of

of water by the force of Steam, raised from water by means of fire; and he mentions an engine of that kind, of his own contrivance, which could raise a continual stream like a fountain 40 feet high, by means of two cocks which were alternately and successively turned by a man to admit the Steam, and to re-fill the vessel with cold water, the fire being continually kept up.

However, this invention not meeting with encouragement, probably owing to the confused state of public affairs at that time, it was neglected, and lay dormant several years, until one Captain Thomas Savery, having read the marquis of Worcester's books, several years afterwards, tried many experiments upon the force and power of Steam; and at last hit upon a method of applying it to raise water. He then bought up and destroyed all the marquis's books that could be got, and claimed the honour of the invention to himself, and obtained a patent for it, pretending that he had discovered this secret of nature by accident. He contrived an engine which, after many experiments, he brought to some degree of perfection, so as to raise water in small quantities: but he could not succeed in raising it to any great height, or in large quantities, for the draining of mines; to effect which by his method, the Steam was required to be so strong as would have burst all his vessels; so that he was obliged to limit himself to raising the water only to a small height, or in small quantities. The largest engine he erected, was for the York-buildings Company in London, for supplying the inhabitants in the Strand and that neighbourhood with water.

The principle of this machine was as follows: H (fig. 3, pl. 27) represents a copper boiler placed on a furnace. E is a strong iron vessel, communicating with the boiler by means of a pipe at top, and with the main pipe AB by means of a pipe I at bottom; AB is the main pipe immersed in the water at B; D and C are two fixed valves, both opening upwards, one being placed above, and the other below the pipe of communication I. Lastly, at G is a cock that serves occasionally to wet and cool the vessel E, by water from the main pipe, and F is a cock in the pipe of communication between the vessel E and the boiler.

The engine is set to work, by filling the copper in part with water, and also the upper part of the main pipe above the valve C, the fire in the furnace being lighted at the same time. When the water boils strongly, the cock F is opened, the Steam rushes into the vessel E, and expels the air from thence through the valve C. The vessel E thus filled, and violently heated by the Steam, is suddenly cooled by the water which falls upon it by turning the cock C; the cock F being at the same time shut, to prevent any fresh accession of Steam from the boiler. Hence, the Steam in E becoming condensed, it leaves the cavity within almost intirely a vacuum; and therefore the pressure of the atmosphere at B forces the water through the valve D till the vessel E is nearly filled. The condensing cock G is then shut, and the Steam cock F again opened; hence the Steam, rushing into E, expels the water through the valve C, as it before did the air. Thus E becomes again filled with hot Steam, which is again cooled and condensed by the water from G, the supply of Steam being cut off by shutting F, as in the former operation: the water consequently rushes through D, by the pressure of the atmosphere at B, and E is again filled. This water is forced up the main pipe through C, by opening F and shutting G, as before. And thus it is easy to conceive, that by this alternate opening and shutting the cocks, water will be continually raised, as long as the boiler continues to supply the Steam.

For the sake of perspicuity, the drawing is divested of the apparatus that serves to turn the two cocks at once, and of the contrivances for filling the copper to the proper quantity. But it may be found complete, with a full account of its uses and application, in Mr. Savery's book intituled the *Miner's Friend*. The engines of this construction were usually made to work with two receivers or Steam vessels, one to receive the Steam, while the other was raising water by the condensation. This engine has been since improved, by admitting the end of the condensing pipe G into the vessel E, by which means the Steam is more suddenly and effectually condensed than by water on the outside of the vessel.

The advantages of this engine are, that it may be erected in almost any situation, that it requires but little room, and is subject to very little friction in its parts.—Its disadvantages are, that great part of the Steam is condensed and loses its force upon coming into contact with the water in the vessel E, and that the heat and elasticity of the Steam must be increased in proportion to the height that the water is required to be raised to. On both these accounts a large fire is required, and the copper must be very strong, when the height is considerable, otherwise there is danger of its bursting.

While captain Savery was employed in perfecting his engine, Dr. Papin of Marburg was contriving one on the same principles, which he describes in a small book published in 1707, intitled *Ars Nova ad Aquam Ignis adminiculo efficacissimè elevandam*. Capt. Savery's engine however was much completer than that proposed by Dr. Papin.

About the same time also one Monf. Amontons of Paris was engaged in the same pursuit: but his method of applying the force of Steam was different from those before-mentioned; for he intended it to drive or turn a wheel, which he called a *fire-mill*, which was to work pumps for raising water; but he never brought it to perfection. Each of these three gentlemen claimed the originality of the invention; but it is most probable they all took the hint from the book published by the marquis of Worcester, as before-mentioned.

In this imperfect state it continued, without farther improvements, till the year 1705, when Mr. Newcomen, an iron-monger, and Mr. John Cowley, a glazier, both of Dartmouth, contrived another way to raise water by Steam, bringing the engine to work with a beam and piston, and where the Steam, even at the greatest depths of mines, is not required to be greater than the pressure of the atmosphere: and this is the structure of the engine as it has since been chiefly used. These gentlemen obtained a patent for the sole use of this invention, for 14 years. The first proposal they made for draining of mines by this engine, was in the year 1711; but they were very coldly received by many

many perfons in the fouth of England, who did not underftand the nature of it. In 1712 they came to an agreement with the owners of a colliery at Griff in Warwickfhire, where they erected an engine with a cylinder of 22 inches diameter. At firft they were under great difficulties in many things; but by the affiftance of fome good workmen they got all the parts put together in fuch a manner, as to anfwer their intention tolerably well: and this was the firft engine of the kind erected in England. There was at firft one man to attend the Steam-cock, and another to attend the injection cock; but they afterwards contrived a method of opening and fhutting them by fome fmall machinery connected with the working beam. The next engine erected by thefe patentees, was at a colliery in the county of Durham, about the year 1718, where was concerned, as an agent, Mr. Henry Beighton, F. R. S. and conductor of the Ladies' Diary from the year 1714 to the year 1744: this gentleman, not approving of the intricate manner of opening and fhutting the cocks by ftrings and catches, as in the former engine, fubftituted the hanging beam for that purpofe as at prefent ufed, and likewife made improvements in the pipes, valves, and fome other parts of the engine.

In a few years afterwards, thefe engines came to be better underftood than they had been; and their advantages, efpecially in draining of mines, became more apparent: and from the great number of them erected, they received additional improvements from different perfons, till they arrived at their prefent degree of perfection: as will appear in the fequel, after we have a little confidered the general principles of this engine, which are as follow.

Principles of the Steam Engine.

The principles on which this engine acts, are truly philofophical; and when all the parts of the machine are proportioned to each other according to thefe principles, it never fails to anfwer the intention of the engineer.

1. It has been proved in pneumatics, that the preffure of the atmofphere upon a fquare inch at the earth's furface, is about $14\frac{3}{4}$lb avoirdupois at a medium, or $11\frac{1}{2}$lb on a circular inch, that is on a circle of an inch diameter. And,

2. If a vacuum be made by any means in a cylinder, which has a moveable pifton fufpended at one end of a lever equally divided, the air will endeavour to rufh in, and will prefs down the pifton, with a force proportionable to the area of the furface, and will raife an equal weight at the other end of the lever.

3. Water may be rarefied near 14000 times by being reduced into Steam, and violently heated: the particles of it are fo ftrongly repellent, as to drive away air of the common denfity, only by a heat fufficient to keep the water in a boiling ftate, when the Steam is almoft 3000 times rarer than water, or $3\frac{1}{2}$ times rarer than air, as appears by an experiment of Mr. Beighton's: by increafing the heat, the Steam may be rendered much ftronger; but this requires great ftrength in the veffels. This Steam may be again condenfed into its former ftate by a jet of cold water difperfed through it; fo that 14000 cubic inches of Steam admitted into a cylinder, may be reduced into the fpace of one cubic inch of water only, by which means a partial vacuum is obtained.

4. Though the preffure of the atmofphere be about $14\frac{1}{4}$ pounds upon every fquare inch, or $11\frac{1}{4}$ pounds upon a circular inch; yet, on account of the friction of the feveral parts, the refiftance from fome air which is unavoidably admitted with the jet of cold water, and from fome remainder of Steam in the cylinder, the vacuum is very imperfect, and the pifton does not defcend with a force exceeding 8 or 9 pounds upon every fquare inch of its furface.

5. The gallon of water of 282 cubic inches weighs $10\frac{1}{5}$ pounds avoirdupois, or a cubic foot $62\frac{1}{2}$ pounds, or 1000 ounces. The pifton being preffed by the atmofphere with a force proportional to its area in inches, multiplied by about 8 or 9 pounds, depreffes that end of the lever, and raifes a column of water in the pumps of equal weight at the other end, by means of the pump-rods fufpended to it. When the Steam is again admitted, the pump-rods fink by their fuperior weight, and the pifton rifes; and when that Steam is condenfed, the pifton defcends, and the pump-rods lift; and fo on alternately as long as the pifton works.

It has been obferved above, that the pifton does not defcend with a force exceeding 8 or 9 pounds upon every fquare inch of its furface; but by reafon of accidental frictions, and alterations in the denfity of the air, it will be fafeft, in calculating the power of the cylinder, to allow fomething lefs than 8 pounds for the preffure of the atmofphere, upon every fquare inch, viz 7lb. 10 oz. = 7·64lb, or juft 6lb. upon every circular inch; and it being allowed that the gallon of water, of 282 cubic inches, weighs $10\frac{1}{5}$lb, from thefe premifes the dimenfions of the cylinder, pumps, &c, for any Steam-engine, may be deduced as follows:— Suppofe

c = the cylinder's diameter in inches,
p = the pump's ditto,
f = the depth of the pit in fathoms,
g = gallons drawn by a ftroke of 6 feet or a fathom,
h = the hogfheads drawn per hour,
s = the number of ftrokes per minute.

Then c^2 is the area of the cylinder in circular inches, theref. $6c^2$ is the power of the cylinder in pounds.

And $\frac{p^2 \times \cdot 7854 \times 72}{282}$ or $\frac{1}{5}p^2$ is $= g$ the gallons contained in one fathom or 72 inches of any pump; which multiplied by f fathoms, gives $\frac{1}{5}p^2f$ for the gallons contained in f fathoms of any pump whofe diameter is p.

Hence $\frac{1}{5}p^2f \times 10\frac{1}{5}$lb. gives $2p^2f$ nearly, for the weight in pounds of the column of water which is to be equal to the power of the cylinder, which was before found equal to $6c^2$. Hence then we have the 2d equation,

viz, $6c^2 = 2p^2f$, or $3c^2 = p^2f$;
the firft equation being $\frac{1}{5}p^2 = g$, or $p^2 = 5g$.

From which two equations, any particular circumftance may be determined.

Or if, inftead of 6lb, for the preffure of the air on each circular inch of the cylinder, that force be fuppofed

posed any number as a pounds; then will the power of the cyclinder be ac^2, and the 2d equation becomes $ac^2 = 2p^2f = 10fg$, by substituting $5g$ instead of p^2.

And farther, $63h = 60gs$, or $21h = 20gs$.

From a comparison of these equations, the following theorems are derived, which will determine the size of the cylinder and pumps of any Steam-engine capable of drawing a certain quantity of water from any assigned depth, with the pressure of the atmosphere on each circular inch of the cylinder's area.

These theorems are more particularly adapted to one pump in a pit. But it often happens in practice, that an engine has to draw several pumps of different diameters from different depths; and in this case, the square of the diameter of each pump must be multiplied by its depth, and double the sum of all the products will be the weight of water drawn at each stroke, which is to be used instead of $2p^2f$ for the power of the cylinder.

The following is a Table, calculated from the foregoing theorems, of the powers of cylinders from 30 to 70 inches diameter; and the diameter and lengths of pumps which those cylinders are capable of working, from a 6 inch bore to that of 20 inches, together with the quantity of water drawn per stroke and per hour, allowing the engine to make 12 strokes of 6 feet per minute, and the pressure of the atmosphere at the rate of 7 lb 10 oz per square inch, or 6 lb per circular inch.

A Table *of* Theorems *for the readier computing the Powers of a* Steam-Engine.

1	$a = \dfrac{2fp^2}{c^2} = \dfrac{10fg}{c^2} = \dfrac{21fh}{2c^2s}$
2	$c = \sqrt{\dfrac{2fp^2}{a}} = \sqrt{\dfrac{10fg}{a}} = \sqrt{\dfrac{21fh}{2as}}$
3	$f = \dfrac{ac^2}{2p^2} = \dfrac{ac^2}{10g} = \dfrac{2ac^2s}{21h}$
4	$g = \dfrac{p^2}{5} = \dfrac{ac^2}{10f} = \dfrac{21h}{20s}$
5	$h = \dfrac{4p^2s}{21} = \dfrac{20gs}{21} = \dfrac{2ac^2s}{21f}$
6	$p = \sqrt{5g} = \sqrt{\dfrac{ac^2}{2g}} = \sqrt{\dfrac{21h}{4s}}$
7	$s = \dfrac{21h}{4p^2} = \dfrac{21h}{20g} = \dfrac{21fh}{2ac^2}$

Table *of the Power and Effects of* **Steam-Engines,** *allowing* 12 *Strokes, of* 6 *Feet long each, per Minute, and the pressure of the Air* 7*lb* 10*oz per Square Inch, or* 6*lb per Circular Inch.*

Let us now describe the several parts of an engine, and exemplify the application of the foregoing principles, in the construction of one of the completest of the modern engines. See fig. 4. pl. 27.

A represents the fire-place under the boiler, for the boiling of the water, and the ash-hole below it.

B, the boiler, filled with water about three feet above the bottom, made of iron plates.

C, the Steam pipe, through which the Steam passes from the boiler into the receiver.

D, the receiver, a close iron vessel, in which is the regulator or Steam-cock, which opens and shuts the hole of communication at each stroke.

E, the communication pipe between the receiver and the cylinder; it rises 5 or 6 inches up, in the inside of the cylinder bottom, to prevent the injected water from descending into the receiver.

F, the cylinder, of cast iron, about 10 feet long, bored smooth in the inside; it has a broad flanch in the middle on the outside, by which it is supported when hung in the cylinder-beams.

G, the piston, made to fit the cylinder exactly: it has a flanch rising 4 or 5 inches upon its upper surface, between which and the side of the cylinder a quantity of junk or oakum is stuffed, and kept down by weights, to prevent the entrance of air or water and the escaping of Steam.

H, the chain and piston shank, by which it is connected to the working beam.

I I, the working-beam or lever: it is made of two or more large logs of timber, bent together at each end, and kept at the distance of 8 or 9 inches from each other in the middle by the gudgeon, as represented in the Plate. The arch-heads, II, at the ends, are for giving a perpendicular direction to the chains of the piston and pump-rods.

K, the pump-rod which works in the sucking pump.

L, and draws the water from the bottom of the pit to the surface.

M, a cistern, into which the water drawn out of the pit is conducted by a trough, so as to keep it always full: and the superfluous water is carried off by another trough.

N, the jack-head pump, which is a sucking-pump wrought by a small lever or working-beam, by means of a chain connected to the great beam or lever near the arch *g* at the inner end, and the pump-rod at the outer end. This pump commonly stands near the corner of the front of the house, and raises the column of water up to the cistern O, into which it is conducted by a trough.

O, the jack-head cistern for supplying the injection, which is always kept full by the pump N: it is fixed so high as to give the jet a sufficient velocity into the cylinder when the cock is opened. This cistern has a pipe on the opposite side for conveying away the superfluous water.

P P, the injection-pipe, of 3 or 4 inches diameter, which turns up in a curve at the lower end, and enters the cylinder bottom: it has a thin plate of iron upon the end *a*, with 3 or 4 adjutage holes in it, to prevent the jet of cold water of the jack-head cistern from flying up against the piston, and yet to condense the Steam each stroke, when the injection-cock is open.

e, a valve upon the upper end of the injection pipe within the cistern, which is shut when the engine is not working, to prevent any waste of the water.

f, a small pipe which branches off from the injection-pipe, and has a small cock to supply the piston with a little water to keep it air-tight.

Q, the working plug, suspended by a chain to the arch *g* of the working beam. It is usually a heavy piece of timber, with a slit vertically down its middle, and holes bored horizontally through it, to receive pins for the purpose of opening and shutting the injection and Steam cocks, as it ascends and descends by the motion of the working beam.

h, the handle of the steam-cock or regulator. It is fixed to the regulator by a spindle which comes up through the top of the receiver. The regulator is a circular plate of brass or cast iron, which is moved horizontally by the handle *h*, and opens or shuts the communication at the lower end of the pipe E within the receiver. It is represented in the plate by a circular dotted line.

i i, the spanner, which is a long rod or plate of iron for communicating motion to the handle of the regulator: to which it is fixed by means of a slit in the latter, and some pins put through to fasten it.

k l, the vibrating lever, called the Y, having the weight *k* at one end and two legs at the other end. It is fixed to an horizontal axis, moveable about its centre-pins or pivots *mn*, by means of the two shanks *op* fixed to the same axis, which are alternately thrown backwards and forwards by means of two pins in the working plug; one pin on the outside depressing the shank *o*, throws the loaded end *k* of the Y from the cylinder into the position represented in the plate, and causes the leg *l* to strike against the end of the spanner; which forcing back the handle of the regulator or steam cock, opens the communication, and permits the steam to fly into the cylinder. The piston immediately rising by the admission of the Steam, the working beam II rises; which also raises the working-plug, and another pin which goes through the slit raises the shank *p*, which throws the end *k* of the Z towards the cylinder, and, striking the end of the spanner, forces it forward, and shuts the regulator Steam-cock.

qr, the lever for opening and shutting the injection cock, called the F. It has two toes from its centre, which take between them the key of the injection cock. When the working-plug has ascended nearly to its greatest height, and shut the regulator, a pin catches the end *q* of the F and raises it up, which opens the injection-cock, admits a jet of cold water to fly into the cylinder, and, condensing the Steam, makes a vacuum; then the pressure of the atmosphere bringing down the piston in the cylinder, and also the plug-frame, another pin fixed in it catches the end of the lever in its descent, and, by pressing it down, shuts the injection-cock, at the same time the regulator is opened to admit Steam, and so on alternately; when the regulator is shut the injection is open, and when the former is open the latter is shut.

R, the

R, the hot-well, a small cistern made of planks, which receives all the waste water from the cylinder.

S, the sink-pit to convey away the water which is injected into the cylinder at each stroke. Its upper end is even with the inside of the cylinder bottom, its lower end has a lid or cover moveable on a hinge which serves as a valve to let out the injected water, and shuts close each stroke of the engine, to prevent the water being forced up again when the vacuum is made.

T, the feeding pipe, to supply the boiler with water from the hot-well. It has a cock to let in a large or small quantity of water as occasion requires, to make up for what is evaporated; it goes nearly down to the boiler bottom.

U, two gage cocks, the one larger than the other, to try when a proper quantity of water is in the boiler: upon opening the cocks, if one give Steam and the other water, it is right; if they both give Steam, there is too little water in the boiler; and if they both give water, there is too much.

W, a plate which is screwed on to a hole on the side of the boiler, to allow a passage into the boiler for the convenience of cleaning or repairing it.

X, the Steam-clack or puppet valve, which is a brass valve on the top of a pipe opening into the boiler, to let off the Steam when it is too strong. It is loaded with lead, at the rate of one pound to an inch square; and when the Steam is nearly strong enough to keep it open, it will do for the working of the engine.

f, the snifting valve, by which the air is discharged from the cylinder each stroke, which was admitted with the injection, and would otherwise obstruct the due operation of the engine.

tt, the cylinder-beams; which are strong joists going through the house for supporting the cylinder.

v, the cylinder cap of lead, soldered on the top of the cylinder, to prevent the water upon the piston from flashing over when it rises too high.

w, the waste-pipe, which conducts the superfluous water from the top of the cylinder to the hot-well.

xx, iron bars, called the catch-pins, fixed horizontally through each arch head, to prevent the beam descending too low in case the chain should break.

yy, two strong wooden springs, to weaken the blow given by the catch pins when the stroke is too long.

zz, two friction wheels, on which the gudgeon or centre of the great beam is hung; they are the third or fourth part of a circle, and move a little each way as the beam vibrates. Their use is to diminish the friction of the axis, which, in so heavy a lever, would otherwise be very great.

When this engine is to be set to work, the boiler must be filled about three or four feet deep with water, and a large fire made under it; and when the Steam is found to be of a sufficient strength by the puppet-clack, then by thrusting back the spanner, which opens the regulator or Steam-cock, the Steam is admitted into the cylinder, which raises the piston to the top of the cylinder, and forces out all the air at the snifting valve; then by turning the key of the injection-cock, a jet of cold water is admitted into the cylinder, which condenses the Steam and makes a vacuum; and the atmosphere then pressing upon the piston, forces it down to the lower part of the cylinder, and makes a stroke by raising the column of water at the other end of the beam. After two or three strokes are made in this manner, by a man opening and shutting the cocks to try if they be right, then the pins may be put into the pin-holes in the working plug, and the engine left to turn the cocks of itself; which it will do with greater exactness than any man can do.

There are in some engines, methods of shutting and opening the cocks different from the one above described, but perhaps none better adapted to the purpose; and as the principles on which they all act are originally the same, any difference in the mechanical construction of the small machinery will have no influence of consequence upon the total effect of the grand machine.

The furnace or fire-place should not have the bars so close as to prevent the free admission of fresh air to the fire, nor so open as to permit the coals to fall through them; for which purpose two inches or thereabouts is sufficient for the distance betwixt the bars. The size of the furnace depends upon the size of the boiler; but in every case the ash-hole ought to be capacious to admit the air, and the greater its height the better. If the flame is conducted in a flue or chimney round the outside of the boiler, or in a pipe round the inside of it, it ought to be gradually diminished from the entrance at the furnace to its egress at the chimney; and the section of the chimney at that place should not exceed the section of the flue or pipe, and should also be somewhat less at the chimney-top.

The boiler or vessel in which the water is rarefied by the force of fire, may be made of iron plates, or cast iron, or such other materials as can withstand the effects of the fire, and the elastic force of the Steam. It may be considered as consisting of two parts; the upper part which is exposed to the Steam, and the under part which is exposed to the fire. The form of the latter should be such as to receive the full force of the fire in the most advantageous manner, so that a certain quantity of fuel may have the greatest possible effect in heating and evaporating the water; which is best done by making the sides cylindrical, and the bottom a little concave, and then conducting the flame by an iron flue or pipe round the inside of the boiler beneath the surface of the water, before it reach the chimney. For, by this means, after the fire in the furnace has heated the water by its effect on the bottom, the flame heats it again by the pipe being wholly included in the water, and having every part of its surface in contact with it; which is preferable to carrying it in a flue or chimney round the outside of the boiler, as a third or a half of the surface of the flame only could be in contact with the boiler, the other being spent upon the brick-work. This cylindric lower part may be less in its diameter than the upper part, and may contain from four to six feet perpendicular height of water in it.

The upper part of the boiler is beſt made hemiſpherical, for reſiſting the elaſticity of the Steam; yet any other form may do, provided it be of ſufficient ſtrength for the purpoſe. The quick going of the engine depends much on the capaciouſneſs of the boiler-top; for if it be too ſmall, it requires the Steam to be heated to a great degree, to increaſe its elaſtic force ſo much as to work the engine. If the top is ſo capacious as to contain eight or ten times the quantity of Steam uſed each ſtroke, it will require no more fire to preſerve its elaſticity than is ſufficient to keep the water in a proper ſtate of boiling; this, therefore, is the beſt ſize for a boiler top. If the diameter of the cylinder be c, and works a ſix foot ſtroke, and the diameter of the boiler be ſuppoſed b, then

$$200c^2 = b^3, \text{ or } b = \sqrt[3]{200c^2}.$$

The effect of the injection in condenſing the Steam in the cylinder, depends upon the height of the reſervoir and the diameter of the adjutage. If the engine makes a 6 feet ſtroke, then the jackhead ciſtern ſhould be 12 feet perpendicular above the bottom of the cylinder or the adjutage. The ſize of the adjutage may be from 1 to 2 inches in diameter; or if the cylinder be very large, it is proper to have three or four holes rather than one large one, in order that the jet may be diſperſed the more effectually over the whole area of the cylinder. The injection pipe, or pipe of conduct, ſhould be ſo large as to ſupply the injection freely with water; if the diameter of the injection pipe be called p, and the diameter of the adjutage, a, then $4a^2 = p^2$, and $a^2 = \frac{1}{4}p^2$, or $a = \frac{1}{2}p$.

For a further account of theſe engines, ſee Deſaguliers's Exp. Philoſ. vol. 2, ſect. 14, pa. 465, &c.; or for an abſtract, Martin's Phil. Brit. number 461, or Nicholſon's Nat. Philoſ. p. 83 &c. And for an account of the improvement made in the fire-engine by Mr. Payne, ſee Philoſ. Tranſ. number 461, or Martin's Philoſ. Brit. p. 87 &c.

Mr. Blakey communicated to the Royal Society, in 1752, remarks on the beſt proportions for Steam-engine cylinders of a given content: and Mr. Smeaton deſcribes an engine of this kind, invented by Mr. De Moura of Portugal, being an improvement of Savery's conſtruction, to render it capable of working itſelf: for both which accounts, ſee Philoſ. Tranſ. vol. 47 art. 29 and 72.

We are informed in the new edit. of the Biograph. Brit. in the article Brindley, that in 1756 this gentleman, ſo well known for his concern in our inland navigations, undertook to erect a Steam-engine near Newcaſtle-under-Line, upon a new plan. The boiler of it was made with brick and ſtone, inſtead of iron plates, and the water was heated by iron flues of a peculiar conſtruction; by which contrivances the conſumption of fuel, neceſſary for working a Steam engine, was reduced one half. He introduced alſo in his engine, wooden cylinders, made in the manner of cooper's ware, inſtead of iron ones; the former being both cheaper and more eaſily managed in the ſhafts: and he likewiſe ſubſtituted wood for iron in the chains which worked at the end of the beam. He had formed deſigns of introducing other improvements into the conſtruction of this uſeful engine; but was diſcouraged by obſtacles that were thrown in his way.

Mr. Blakey, ſome years ago, obtained a patent for his improvement of Savery's Steam-engine, by which it is excellently adapted for raiſing water out of ponds, rivers, wells, &c, and for forcing it up to any height wanted for ſupplying houſes, gardens, and other places; though it has not power ſufficient to drain off the water from a deep mine. The principles of his conſtruction are explained by Mr. Ferguſon, in the Supplement to his Lectures, pa. 19; and a more particular deſcription of it, accompanied with a drawing, is given by the patentee himſelf in the Gentleman's Magazine for 1769, p. 392.

Mr. Blakey, it is ſaid, is the firſt perſon who ever thought of making uſe of air as an intermediate body between Steam and water; by which means the Steam is always kept from touching the water, and conſequently from being condenſed by it: and on this new principle he has obtained a patent. The engine may be built at a trifling expence, in compariſon of the common fire-engine now in uſe; it will ſeldom need repairs, and will not conſume half ſo much fuel. And as it has no pumps with piſtons, it is clear of all their friction; and the effect is equal to the whole ſtrength or compreſſive force of the Steam; which the effect of the common fire-engine never is, on account of the great friction of the piſtons in their pumps.

Ever ſince Mr. Newcomen's invention of the Steam fire engine, the great conſumption of fuel with which it is attended, has been complained of as an immenſe drawback upon the profits of our mines. It is a known fact, that every fire-engine of conſiderable ſize conſumes to the amount of three thouſand pounds worth of coals in every year. Hence many of our engineers have endeavoured, in the conſtruction of theſe engines, to ſave fuel. For this purpoſe, the fire-place has been diminiſhed, the flame has been carried round from the bottom of the boiler in a ſpiral direction, and conveyed through the body of the water in a tube before its arrival at the chimney; ſome have uſed a double boiler, ſo that fire might act in every poſſible point of contact; and ſome have built a moor-ſtone boiler, heated by three tubes of flame paſſing through it. But the moſt important improvements which have been made in the Steam-engine for more than thirty years paſt, we owe to the ſkill of Mr. James Watt; of which we ſhall give ſome account: premiſing, that the internal ſtructure of his new engines ſo much reſembles that of the common ones, that thoſe who are acquainted with them will not fail to underſtand the mechaniſm of his from the following deſcription: he has contrived to obſerve an uniform heat in the cylinder of his engines, by ſuffering no cold water to touch it, and by protecting it from the air, or other cold bodies, by a ſurrounding caſe filled with Steam, or with hot air or water, and by coating it over with ſubſtances that tranſmit heat ſlowly. He makes his vacuum to approach nearly to that of the barometer, by condenſing the Steam in a ſeparate veſſel, called the condenſer, which may be cooled at pleaſure without cooling the cylinder, either by an injection of cold water, or by ſurrounding the

the condenser with it, and generally by both. He extracts the injection water, and detached air, from the cylinder or condenser by pumps, which are wrought by the engine itself, or blows them out by the Steam. As the entrance of air into the cylinder would stop the operation of the engines, and as it is hardly to be expected that such enormous pistons as those of Steam-engines can move up and down, and yet be absolutely tight in the common engines; a stream of water is kept always running upon the piston, which prevents the entry of the air: but this mode of securing the piston, though not hurtful in the common ones, would be highly prejudicial to the new engines. Their piston is therefore made more accurately; and the outer cylinder, having a lid, covers it, the Steam is introduced above the piston; and when a vacuum is produced under it, acts upon it by its elasticity, as the atmosphere does upon common engines by its gravity. This way of working effectually excludes the air from the inner cylinder, and gives the advantage of adding to the power, by increasing the elasticity of the Steam.

In Mr. Watt's engines, the cylinder, the great beams, the pumps, &c, stand in their usual positions. The cylinder is smaller than usual, in proportion to the load, and is very accurately bored.

In the most complete engines, it is surrounded at a small distance, with another cylinder, furnished with a bottom and a lid. The interstice between the cylinders communicates with the boilers by a large pipe, open at both ends: so that it is always filled with Steam, and thereby maintains the inner cylinder always of the same heat with the Steam, and prevents any condensation within it, which would be more detrimental than an equal condensation in the outer one. The inner cylinder has a bottom and piston as usual: and as it does not reach up quite to the lid of the outer cylinder, the Steam in the interstice has always free access to the upper side of the piston. The lid of the outer cylinder has a hole in its middle; and the piston rod, which is truly cylindrical, moves up and down through that hole, which is kept Steam-tight by a collar of oakum screwed down upon it. At the bottom of the inner cylinder, there are two regulating valves, one of which admits the Steam to pass from the interstice into the inner cylinder below the piston, or shuts it out at pleasure: the other opens or shuts the end of a pipe, which leads to the condenser. The condenser consists of one or more pumps furnished with clacks and buckets (nearly the same as in common pumps) which are wrought by chains fastened to the great working beam of the engine. The pipe, which comes from the cylinder, is joined to the bottom of these pumps, and the whole condenser stands immersed in a cistern of cold water supplied by the engine. The place of this cistern is either within the house or under the floor, between the cylinder and the lever wall; or without the house between that wall and the engine shaft, as conveniency may require. The condenser being exhausted of air by blowing, and both the cylinders being filled with Steam, the regulating valve which admits the Steam into the inner cylinder is shut, and the other regulator which communicates with the condenser is opened, and the Steam rushes into the vacuum of the condenser with violence: but there it comes into contact with the cold sides of the pumps and pipes, and meets a jet of cold water, which was opened at the same time with the exhaustion regulator; these instantly deprive it of its heat, and reduce it to water; and the vacuum remaining perfect, more Steam continues to rush in, and be condensed until the inner cylinder be exhausted. Then the Steam which is above the piston, ceasing to be counteracted by that which was below it, acts upon the piston with its whole elasticity, and forces it to descend to the bottom of the cylinder, and so raises the buckets of the pumps which are hung to the other end of the beam. The exhaustion regulator is now shut, and the Steam one opened again, which, by letting in the Steam, allows the piston to be pulled up by the superior weight of the pump rods; and so the engine is ready for another stroke.

But the nature of Mr. Watt's improvement will be perhaps better understood from the following description of it as referred to a figure.—The cylinder or Steam vessel A, of this engine (fig. 5, pl. 27), is shut at bottom and opened at top as usual; and is included in an outer cylinder or case BB, of wood or metal, covered with materials which transmit heat slowly. This case is at a small distance from the cylinder, and close at both ends. The cover C has a hole in it, through which the piston rod E slides; and near the bottom is another hole F, by which the Steam from the boiler has always free entrance into this case or outer cylinder, and by the interstice GG between the two cylinders has access to the upper side of the piston HH. To the bottom of the inner cylinder A is joined a pipe I, with a cock or valve K, which is opened and shut when necessary, and forms a passage to another vessel L called a *Condenser*, made of thin metal. This vessel is immersed in a cistern M full of cold water, and it is contrived so as to expose a very great surface externally to the water, and internally to the Steam. It is also made air-tight, and has pumps N wrought by the engine, which keep it always exhausted of air and water.

Both the cylinders A and BB being filled with Steam, the passage K is opened from the inner one to the condenser L, into which the Steam violently rushes by its elasticity, because that vessel is exhausted; but as soon as it enters it, coming into contact with the cold matter of the condenser, it is reduced to water, and, the vacuum still remaining, the Steam continues to rush in till the inner cylinder A below the piston is left empty. The Steam which is above the piston, ceasing to be counteracted by that which is below it, acts upon the piston HH, and forces it to descend to the bottom of the cylinder, and so raises the bucket of the pump by means of the lever. The passage K between the inner cylinder and the condenser is then shut, and another passage O is opened, which permits the Steam to pass from the outer cylinder, or from the boiler into the inner cylinder under the piston; and then the superior weight of the bucket and pump rods pulls down the outer end of the lever or great beam, and raises the piston, which is suspended to the inner end of the same beam.

The advantages that accrue from this construction are, first, that the cylinder being surrounded with the Steam from the boiler, it is kept always uniformly as hot as the Steam itself, and is therefore incapable of destroy-

ing any part of the Steam, which should fill it, as the common engines do. Secondly, the condenser being kept always as cold as water can be procured, and colder than the point at which it boils in vacuo, the Steam is perfectly condensed, and does not oppose the descent of the piston; which is therefore forced down by the full power of the Steam from the boiler, which is somewhat greater than that of the atmosphere.

In the common fire-engines, when they are loaded to 7 pounds upon the inch, and are of a middle size, the quantity of Steam which is condensed in restoring to the cylinder the heat which it had been deprived of by the former injection of cold water, is about one full of the cylinder, besides what it really required to fill that vessel; so that twice the full of the cylinder is employed to make it raise a column of water equal to about 7 pounds f[illegible]h square inch of the piston: or, to take it more[illegible] a cubic foot of Steam raises a cubic foot of [illegible]bout 8 feet high, besides overcoming the friction of the engine, and the resistance of the water to motion.

In the improved engine, about one full and a fourth of the cylinder is required to fill it, because the Steam is one-fourth more dense than in the common engine. This engine raises a load equal to 12 pounds and a half upon the square inch of the piston; and each cubic foot of Steam of the density of the atmosphere, raises one cubic foot of water 22 feet high.

The working of these engines is more regular and steady than the common ones, and from what has been said, their other advantages seem to be very considerable.

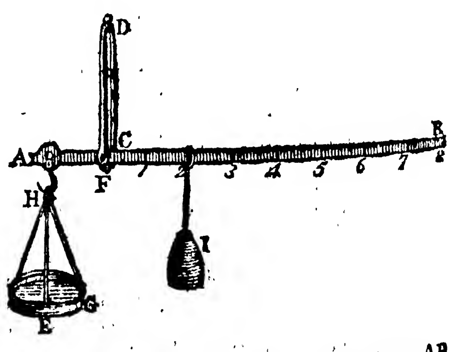
It is said, that the savings amount at least to two thirds of the fuel, which is an important object, especially where coals are dear. The new engines will raise from twenty thousand to twenty-four thousand cubic feet of water, to the height of twenty-four feet by one hundred weight of good pit coal: and Mr. Watt has proposed to produce engines upon the same principles, though somewhat differing in construction, which will require still much less fuel, and be more convenient for the purposes of mining, than any kind of engine yet used. Mr. Watt has also contrived a kind of mill wheel, which turns round by the power of Steam exerted within it.

The improvements above recited were invented by Mr. James Watt, at Glasgow, in Scotland, in 1764: he obtained the king's letters patent for the sole use of his invention in 1768; but meeting with difficulties in the execution of a large machine, and being otherwise employed, he laid aside the undertaking till the year 1774, when, in conjunction with Mr. Boulton near Birmingham, he completed both a reciprocating and rotative or wheel engine. He then applied to parliament for a prolongation of the term of his patent, which was granted by an act passed in 1775. Since that time, Mr. Watt and Mr. Boulton have erected several engines in Staffordshire, Shropshire, and Warwickshire, and a small one at Stratford near London. They have also lately finished another at Hawkesbury colliery near Coventry, which is justly supposed to be the most powerful engine in England. It has a cylinder 58 inches in diameter, which works a pump 14 inches in diameter, 65 fathoms high, and makes regularly twelve strokes, each 8 feet long, in a minute. They have also erected several engines in Cornwall; one of which has a cylinder 30 inches in diameter, that works a pump $6\frac{1}{2}$ inches in diameter in two shafts, by flat rods with great friction, 300 feet distant from each other, 45 fathoms high in each shaft, equal in all to 90 fathoms, and can make 14 strokes, 8 feet long, in a minute, with a consumption of coals less than 20 bushels in 24 hours. The terms they offer to the public are, to take, in lieu of all profits, one third part of the annual savings in fuel, which their engine makes when compared with a common engine of the same dimensions in the neighbourhood. The engines are built at the expence of those who use them, and Messrs. Boulton and Watt furnish such drawings, directions, and attendance, as may be necessary to enable a resident engineer to complete the machine. See the appendix to Pryce's Mineralogia, &c, 1778.

It has been said that some useful improvements have been made in the Steam engine by Mr. William Powel, who had lately the direction and care of an engine of this kind at a colliery near Swansea, in Glamorganshire.

It is hardly necessary to add, that Dr. Falck, in 1776, published an account and description of an improved Steam-engine, which, as he says, will, with the same quantity of fuel, and in an equal space of time, raise above double the quantity of water raised by any lever engine of the same dimensions; as he does not seem to have constructed even a working model of his proposed engine. The principal improvement, however, which he suggests, is to use two cylinders; into which the Steam is let alternately to ascend, by a common regulator, which always opens the communication of the Steam to one, whilst it shuts up the opening of the other: the piston rods are kept (by means of a wheel fixed to an arbour) in a continual ascending and descending motion, by which they move the common arbour, to which is affixed another wheel, moving the pump rods, in the same alternate direction as the piston rods, by which continual motion the pumps are kept in constant action.

STEELYARD, or STILYARD, in Mechanics, a kind of balance, called also, *Statera Romana*, or the *Roman Balance*, by means of which the weights of different bodies are discovered by using one single weight only.



The common Steelyard consists of an iron beam AB, in

in which is assumed a point at pleasure, as C, on which is raised a perpendicular CD. On the shorter arm AC is hung a scale or bason to receive the bodies weighed: the moveable weight I is shifted backward and forward on the beam, till it be a counterbalance to 1, 2, 3, 4, &c pounds placed in the scale; and the points are noted where the constant weight I weighs, as 1, 2, 3, 4, &c pounds. From this construction of the Steelyard, the manner of using it is evident. But the instrument is very liable to deceit, and therefore is not much used in ordinary commerce.

Chinese STEELYARD. The Chinese carry this Statera about them to weigh their gems, and other things of value. The beam or yard is a small rod of wood or ivory, about a foot in length: upon this are three rules of measure, made of a fine silver-studded work; they all begin from the end of the beam, whence the first is extended 8 inches, the second $6\frac{1}{2}$, the third $8\frac{1}{2}$. The first is the European measure, the other two seem to be Chinese measures. At the other end of the yard hangs a round scale, and at three several distances from this end are fastened so many slender strings, as different points of suspension. The first distance makes $1\frac{3}{5}$ or $\frac{8}{5}$ of an inch, the second $3\frac{1}{5}$ or double the first, and the third $4\frac{4}{5}$ or triple of the first. When they weigh any thing, they hold up the yard by some one of these strings, and hang a sealed weight, of about $1\frac{1}{4}$oz troy weight, upon the respective divisions of the rule, as the thing requires. Grew's Museum, pa. 369.

Spring STEELYARD, is a kind of portable balance, serving to weigh any matter, from 1 to about 40 pounds.

It is composed of a brass or iron tube, into which goes a rod, and about that is wound a spring of tempered steel in a spiral form. On this rod are the divisions of pounds and parts of pounds, which are made by successively hanging on, to a hook fastened to the other end, 1, 2, 3, 4, &c, pounds.

Now the spring being fastened by a screw to the bottom of the rod; the greater the weight is that is hung upon the hook, the more will the spring be contracted, and consequently a greater part of the rod will come out of the tube; the proportions or quantities of which greater weights are indicated by the figures appearing against the extremity of the tube.

STEELYARD-*Swing*. In the Philos. Trans. (no. 462, sect. 5) is given an account of a Steelyard swing, proposed as a mechanical method for assisting children labouring under deformities, owing to the contraction of the muscles on one side of the body. The crooked person is suspended with cords under his arm, and these are placed at equal distances from the centre of the beam. It is supposed that the gravity of the body will affect the contracted side, so as to put the muscles upon the stretch; and hence by degrees the defect may be remedied.

STEEPLE, an appendage usually raised on the western end of a church to contain the bells.—Steeples are denominated from their form, either *spires*, or *towers*. The first are such as rise continually diminishing like a cone or other pyramid. The latter are mere parallelopipedons, or some other prism, and are covered at top platform-like.—In each kind there is usually a sort of windows, or loop-holes, to let out the sound, and so contrived as to throw it downward.

Masius, in his treatise on bells, treats likewise of Steeples. The most remarkable in the world, it is said, is that at Pisa, which leans so much to one side, that you fear every moment it will fall; yet is in no danger. This odd disposition, he observes, is not owing to a shock of an earthquake, as is generally imagined; but was contrived so at first by the architect; as is evident from the cielings, windows, doors, &c, which are all in the bevel.

STEERAGE, in a ship, that part next below the quarter-deck, before the bulk-head of the great cabin, where the steersman stands in most ships of war. In large ships of war it is used as a hall, through which it is necessary to pass to or from the great cabin. In merchant ships it is mostly the habitation of the lower officers and ship's crew.

STEERAGE, in Sea-language, is also used to express the effort of the helm: and hence

STEERAGE-*way* is that degree of progressive motion communicated to a ship, by which she becomes susceptible of the effect of the helm to govern her course.

STEERING, in Navigation, the art of directing the ship's way by the movements of the helm; or of applying its efforts to regulate her course when she advances.

The perfection of Steering consists in a vigilant attention to the motion of the ship's head, so as to check every deviation from the line of her course in the first instant of its motion; and in applying as little of the power of the helm as possible. By this means she will run more uniformly in a straight path, as declining less to the right and left; whereas, if a greater effort of the helm be employed, it will produce a greater declination from the course, and not only increase the difficulty of Steering, but also make a crooked and irregular path through the water.

The helmsman, or steersman, should diligently watch the movements of the head by the land, clouds, moon, or stars; because, although the course is in general regulated by the compass, yet the vibrations of the needle are not so quickly perceived, as the sallies of the ship's head to the right or left, which, if not immediately restrained, will acquire additional velocity in every instant of their motion, and require a more powerful impulse of the helm to reduce them; the application of which will operate to turn her head as far on the contrary side of her course.

The phrases used in Steering a ship, vary according to the relation of the wind to her course. Thus, when the wind is large or fair, the phrases used by the pilot or officer who superintends the Steerage, are *port*, *starboard*, and *steady*: the first of which is intended to direct the ship's course farther to the right; the second to the left; and the last is designed to keep her exactly in the line on which she advances, according to the intended course. The excess of the first and second movement is called *hard a port*, and *hard-a-starboard*: the former of which gives her the greatest possible inclination to the right, and the latter an equal tendency to the left.—If, on the contrary, the wind be scant or foul, the phrases are *luff*, *thus*, and *no nearer*: the first of which is the order to keep her close to the wind; the second, to retain her

her in her present situation; and the third, to keep her sails full.

STELLA. See STAR.

STENTOROPHONIC *Tube*, a *Speaking Trumpet*, or tube employed to speak to a person at a great distance. It has been so called from Stentor, a person mentioned in the 5th book of the Iliad, who, as Homer tells us, could call out louder than 50 men. The Stentorophonic horn of Alexander the Great is famous; with this it is said he could give orders to his army at the distance of 100 stadia, which is about 12 English miles.

The present speaking trumpet it is said was invented by Sir Samuel Moreland. But Derham, in his Physico-Theology, lib. 4, ch. 3, says, that Kircher found out this instrument 20 years before Moreland, and published it in his Mesurgia; and it is farther said that Gaspar Schottus had seen one at the Jesuits' College at Rome. Also one Conyers, in the Philos. Trans. number 141, gives a description of an instrument of this kind, different from those commonly made. Gravesande, in his Philosophy, disapproves of the usual figures of these instruments; he would have them to be parabolic conoids, with the focus of one of its parabolic sections at the mouth.—Concerning this instrument, see Sturmy's Collegium Curiosum, Pt. 2, Tentam. 8; also Philos. Trans. vol. 6, pa. 3056, vol. 12, pa. 1027, or Abridg. vol. 1, pa. 505.

STEREOGRAPHIC *Projection of the Sphere*, is that in which the eye is supposed to be placed in the surface of the sphere. Or it is the projection of the circles of the sphere on the plane of some one great circle, when the eye, or a luminous point, is placed in the pole of that circle.—For the fundamental principles and chief properties of this kind of projection, see PROJECTION.

STEREOGRAPHY, is the art of drawing the forms of solids upon a plane.

STEVIN, STEVINUS (SIMON), a Flemish mathematician of Bruges, who died in 1633. He was master of mathematics to prince Maurice of Nassau, and inspector of the dykes in Holland. It is said he was the inventor of the sailing chariots, sometimes made use of in Holland. He was a good practical mathematician and mechanist, and was author of several useful works: as, treatises on Arithmetic, Algebra, Geometry, Statics, Optics, Trigonometry, Geography, Astronomy, Fortification, and many others, in the Dutch language, which were translated into Latin, by Snellius, and printed in 2 volumes folio. There are also two editions in the French language, in folio, both printed at Leyden, the one in 1608, and the other in 1634, with curious notes and additions, by Albert Girard.—For a particular account of Stevin's inventions and improvements in Algebra, which were many and ingenious, see our article Algebra, vol. 1, pa. 82 and 83.

STEWART (the Rev. Dr. MATTHEW), late professor of mathematics in the university of Edinburgh, was the son of the reverend Mr. Dugald Stewart, minister of Rothsay in the Isle of Bute, and was born at that place in the year 1717. After having finished his course at the grammar school, being intended by his father for the church, he was sent to the university of Glasgow, and was entered there as a student in 1734. His academical studies were prosecuted with diligence and success; and he was so happy as to be particularly distinguished by the friendship of Dr. Hutcheson, and Dr. Simson the celebrated geometrician, under whom he made great progress in that science.

Mr. Stewart's views made it necessary for him to attend the lectures in the university of Edinburgh in 1741; and that his mathematical studies might suffer no interruption, he was introduced by Dr. Simson to Mr. Maclaurin, who was then teaching with so much success, both the geometry and the philosophy of Newton, and under whom Mr. Stewart made that proficiency which was to be expected from the abilities of such a pupil, directed by those of so great a master. But the modern analysis, even when thus powerfully recommended, was not able to withdraw his attention from the relish of the ancient geometry, which he had imbibed under Dr. Simson. He still kept up a regular correspondence with this gentleman, giving him an account of his progress, and of his discoveries in geometry, which were now both numerous and important, and receiving in return many curious communications with respect to the *Loci Plani*, and the Porisms of Euclid. Mr. Stewart pursued this latter subject in a different, and new direction. In doing so, he was led to the discovery of those curious and interesting propositions, which were published, under the title of *General Theorems*, in 1746. They were given without the demonstrations; but they did not fail to place their discoverer at once among the geometricians of the first rank. They are, for the most part, Porisms, though Mr. Stewart, careful not to anticipate the discoveries of his friend, gave them only the name of Theorems. They are among the most beautiful, as well as most general propositions, known in the whole compass of geometry, and are perhaps only equalled by the remarkable locus to the circle in the second book of Apollonius, or by the celebrated theorem of Mr. Cotes.

Such is the history of the invention of these propositions; and the occasion of the publication of them was as follows. Mr. Stewart, while engaged in them, had entered into the church, and become minister of Roseneath. It was in that retired and romantic situation, that he discovered the greater part of those theorems. In the summer of 1746, the mathematical chair in the university of Edinburgh became vacant, by the death of Mr. Maclaurin. The General Theorems had not yet appeared; Mr. Stewart was known only to his friends; and the eyes of the public were naturally turned on Mr. Stirling, who then resided at Leadhills, and who was well known in the mathematical world. He however declined appearing as a candidate for the vacant chair; and several others were named, among whom was Mr. Stewart. Upon this occasion he printed the *General Theorems*, which gave their author a decided superiority above all the other candidates. He was accordingly elected professor of mathematics in the university of Edinburgh, in September 1747.

The duties of this office gave a turn somewhat different to his mathematical pursuits, and led him to think of the most simple and elegant means of explaining those difficult propositions, which were hitherto only accessible to men deeply versed in the modern analysis. In doing this, he was pursuing the object which, of

of all others, he most ardently wished to attain, viz, the application of geometry to such problems as the algebraic calculus alone had been thought able to resolve. His solution of Kepler's problem was the first specimen of this kind which he gave to the world; and it was perhaps impossible to have produced one more to the credit of the method he followed, or of the abilities with which he applied it. Among the excellent solutions hitherto given of this famous problem, there were none of them at once direct in its method, and simple in its principles. Mr. Stewart was so happy as to attain both these objects. He founds his solution on a general property of curves, which, though very simple, had perhaps never been observed; and by a most ingenious application of that property, he shows how the approximation may be continued to any degree of accuracy, in a series of results which converge with great rapidity.

This solution appeared in the second volume of the Essays of the Philosophical Society of Edinburgh, for the year 1756. In the first volume of the same collection, there are some other propositions of Mr. Stewart's, which are an extension of a curious theorem in the 4th book of Pappus. They have a relation to the subject of Porisms, and one of them forms the 91st of Dr. Simson's Restoration.

It has been already mentioned, that Mr. Stewart had formed the plan of introducing into the higher parts of mixed mathematics, the strict and simple form of ancient demonstration. The prosecution of this plan produced the *Tracts Physical and Mathematical*, which were published in 1761. In the first of these, Mr. Stewart lays down the doctrine of centripetal forces, in a series of propositions, demonstrated (if we admit the quadrature of curves) with the utmost rigour, and requiring no previous knowledge of the mathematics, except the elements of plane Geometry, and of Conic Sections. The good order of these propositions, added to the clearness and simplicity of the demonstrations, renders this Tract perhaps the best elementary treatise of Physical Astronomy that is any where to be found.

In the three remaining Tracts, our author had it in view to determine, by the same rigorous method, the effect of those forces which disturb the motions of a secondary planet. From this he proposed to deduce, not only a theory of the moon, but a determination of the sun's distance from the earth. The former, it is well known, is the most difficult subject to which mathematics have been applied, and the resolution required and merited all the clearness and simplicity which our author possessed in so eminent a degree. It must be regretted therefore, that the decline of Dr. Stewart's health, which began soon after the publication of the Tracts, did not permit him to pursue this investigation.

The other object of the Tracts was, to determine the distance of the sun, from his effect in disturbing the motions of the moon; and his enquiries into the lunar irregularities had furnished him with the means of accomplishing it.

The theory of the composition and resolution of forces enables us to determine what part of the solar force is employed in disturbing the motions of the moon; and therefore, could we measure the instantaneous effect of that force, or the number of feet by which it accelerates or retards the moon's motion in a second, we should be able to determine how many feet the whole force of the sun would make a body, at the distance of the moon, or of the earth, descend in a second of time, and consequently how much the earth is, in every instant, turned out of its rectilineal course. Thus the curvature of the earth's orbit, or, which is the same thing, the radius of that orbit, that is, the distance of the sun from the earth, would be determined. But the fact is, that the instantaneous effects of the sun's disturbing force are too minute to be measured; and that it is only the effect of that force, continued for an entire revolution, or some considerable portion of a revolution, which astronomers are able to observe.

There is yet a greater difficulty which embarrasses the solution of this problem. For as it is only by the difference of the forces exerted by the sun on the earth and on the moon, that the motions of the latter are disturbed, the farther off the sun is supposed, the less will be the force by which he disturbs the moon's motions; yet that force will not diminish beyond a fixed limit, and a certain disturbance would obtain, even if the distance of the sun were infinite. Now the sun is actually placed at so great a distance, that all the disturbances, which he produces on the lunar motions, are very near to this limit, and therefore a small mistake in estimating their quantity, or in reasoning about them, may give the distance of the sun infinite, or even impossible. But all this did not deter Dr. Stewart from undertaking the solution of the problem, with no other assistance than that which geometry could afford. Indeed the idea of such a problem had first occurred to Mr. Machin, who, in his book on the laws of the moon's motion, has just mentioned it, and given the result of a rude calculation (the method of which he does not explain), which assigns 8″ for the parallax of the sun. He made use of the motion of the nodes; but Dr. Stewart considered the motion of the apogee, or of the longer axis of the moon's orbit, as the irregularity best adapted to his purpose. It is well known that the orbit of the moon is not immoveable; but that, in consequence of the disturbing force of the sun, the longer axis of that orbit has an angular motion, by which it goes back about 3 degrees in every lunation, and completes an entire revolution in 9 years nearly. This motion, though very remarkable and easily determined, has the same fault, in respect of the present problem, that was ascribed to the other irregularities of the moon: for a very small part of it only depends on the parallax of the sun; and of this Dr. Stewart seems not to have been perfectly aware.

The propositions however which defined the relation between the sun's distance and the mean motion of the apogee, were published among the Tracts, in 1761. The transit of Venus happened in that same year: the astronomers returned, who had viewed that curious phenomenon, from the most distant stations; and no very satisfactory result was obtained from a comparison of their observations. Dr. Stewart then resolved to apply the principles he had already laid down; and, in 1763, he published his essay on the Sun's Distance, where the computation being actually made, the parallax of the sun was found to be no more than 6″. 9, and

and consequently his distance almost 29875 semidiameters of the earth, or nearly 119 millions of miles.

A determination of the sun's distance, that so far exceeded all former estimations of it, was received with surprise, and the reasoning on which it was founded was likely to undergo a severe examination. But, even among astronomers, it was not every one who could judge in a matter of such difficult discussion. Accordingly, it was not till about 5 years after the publication of the sun's distance, that there appeared a pamphlet, under the title of *Four Propositions*, intended to point out certain errors in Dr. Stewart's investigation, which had given a result much greater than the truth. From his desire of simplifying, and of employing only the geometrical method of reasoning, he was reduced to the necessity of rejecting quantities, which were considerable enough to have a great effect on the last result. An error was thus introduced, which, had it not been for certain compensations, would have become immediately obvious, by giving the sun's distance near three times as great as that which has been mentioned.

The author of the pamphlet, referred to above, was the first who remarked the dangerous nature of these simplifications, and who attempted to estimate the error to which they had given rise. This author remarked what produced the compensation above mentioned, viz, the immense variation of the sun's distance, which corresponds to a very small variation of the motion of the moon's apogee. And it is but justice to acknowledge that, besides being just in the points already mentioned, they are very ingenious, and written with much modesty and good temper. The author, who at first concealed his name, but has now consented to its being made public, was Mr. Dawson, a surgeon at Sudbury in Yorkshire, and one of the most ingenious mathematicians and philosophers this country now possesses.

A second attack was soon after this made on the Sun's Distance, by Mr. Landen; but by no means with the same good temper which has been remarked in the former. He fancied to himself errors in Dr. Stewart's investigation, which have no existence; he exaggerated those that were real, and seemed to triumph in the discovery of them with unbecoming exultation. If there are any subjects on which men may be expected to reason dispassionately, they are certainly the properties of number and extension; and whatever pretexts moralists or divines may have for abusing one another, mathematicians can lay claim to no such indulgence. The asperity of Mr. Landen's animadversions ought not therefore to pass uncensured, though it be united with sound reasoning and accurate discussion. The error into which Dr. Stewart had fallen, though first taken notice of by Mr. Dawson, whose pamphlet was sent by me to Mr. Landen as soon as it was printed (for I had the care of the edition of it) yet this gentleman extended his remarks upon it to greater exactness. But Mr. Landen, in the zeal of correction, brings many other charges against Dr. Stewart, the greater part of which seem to have no good foundation. Such are his objections to the second part of the investigation, where Dr. Stewart finds the relation between the disturbing force of the sun, and the motion of the apses of the lunar orbit. For this part, instead of being liable to objection, is deserving of the greatest praise, since it resolves, by geometry alone, a problem which had eluded the efforts of some of the ablest mathematicians, even when they availed themselves of the utmost resources of the integral calculus. Sir Isaac Newton, though he assumed the disturbing force very near the truth, computed the motion of the apses from thence only at one half of what it really amounts to; so that, had he been required, like Dr. Stewart, to invert the problem, he would have committed an error, not merely of a few thousandth parts, as the latter is alleged to have done, but would have brought out a result double of the truth. (*Princip. Math. lib.* 3, *prop.* 3.) Machin and Callendrini, when commenting on this part of the Principia, found a like inconsistency between their theory and observation. Three other celebrated mathematicians, Clairaut, D'Alembert, and Euler, severally experienced the same difficulties, and were led into an error of the same magnitude. It is true, that, on resuming their computations, they found that they had not carried their approximations to a sufficient length, which when they had at last accomplished, their results agreed exactly with observation. Mr. Walmesley and Dr. Stewart were, I think, the first mathematicians who, employing in the solution of this difficult problem, the one the algebraic calculus, and the other the geometrical method, were led immediately to the truth; a circumstance so much for the honour of both, that it ought not to be forgotten. It was the business of an impartial critic, while he examined our author's reasonings, to have remarked and to have weighed these considerations.

The *Sun's Distance* was the last work which Dr. Stewart published; and though he lived to see the animadversions made on it, that have been taken notice of above, he declined entering into any controversy. His disposition was far from polemical; and he knew the value of that quiet, which a literary man should rarely suffer his antagonists to interrupt. He used to say, that the decision of the point in question was now before the public; that if his investigation was right, it would never be overturned, and that if it was wrong, it ought not to be defended.

A few months before he published the Essay just mentioned, he gave to the world another work, entitled, *Propositiones More Veterum Demonstratæ*. It consists of a series of geometrical theorems, mostly new; investigated, first by an analysis, and afterwards synthetically demonstrated by the inversion of the same analysis. This method made an important part in the analysis of the ancient geometricians; but few examples of it have been preserved in their writings, and those in the *Propositiones Geometricæ* are therefore the more valuable.

Doctor Stewart's constant use of the geometrical analysis had put him in possession of many valuable propositions, which did not enter into the plan of any of the works that have been enumerated. Of these, not a few have found a place in the writings of Dr. Simson, where they will for ever remain, to mark the friendship of these two mathematicians, and to evince the esteem which Dr. Simson entertained for the abilities of his pupil. Many of these are in the work upon the Porisms, and others in the Conic Sections, viz, marked with the letter x; also a theorem in the edition of Euclid's Data.

Soon

Soon after the publication of the *Sun's Diſtance*, Dr. Stewart's health began to decline, and the duties of his office became burdenſome to him. In the year 1772, he retired to the country, where he afterwards ſpent the greater part of his life, and never reſumed his labours in the univerſity. He was however ſo fortunate as to have a ſon to whom, though very young, he could commit the care of them with the greateſt confidence. Mr. Dugald Stewart, having begun to give lectures for his father from the period above mentioned, was elected joint profeſſor with him in 1775, and gave an early ſpecimen of thoſe abilities, which have not been confined to a ſingle ſcience.

After mathematical ſtudies (on account of the bad ſtate of health into which Dr. Stewart was falling) had ceaſed to be his buſineſs, they continued to be his amuſement. The analogy between the circle and hyperbola had been an early object of his admiration. The extenſive views which that analogy is continually opening; the alternate appearance and diſappearance of reſemblance in the midſt of ſo much diſſimilitude, make it an object that aſtoniſhes the experienced, as well as the young geometrician. To the conſideration of this analogy therefore the mind of Dr. Stewart very naturally returned, when diſengaged from other ſpeculations. His uſual ſucceſs ſtill attended his inveſtigations; and he has left among his papers ſome curious approximations to the areas, both of the circle and hyperbola. For ſome years toward the end of his life, his health ſcarcely allowed him to proſecute ſtudy even as an amuſement. He died the 23d of January 1785, at 68 years of age.

The habits of ſtudy, in a man of original genius, are objects of curioſity, and deſerve to be remembered. Concerning thoſe of Dr. Stewart, his writings have made it unneceſſary to remark, that from his youth he had been accuſtomed to the moſt intenſe and continued application. In conſequence of this application, added to the natural vigour of his mind, he retained the memory of his diſcoveries in a manner that will hardly be believed. He ſeldom wrote down any of his inveſtigations, till it became neceſſary to do ſo for the purpoſe of publication. When he diſcovered any propoſition, he would ſet down the enunciation with great accuracy, and on the ſame piece of paper would conſtruct very neatly the figure to which it referred. To theſe he truſted for recalling to his mind, at any future period, the demonſtration, or the analyſis, however complicated it might be. Experience had taught him that he might place this confidence in himſelf without any danger of diſappointment; and for this ſingular power, he was probably more indebted to the activity of his invention, than to the mere tenacioufneſs of his memory.

Though Dr. Stewart was extremely ſtudious, he read but few books, and thus verified the obſervation of D'Alembert, that, of all the men of letters, mathematicians read leaſt of the writings of one another. Our author's own inveſtigations occupied him ſufficiently; and indeed the world would have had reaſon to regret the miſapplication of his talents, had he employed, in the mere acquiſition of knowledge, that time which he could dedicate to works of invention.

It was Dr. Stewart's cuſtom to ſpend the ſummer at a delightful retreat in Ayrſhire, where, after the academical labours of the winter were ended, he found the leiſure neceſſary for the proſecution of his reſearches. In his way thither, he often made a viſit to Dr. Simſon of Glaſgow, with whom he had lived from his youth in the moſt cordial and uninterrupted friendſhip. It was pleaſing to obſerve, in theſe two excellent mathematicians, the moſt perfect eſteem and affection for each other, and the moſt entire abſence of jealouſy, though no two men ever trode more nearly in the ſame path. The ſimilitude of their purſuits ſerved only to endear them to each other, as it will ever do with men ſuperior to envy. Their ſentiments and views of the ſcience they cultivated, were nearly the ſame; they were both profound geometricians; they equally admired the ancient mathematicians, and were equally verſed in their methods of inveſtigation; and they were both apprehenſive that the beauty of their favourite ſcience would be forgotten, for the leſs elegant methods of algebraic computation. This innovation they endeavoured to oppoſe; the one, by reviving thoſe books of the ancient geometry which were loſt; the other, by extending that geometry to the moſt difficult enquiries of the moderns. Dr. Stewart, in particular, had remarked the intricacies, in which many of the greateſt of the modern mathematicians had involved themſelves in the application of the calculus, which a little attention to the ancient geometry would certainly have enabled them to avoid. He had obſerved too the elegant ſynthetical demonſtrations that, on many occaſions, may be given of the moſt difficult propoſitions, inveſtigated by the inverſe method of fluxions. Theſe circumſtances had perhaps made a ſtronger impreſſion than they ought, on a mind already filled with admiration of the ancient geometry, and produced too unfavourable an opinion of the modern analyſis. But if it be confeſſed that Dr. Stewart rated, in any reſpect too high, the merit of the former of theſe ſciences, this may well be excuſed in the man whom it had conducted to the diſcovery of the *General Theorems*, to the *ſolution of Kepler's Problem*, and to an *accurate* determination of the *Sun's diſturbing force*. His great modeſty made him aſcribe to the method he uſed, that ſucceſs which he owed to his own abilities.

The foregoing account of Dr. Stewart and his writings, is chiefly extracted from the learned hiſtory of them, by Mr. Playfair, in the 1ſt volume of the Edinburgh Philoſophical Tranſactions, pa. 57, &c.

STIFELS, Stifelius (Michael), a Proteſtant miniſter, and very ſkilful mathematician, was born at Eſlingen a town in Germany; and died at Jena in Thuringia, in the year 1567, at 58 years of age according to Voſſius, but ſome others ſay 80. Stifels was one of the beſt mathematicians of his time. He publiſhed, in the German language, a treatiſe on Algebra, and another on the Calendar or Eccleſiaſtical computation. But his chief work, is the *Arithmetica Integra*, a complete and excellent treatiſe, in Latin, on Arithmetic and Algebra, printed in 4to at Norimberg 1544. In this work there are a number of ingenious inventions, both in common arithmetic and in algebra; of which, thoſe relating to the latter are amply explained under the article *Algebra* in this dictionary, vol. 1, pa. 77 &c; to which may be added ſome particulars

ticulars concerning the arithmetic, from my volume of *Tracts* printed in 1786, pa. 68. In this original work are contained many curious things, some of which have mistakenly been ascribed to a much later date. He here treats pretty fully and ably, of progressional and figurate numbers, and in particular of the triangular table, for constructing both them and the coefficients of the terms of all powers of a binomial; which has been so often used since his time for these and other purposes, and which more than a century after was, by Pascal, otherwise called the Arithmetical Triangle, and who only mentioned some additional properties of the table. Stifels shews, that the horizontal lines of the table furnish the coefficients of the terms of the corresponding powers of a binomial; and teaches how to make use of them in the extraction of roots of all powers whatever. Cardan seems to ascribe the invention of that table to Stifelius; but I apprehend that is only to be understood of its application to the extraction of roots.

It is remarkable too, how our author, at p. 35 &c of the same book, treats of the nature and use of logarithms; not under that name indeed, but under the idea of a series of arithmeticals, adapted to a series of geometricals. He there explains all their uses; such as, that the addition of them answers to the multiplication of their geometricals; subtraction to division; multiplication of exponents, to involution; and dividing of exponents to evolution. He also exemplifies the use of them in cases of the Rule-of-three, and in finding mean proportionals between given terms, and such like, exactly as is done in logarithms. So that he seems to have been in the full possession of the idea of logarithms, and wanted only the necessity of troublesome calculations to induce him to make a table of such numbers.

Stifels was a zealous, though weak disciple of Luther. He took it into his head to become a prophet, and he predicted that the end of the world would happen on a certain day in the year 1553, by which he terrified many people. When the proposed day arrived, he repaired early, with multitudes of his followers, to a particular place in the open air, spending the whole day in the most fervent prayers and praises, in vain looking for the coming of the Lord, and the universal conflagration of the elements, &c.

STILE. See Style.

STILYARD. See Steelyard.

STOFLER (John), a German mathematician, was born at Justingen in Suabia, in 1452, and died in 1531, at 79 years of age. He taught mathematics at Tubinga, where he acquired a great reputation, which however he in a great measure lost again, by intermeddling with the prediction of future events. He announced a great deluge, which he said would happen in the year 1524, a prediction with which he terrified all Germany, where many persons prepared vessels proper to escape with from the floods. But happily the prediction failing, it enraged the astrologer, though it served to convince him of the vanity of his prognostications.—He was author of several works in mathematics, and astrology, full of foolish and chimerical ideas; such as,

1. Elucidatio Fabric. Ususque Astrolabii; fol. 1513.
2. Procli Sphæram Comment. fol. 154.
3. Cosmographicæ aliquot Descriptiones; 4to, 1537.

STONE, (Edmund), a good Scotch mathematician, who was author of several ingenious works. I know not the particular place or date of his birth, but it was probably in the shire of Argyle, and about the beginning of the present century, or conclusion of the last. Nor have we any memoirs of his life, except a letter from the Chevalier de Ramsay, author of the Travels of Cyrus, in a letter to father Castel, a Jesuit at Paris, and published in the Memoires de Trevoux, p. 109, as follows: "True genius overcomes all the disadvantages of birth, fortune, and education; of which Mr. Stone is a rare example. Born a son of a gardener of the duke of Argyle, he arrived at 8 years of age before he learnt to read.—By chance a servant having taught young Stone the letters of the alphabet, there needed nothing more to discover and expand his genius. He applied himself to study, and he arrived at the knowledge of the most sublime geometry and analysis, without a master, without a conductor, without any other guide but pure genius."

"At 18 years of age he had made these considerable advances without being known, and without knowing himself the prodigies of his acquisitions. The duke of Argyle, who joined to his military talents, a general knowledge of every science that adorns the mind of a man of his rank, walking one day in his garden, saw lying on the grass a Latin copy of Sir Isaac Newton's celebrated Principia. He called some one to him to take and carry it back to his library. Our young gardener told him that the book belonged to him. *To you?* replied the Duke. *Do you understand geometry, Latin, Newton?* I know a little of them, replied the young man with an air of simplicity arising from a profound ignorance of his own knowledge and talents. The Duke was surprised; and having a taste for the sciences, he entered into conversation with the young mathematician: he asked him several questions, and was astonished at the force, the accuracy, and the candour of his answers. *But how*, said the Duke, *came you by the knowledge of all these things?* Stone replied, *A servant taught me, ten years since, to read: does one need to know any thing more than the 24 letters in order to learn every thing else that one wishes?* The Duke's curiosity redoubled—he sat down upon a bank, and requested a detail of all his proceedings in becoming so learned."

"*I first learned to read*, said Stone: *the masons were then at work upon your house: I went near them one day, and I saw that the architect used a rule, compasses, and that he made calculations. I enquired what might be the meaning of and use of these things; and I was informed that there was a science called Arithmetic; I purchased a book of arithmetic, and I learned it.—I was told there was another science called Geometry: I bought the books, and I learnt geometry. By reading I found that there were good books in these two sciences in Latin: I bought a dictionary, and I learned Latin. I understood also that there were good books of the same kind in French: I bought a dictionary, and I learned French. And this, my lord, is what I have done: it seems to me that we may learn every thing when we know the 24 letters of the alphabet.*"

This account charmed the Duke. He drew this wonderful genius out of his obscurity; and he provided him with an employment which left him plenty of

of time to apply himself to the sciences. He discovered in him also the same genius for music, for painting, for architecture, for all the sciences which depend on calculations and proportions."

"I have seen Mr. Stone. He is a man of great simplicity. He is at present sensible of his own knowledge: but he is not puffed up with it. He is possessed with a pure and distinterested love for the mathematics; though he is not solicitous to pass for a mathematician; vanity having no part in the great labour he sustains to excel in that science. He despises fortune also: and he has solicited me twenty times to request the duke to give him less employment, which may not be worth the half of that he now has, in order to be more retired, and less taken off from his favourite studies. He discovers sometimes, by methods of his own, truths which others have discovered before him. He is charmed to find on these occasions that he is not a first inventor, and that others have made a greater progress than he thought. Far from being a plagiary, he attributes ingenious solutions, which he gives to certain problems, to the hints he has found in others, although the connection is but very distant," &c.

Mr. Stone was author and translator of several useful works; viz.

1. A New Mathematical Dictionary, in 1 vol. 8vo, first printed in 1726.

2. Fluxions, in 1 vol. 8vo, 1730. The Direct Method is a translation from the French, of Hospital's Analyse des Infiniments Petits; and the Inverse Method was supplied by Stone himself.

3. The Elements of Euclid, in 2 vols. 8vo, 1731. A neat and useful edition of those Elements, with an account of the life and writings of Euclid, and a defence of his elements against modern objectors.

Beside other smaller works.

Stone was a fellow of the Royal Society, and had inserted in the Philos. Transactions (vol. 41, pa. 218) an "Account of two species of lines of the 3d order, not mentioned by Sir Isaac Newton, or Mr. Stirling."

STRABO, a celebrated Greek geographer, philosopher, and historian, was born at Amasia, and was descended from a family settled at Gnossus in Crete. He was the disciple of Xenarchus, a Peripatetic philosopher, but at length attached himself to the Stoics. He contracted a strict friendship with Cornelius Gallus, governor of Egypt; and travelled into several countries, to observe the situation of places, and the customs of nations.

Strabo flourished under Augustus; and died under Tiberius about the year 25, in a very advanced age.—He composed several works; all of which are lost, except his *Geography*, in 17 books; which are justly esteemed very precious remains of antiquity. The first two books are employed in showing, that the study of geography is not only worthy of a philosopher, but even necessary to him; the 3d describes Spain; the 4th, Gaul and the Britannic isles; the 5th and 6th, Italy and the adjacent isles; the 7th, which is imperfect at the end, Germany, the countries of the Getæ and Illyrii, Taurica, Chersonesus, and Epirus; the 8th, 9th, and 10th, Greece with the neighbouring isles; the four following, Asia within Mount Taurus; the 15th and 16th, Asia without Taurus, India, Persia, Syria, Arabia; and the 17th, Egypt, Ethiopia, Carthage, and other parts of Africa.

Strabo's work was published with a Latin version by Xylander, and notes by Isaac Casaubon, at Paris 1620, in folio; but the best edition is that of Amsterdam in 1707, in 2 volumes folio, by the learned Theodore Janson of Almelooveen, with the entire notes of Xylander, Casaubon, Meursius, Cluver, Holsten, Salmasius, Bochart, Ez. Spanheim, Cellar, and others. To this edition is subjoined the *Chrestomathiæ*, or Epitome of Strabo; which, according to Mr. Dodswell, who has written a very elaborate and learned dissertation about it, was made by some unknown person, between the years of Christ 676 and 996. It has been found of some use, not only in helping to correct the original, but in supplying in some measure the defect in the 7th book. Mr. Dodswell's dissertation is prefixed to this edition.

STRAIT, or STRAIGHT, or STREIGHT, in Hydrography, is a narrow channel or arm of the sea, shut up between lands on either side, and usually affording a passage out of one great sea into another. As the Straits of Magellan, of Le Maire, of Gibraltar, &c.

STRAIT is also sometimes used, in Geography, for an isthmus, or neck of land between two seas, preventing their communication.

STRENGTH, *vis*, force, power.

Some authors make the Strength of animals, of the same kind, to depend on the quantity of blood; but most on the size of the bones, joints, and muscles; though we find by daily experience, that the animal spirits contribute greatly to Strength at different times.

Emerson has most particularly treated of the Strength of bodies depending on their dimensions and weight. In the General Scholium after his propositions on this subject, he adds; If a certain beam of timber be able to support a given weight; another beam, of the same timber, similar to the former, may be taken so great, as to be able but just to bear its own weight: while any larger beam cannot support itself, but must break by its own weight; but any less beam will bear something more. For the Strength being as the cube of the depth; and the stress, being as the length and quantity of matter, is as the 4th power of the depth; it is plain therefore, that the stress increases in a greater ratio than the Strength. Whence it follows, that a beam may be taken so large, that the stress may far exceed the Strength: and that, of all similar beams, there is but one that will just support itself, and nothing more. And the like holds true in all machines, and in all animal bodies. And hence there is a certain limit, in regard to magnitude, not only in all machines and artificial structures, but also in natural ones, which neither art nor nature can go beyond; supposing them made of the same matter, and in the same proportion of parts.

Hence it is impossible that mechanic engines can be increased to any magnitude at pleasure. For when they arrive at a particular size, their several parts will break and fall asunder by their weight. Neither can any buildings of vast magnitudes be made to stand, but must fall to pieces by their great weight, and go to ruin.

 It

It is likewise impossible for nature to produce animals of any vast size at pleasure: except some sort of matter can be found, to make the bones of, which may be so much harder and stronger than any hitherto known: or else that the proportion of the parts be so much altered, and the bones and muscles made thicker in proportion; which will make the animal distorted, and of a monstrous figure, and not capable of performing any proper actions. And being made similar and of common matter, they will not be able to stand or move; but, being burthened with their own weight, must fall down. Thus, it is impossible that there can be any animal so large as to carry a castle upon his back; or any man so strong as to remove a mountain, or pull up a large oak by the roots: nature will not admit of these things; and it is impossible that there can be animals of any sort beyond a determinate size.

Fish may indeed be produced to a larger size than land animals; because their weight is supported by the water. But yet even these cannot be increased to immensity, because the internal parts will press upon one another by their weight, and destroy their fabric.

On the contrary, when the size of animals is diminished, their Strength is not diminished in the same proportion as the weight. For which reason a small animal will carry far more than a weight equal to its own, whilst a great one cannot carry so much as its weight. And hence it is that small animals are more active, will run faster, jump farther, or perform any motion quicker, for their weight, than large animals: for the less the animal, the greater the proportion of the Strength to the stress. And nature seems to know no bounds as to the smallness of animals, at least in regard to their weight.

Neither can any two unequal and similar machines resist any violence alike, or in the same proportion; but the greater will be more hurt than the less. And the same is true of animals; for large animals by falling break their bones, while lesser ones, falling higher, receive no damage. Thus a cat may fall two or three yards high, and be no worse, and an ant from the top of a tower.

It is likewise impossible in the nature of things, that there can be any trees of immense size; if there were any such, their limbs, boughs, and branches, must break off and fall down by their own weight. Thus it is impossible there can be an oak a quarter of a mile high; such a tree cannot grow or stand, but its limbs will drop off by their weight. And hence also smaller plants can better sustain themselves than large ones.

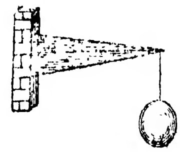
As to the due proportion of Strength in several bodies, according to their particular positions, and the weights they are to bear; he farther observes that, If a piece of timber is to be pierced with a mortise-hole, the beam will be stronger when it is taken out of the middle, than when taken out of either side. And in a beam supported at both ends, it is stronger when the hole is made in the upper side than when made in the under, provided a piece of wood is driven hard in to fill up the hole.

If a piece is to be spliced upon the end of a beam, to be supported at both ends; it will be the stronger when spliced on the under side of a beam: but if the piece is supported only at one end, to bear a weight on the other; it is stronger when spliced on the upper side.

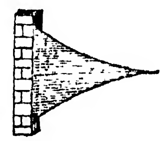
When a small lever, &c, is nailed to a body, to move it or suspend it by; the strain is greater upon the nail nearest the hand, or point where the power is applied.

If a beam be supported at both ends; and the two ends reach over the props, and be fixed down immoveable; it will bear twice as much weight, as when the ends only lie loose or free upon the supporters.

When a slender cylinder is to be supported by two pieces; the distance of the pins ought to be nearly $\frac{4}{7}$ of the length of the cylinder, and the pins equidistant from its ends; and then the cylinder will endure the least bending or strain by its weight.



A beam fixed at one end, and bearing a weight at the other; if it be cut in the form of a wedge, and placed with its parallel sides parallel to the horizon; it will be equally strong every where; and no sooner break in one place than another.



When a beam has all its sides cut in form of a concave parabola, having the vertex at the end, and its abscis perpendicular to the axis of the solid, and the base a square, or a circle, or any regular polygon; such a beam fixed horizontally, at one end, is equally strong throughout for supporting its own weight.

Also when a wall faces the wind, and if the vertical section of it be a right-angled triangle; or if the fore part next the wind &c be perpendicular to the horizon, and the back part a sloping plane; such a wall will be equally strong in all its parts to resist the wind, if the parts of the wall cohere strongly together; but when it is built of loose materials, it is better to be convex on the back part in form of a parabola.

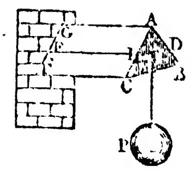
When a wall is to support a bank of earth or any fluid body, it ought to be built concave in form of a semicubical parabola, whose vertex is at the top of the wall, provided the parts of the wall adhere firmly together. But if the parts be loose, then a right line or sloping plane ought to be its figure. Such walls will be equally strong throughout

All spires of churches in the form of cones or pyramids, are equally strong in all parts to resist the wind. But when the parts do not cohere together, then they ought to be parabolic conoids, to be equally strong throughout.

Likewise if there be a pillar erected in form of the logarithmic curve, the asymptote being the axis; it cannot be crushed to pieces in one part sooner than in another, by its own weight. And if such a pillar be turned upside down, and suspended by the thick end, it will not be more liable to separate in one part than another, by its own weight.

Moreover,

Moreover, if AE be a beam in form of a triangular prifm; and if AD = $\frac{1}{9}$AB, and AI = $\frac{1}{9}$ AC, and the edge or fmall fimilar prifm ADIF be cut away parallel to the bafe; the remaining beam DIBEF will bear a greater weight P, than the whole ABCEG, or the part will be ftronger than the whole; which is a paradox in Mechanics.



As to the Strength of feveral forts of wood, drawn from experiments, he fays, On a medium, a piece of good oak, an inch fquare, and a yard long, fupported at both ends, will bear in the middle, for a very fhort time, about 330lb averdupois, but will break with more than that weight. But fuch a piece of wood fhould not, in practice, be trufted for any length of time, with more than a third or a fourth part of that weight. And the proportion of the Strength of feveral forts of wood, he found to be as follows:

Box, oak, plumbtree, yew - - - - - - - - -	11
Afh, elm - - - - - - - - - - - - - - - -	$8\frac{1}{2}$
Thorn, walnut - - - - - - - - - - - - - -	$7\frac{1}{2}$
Apple tree, elder, red fir, holly, plane - -	7
Beech, cherry, hazle - - - - - - - - - - -	$6\frac{3}{4}$
Alder, afp, Birch, white-fir, willow - - -	6
Iron - - - - - - - - - - - - - - - - - - -	107
Brafs - - - - - - - - - - - - - - - - - -	50
Bone - - - - - - - - - - - - - - - - - -	22
Lead - - - - - - - - - - - - - - - - - -	$6\frac{1}{2}$
Fine free ftone - - - - - - - - - - - - -	1

As to the Strength of bodies in direction of the fibres, he obferves, A cylindric rod of good clean fir, of an inch circumference, drawn in length, will bear at extremity 400lb; and a fpear of fir 2 inches diameter, will bear about 7 ton.—A rod of good iron, of an inch circumference, will bear near 3 ton weight. And a good hempen rope of an inch circumference, will bear 100olb. at extremity.

All this fuppofes thefe bodies to be found and good throughout; but none of them fhould be put to bear more than a third or a fourth part of that weight, efpecially for any length of time. From what has been faid; if a fpear of fir, or a rope, or a fpear of iron, of d inches diameter, were to lift $\frac{1}{4}$ the extreme weight; then

The fir would bear $8\frac{4}{5}dd$ hundred weight.
The rope would bear $22dd$ hundred weight.
The iron would bear $6\frac{3}{4}dd$ ton weight.

As to Animals; Men may apply their Strength feveral ways, in working a machine. A man of ordinary Strength turning a roller by the handle, can act for a whole day againft a refiftance equal to 30lb. weight; and if he works 10 hours a day, he will raife a weight of 30lb. through $3\frac{1}{2}$ feet in a fecond of time; or if the weight be greater, he will raife it fo much lefs in proportion. But a man may act, for a fmall time, againft a refiftance of 50lb. or more.

If two men work at a windlafs, or roller, they can more eafily draw up 70lb, than one man can 30lb, provided the elbow of one of the handles be at right angles to that of the other. And with a fly, or heavy w[illegible] applied to it, a man may do $\frac{1}{5}$ part more work; [illegible] for a little while he can act with a force, or overcome a continual refiftance, of 80l; and work a whole day when the refiftance is but 40lb.

Men ufed to bear loads, fuch as porters, will carry, fome 150lb, others 200 or 250lb. according to their Strength.

A man can draw but about 70 or 80lb. horizontally; for he can but apply about half his weight.

If the weight of a man be 140lb, he can act with no greater a force in thrufting horizontally, at the height of his fhoulders, than 27lb.

As to Horfes: A horfe is, generally fpeaking, as ftrong as 5 men. A horfe will carry 240 or 270lb. A horfe draws to greateft advantage, when the line of direction is a little elevated above the horizon, and the power acts againft his breaft: and he can draw 200lb. for 8 hours a day, at $2\frac{1}{2}$ miles an hour. If he draw 240lb, he can work but 6 hours, and not go quite fo faft. And in both cafes, if he carries fome weight, he will draw the better for it. And this is the weight a horfe is fuppofed to be able to draw over a pulley out of a well. But in a cart, a horfe may draw 1000lb, or even double that weight, or a ton weight, or more.

As the moft force a horfe can exert, is when he draws a little above the horizontal pofition: fo the worft way of applying the ftrength of a horfe, is to make him carry or draw uphill: And three men in a fteep hill, carrying each 100lb, will climb up fafter than a horfe with 300l. Alfo, though a horfe may draw in a round walk of 18 feet diameter; yet fuch a walk fhould not be lefs than 25 or 30 feet diameter. Emerfon's Mechan. pa. 111 and 177.

STRIKE, or STRYKE, a meafure, containing 4 bufhels, or half a quarter.

STRIKING-*wheel*, in a clock, the fame as that by fome called the *pin wheel*, becaufe of the pins which are placed on the round or rim, the number of which is the quotient of the pinion divided by the pinion of the detent-wheel. In fixteen-day clocks, the firft or great wheel is ufually the pin-wheel; but in fuch as go 8 days, the fecond wheel is the pin-wheel, or ftriking-wheel.

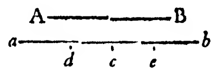
STRING, in Mufic. See CHORD.

If two Strings or chords of a mufical inftrument only differ in length; their tones, or the number of vibrations they make in the fame time, are in the inverfe ratio of their lengths. If they differ only in thicknefs, their tones are in the inverfe ratio of their diameters.

As to the tenfion of Strings, to meafure it regularly, they muft be conceived ftretched or drawn by weights; and then, cæteris paribus, the tones of two Strings are in a direct ratio of the fquare roots of the weights that ftretch them; that is, ex. gr. the tone of a String ftretched by a weight 4, is an octave above the tone of a String ftretched by the weight 1.

It is an obfervation of very old ftanding, that if a viol or lute-ftring be touched with the bow, or the hand, another String on the fame inftrument, or even on another, not far from it, if in unifon with it, or in octave, or the like, will at the fame time tremble of its

own accord. But it is now found, that it is not the whole of that other String that thus trembles, but only the parts, severally, according as they are unisons to the whole, or the parts, of the String so struck. Thus, supposing AB to be an upper octave to *ab*, and therefore an unison to each half of it, stopped at *c*; if while *ab* is open, AB be struck, the two halves of this other, that is, *ac*, and *cb*, will both tremble; but the middle point will be at rest; as will be easily perceived, by wrapping a bit of paper lightly about the string *ab*, and moving it successively from one end of the string to the other. In like manner, if AB were an upper 12th to *ab*, and consequently an unison to its three parts *ad*, *de*, *eb*; then, *ab* being open, if AB be struck, the three parts of the other, *ad*, *de*, *eb* will severally tremble; but the points *d* and *e* remain at rest.



This, Dr. Wallis tells us, was first discovered by Mr. William Noble of Merton college; and after him by Mr. T. Pigot of Wadham college, without knowing that Mr. Noble had observed it before. To which may be added, that M. Sauveur, long afterwards, proposed it to the Royal Academy at Paris, as his own discovery, which in reality it might be; but upon his being informed, by some of the members then present, that Dr. Wallis had published it before, he immediately resigned all the honour of it. Philos. Trans. Abridg. vol. I, pa. 606.

STURM, Sturmius (John Christopher), a noted German mathematician and philosopher, was born at Hippolstein in 1635. He became professor of philosophy and mathematics at Altdorf, where he died in 1703, at 68 years of age.

He was author of several useful works on mathematics and philosophy, the most esteemed of which are,

1. His *Mathesis enucleata*, in 1 vol. 8vo.

2. *Mathesis Juvenilis*, in 2 large volumes 8vo.

3. *Collegium Experimentale, sive Curiosum, in quo primaria Seculi superioris Inventa & Experimenta Physico-Mathematica, Speciatim Campanæ Urinatoriæ, Cameræ obscuræ, Tubi Torricelliani, seu Baroscopii, Antliæ Pneumaticæ, Thermometrorum Phænomena & Effecta; partim ac aliis jampridem exhibita, partim noviter istis superaddita, &c.* in one large vol. 4to, Norimberg, 1701.

This is a very curious work, containing a multitude of interesting experiments, neatly illustrated by copper-plate figures printed upon almost every page, by the side of the letter-press. Of these, the 10th experiment is an improvement on father Lana's project for navigating a small vessel suspended in the atmosphere by several globes exhausted of air.

STYLE, in Chronology, a particular manner of counting time; as the *Old Style*, the *New Style*. See Calendar.

Old Style, is the Julian manner of computing, as instituted by Julius Cæsar, in which the mean year consists of 365¼ days.

New Style, is the Gregorian manner of computation, instituted by pope Gregory the 13th, in the year 1582, and is used by most catholic countries, and many other states of Europe.

The Gregorian, or new Style, agrees with the true solar year, which contains only 365 days 5 hours 49 minutes. In the year of Christ 200, there was no difference of Styles. In the year 1582, when the new Style was first introduced, there was a difference of 10 days. At present there is 11 days difference, and accordingly at the diet of Ratisbon, in the year 1700, it was decreed by the body of protestants of the empire, that 11 days should be retrenched from the old Style, to accommodate it for the future to the new. And the same regulation has since passed into Sweden, Denmark, and into England, where it was established in the year 1752, when it was enacted, that in all dominions belonging to the crown of Great Britain, the supputation, according to which the year of our lord begins on the 25th day of March, shall not be used from and after the last day of December 1751; and that from thenceforth, the 1st day of January every year shall be reckoned to be the first day of the year: and that the natural day next immediately following the 2d day of September 1752, shall be accounted the 14th day of September, omitting the 11 intermediate nominal days of the common calendar. It is farther enacted, that all kinds of writings, &c, shall bear date according to the new method of computation, and that all courts and meetings &c, feasts, fasts, &c, shall be held and observed accordingly. And for preserving the calendar in the same regular course for the future, it is enacted, that the several years of our lord 1800, 1900, 2100, 2200, 2300, &c, except only every 400th year, of which the year 2000 shall be the first, shall be common years of 365 days, and that the years 2000, 2400, 2800, &c, and every other 400th year from the year 2000 inclusive, shall be leap years, consisting of 366 days. See Bissextile and Calendar.

The following table shews by what number of days the new style differs from the old, from 5900 years before the birth of Christ, to 5900 years after it. The days under the sign — (viz from 6000 years before to 200 years after Christ) are to be subtracted from the old Style, to reduce it to the new; and the days under the sign + (viz from 200 to 5900 years after Christ) are to be added to the old Style, to reduce it to the new.—N.B. All the years mentioned in the table are leap years in the old Style; but those only that are marked with an L are leap years in the new.

Years before Christ. New Style.	Days diff. —	Years after Christ. New Style.	Days diff. ∓

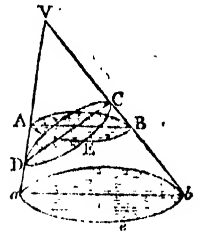
The French nation has lately commenced another new Style, or computation of time, viz, in the year 1792; according to which, the year commences usually on our 22d of September. The year is divided into 12 months of 30 days each; and each month into 3 decades of 10 days each. For the names and computations of which, see the article CALENDAR.

STYLE, in Dialling, *denotes the cock* or *gnomon*, raised above the plane of the dial, to project a Shadow.—The edge of the Style, which by its shadow marks the hours on the face of the dial, is to be set according to the latitude, always parallel to the axis of the world.

STYLOBATA, or STYLOBATON, in Architecture, the same with the pedestal of a column. It is sometimes taken for the trunk of the pedestal, between the cornice and the base, and is then called *truncus*. It is also otherwise named *abacus*.



SUBCONTRARY position, in Geometry, is when two equiangular triangles, as VAB and VCD are so placed as to have one common angle V at the vertex, and yet their bases not parallel. Consequently the angles at the bases are equal, but on the contrary sides; viz, the $\angle A = \angle C$, and the $\angle B = \angle D$.

If the oblique cone VAB or V*ab*, having the circular base AEB, or *aeb*, be so cut by a plane DEC, that the angle D be = the $\angle B$, or the $\angle C = \angle A$, then the cone is said to be cut, by this plane, in a Subcontrary position to the base AEB, or *aeb*; and in this case the section DEC is always a circle, as well as the base AEB or *aeb*.

SUBDUCTION, in Arithmetic, the same as Subtraction.

SUBDUPLE *Ratio*, is when any number or quantity is the half of another, or contained twice in it. Thus, 3 is said to be subduple of 6, as 3 is the half of 6, or is twice contained in it.

SUBDUPLICATE *Ratio*, of any two quantities, is the ratio of their square roots, being the opposite to duplicate ratio, which is the ratio of the squares. Thus, of the quantities, a and b, the subduplicate ratio is that of $\sqrt{a}$ to $\sqrt{b}$ or $a^{\frac{1}{2}}$ to $b^{\frac{1}{2}}$, as the duplicate ratio is that of a^2 to b^2.

SUBLIME *Geometry*, the higher geometry, or that of curve lines. See GEOMETRY.

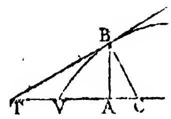
SUBLUNARY, is said of all things below the moon; as all things on the earth, or in its atmosphere, &c.

SUBMULTIPLE, the contrary of a multiple, being a number or quantity which is contained exactly a certain number of times in another of the same kind; or it is the same as an aliquot part of it. Thus, 3 is a Submultiple of 21, or an aliquot part of it, because 21 is a multiple of 3.

SUBMULTIPLE *Ratio*, is the ratio of a Submultiple or aliquot part, to its multiple; as the ratio of 3 to 21.

SUBNORMAL, in Geometry, is the subperpendicular AC, or line under the perpendicular to the curve BC, a term used in curve lines to denote the distance AC in the axis, between the ordinate AB, and the perpendicular

pendicular BC to the curve or to the tangent. And the said perpendicular BC is the normal.



In all curves, the Subnormal AC is a 3d proportional to the subtangent TA and the ordinate AB; and in the parabola, it is equal to half the parameter of the axis.

SUBSTITUTION, in Algebra, is the putting and using, in an equation, one quantity instead of another which is equal to it, but expressed after another manner. See REDUCTION of Equations.

SUBSTRACTION, or SUBTRACTION, in Arithmetic, is the taking of one number or quantity from another, to find the remainder or difference between them; and is usually made the second rule in arithmetic.

The greater number or quantity is called the *minuend*, the less is the *subtrahend*, and the *remainder* is the *difference*. Also the sign of Subtraction is −, or minus.

SUBTRACTION *of Whole Numbers*, is performed by setting the less number below the greater, as in addition, units under units, tens under tens, &c; and then, proceeding from the right hand towards the left, subtract or take each lower figure from that just above, and set down the several remainders or differences underneath; and these will compose the whole remainder or difference of the two given numbers. But when any one of the figures of the under number is greater than that of the upper, from which it is to be taken, you must add 10 (in your mind) to that upper figure, then take the under one from this sum, and set the difference underneath, carrying or adding 1 to the next under figure to be subtracted. Thus, for example, to subtract 2904821 from 37409732

Minuend	37409732
Subtrahend	2904821
Difference	34504911
Proof	37409732

To prove Subtraction: Add the remainder or difference to the less number, and the sum will be equal to the greater when the work is right.

SUBTRACTION *of Decimals*, is performed in the same manner as in whole numbers, by observing only to set the figures or places of the same kind under each other. Thus:

From	351·04	·479	27
Take	72·71	·0573	0·936
Diff.	278·33	·4217	26·064

To Subtract Vulgar Fractions. Reduce the two fractions to a common denominator, if they have different ones; then take the less numerator from the greater, and set the remainder over the common denominator, for the difference sought.—N. B. It is best to set the less fraction after the greater, with the sign (−) of subtraction between them, and the mark of equality (=) after them.

Thus, $\frac{7}{9} - \frac{2}{9} = \frac{5}{9}$.

And $\frac{4}{5} - \frac{2}{3} = \frac{12}{15} - \frac{10}{15} = \frac{2}{15}$.

SUBTRACTION, in Algebra, is performed by changing the signs of all the terms of the subtrahend, to their contrary signs, viz, + into −, and − into +; and then uniting the terms with those of the minuend after the manner of addition of Algebra.

Ex.	From	$+6a$
	Take	$+2a$
	Rem.	$6a - 2a = 4a$.
	From	$+6a$
	Take	$-2a$
	Rem.	$6a + 2a = 8a$.
	From	$-6a$
	Take	$+2a$
	Rem.	$-6a - 2a = -8a$.
	From	$-6a$
	Take	$-4a$
	Rem.	$-6a + 4a = -2a$.
	From	$2a - 3x + 5z - 6$
	Take	$6a + 4x + 5z + 4$
	Rem.	$-4a - 7x \quad 0 - 10$

SUBSTILE, or SUBSTILAR *Line*, in Dialling, a right line upon which the stile or gnomon of a dial is erected, being the common section of the face of the dial and a plane perpendicular to it passing through the stile.

The angle included between this line and the stile, is called the elevation or height of the stile.

In polar, horizontal, meridional, and northern dials, the Substilar line is the meridional line, or line of 12 o'clock; or the intersection of the plane of the dial with that of the meridian.—In all declining dials, the Substile makes an angle with the hour line of 12, and this angle is called the distance of the Substile from the meridian.—In easterly and westerly dials, the substilar line is the line of 6 o'clock, or the intersection of the dial plane with the prime vertical.

SUBSUPERPARTICULAR. } See RATIO.
SUBSUPERPARTICUS. }

SUBTANGENT *of a curve*, is the line TA in the axis below the tangent TB, or limited between the tangent and ordinate to the point of contact. (See the last figure above).

The tangent, subtangent, and ordinate, make a right-angled triangle.

In all paraboliform and hyperboliform figures, the Subtangent is equal to the abscis multiplied by the exponent of the power of the ordinate in the equation of the curve. Thus, in the common parabola, whose property or equation is $px = y^2$, the Subtangent is equal to $2x$, double the abscis. And if $ax^2 = y^3$, or $px =$

$px = y^2$, then the Subtangent is $= \frac{1}{2}x$. Also if $a^m x^n = y^{m+n}$, or $px = y^{\frac{m+n}{n}}$, the Subtangent is $= \frac{m+n}{n}x$. See *Method of* TANGENTS.

SUBTENSE, in Geometry, of an arc, is the same as the chord of the arc; but of an angle, it is a line drawn across from the one leg of the angle to the other, or between the two extremes of the arc that measures the angle.

SUBTRACTION. See SUBSTRACTION.

SUBTRIPLE, is when one quantity is the 3d part of another; as 2 is Subtriple of 6. And SUBTRIPLE *Ratio*, is the ratio of 1 to 3.

SUBTRIPLICATE *Ratio*, is the ratio of the cube roots. So the Subtriplicate ratio of a to b, is the ratio of $\sqrt[3]{a}$ to $\sqrt[3]{b}$, or of $a^{\frac{1}{3}}$ to $b^{\frac{1}{3}}$.

SUCCESSION *of Signs*, in Astronomy, is the order in which they are reckoned, or follow one another, and according to which the sun enters them; called also *consequentia*. As Aries, Taurus, Gemini, Cancer, &c.

When a planet goes according to the order and succession of the signs, or *in consequentia*, it is said to be direct; but retrograde when contrary to the succession of the signs, or *in antecedentia*, as from Gemini to Taurus, then to Aries, &c.

SUCCULA, in Mechanics, a bare axis or cylinder with staves in it to move it round; but without any tympanum, or peritrochium.

SUCKER, in Mechanics, a name by which sometimes is called the piston or bucket, in a sucking pump; and sometimes the pump itself is so called.

SUCKING-*Pump*, the common pump, working by two valves opening upwards. See PUMP.

SUMMER, the name of one of the seasons of the year, being one of the quarters when the year is divided into 4 quarters, or one half when the year is divided only into two, Summer and winter. In the former case, Summer is the quarter during which, in northern climates, the sun is passing through the three signs Cancer, Leo, Virgo, or from the time of the greatest declination, till the sun come to the equinoctial again, or have no declination; which is from about the 21st of June, till about the 22d of September. In the latter case, Summer contains the 6 warmer months, while the sun is on one side of the equinoctial; and winter the other 6 months, when the sun is on the other side of it.

It is said, that a frosty winter produces a dry Summer; and a mild winter, a wet Summer. See Philos. Trans. no. 458, sect. 10.

SUMMER *Solstice*, the time or point when the sun comes to his greatest declination, and nearest the zenith of the place. See SOLSTICE.

SUM, the quantity produced by addition, or by adding two or more numbers or quantities together. So the Sum of 6 and 4 is 10, and the Sum of a and b is $a + b$.

SUN, SOL, ☉, in Astronomy, the great luminary which enlightens the world, and by his presence constitutes day.

The Sun, which was reckoned among the planets in the infancy of astronomy, should rather be counted among the fixed stars. He only appears brighter and larger than they do, because we keep constantly near the Sun; whereas we are immensely farther from the stars. But a spectator, placed as near to any star as we are to the Sun, would probably see that star a body as large and as bright as the Sun appears to us; and, on the other hand, a spectator as far distant from the Sun as we are from the stars, would see the Sun as small as we see a star, divested of all his circumvolving planets; and he would reckon it one of the stars in numbering them.

According to the Pythagorean and Copernican hypothesis, which is now generally received, and has been demonstrated to be the true system, the Sun is the common centre of all the planetary and cometary system; around which all the planets and comets, and our earth among the rest, revolve, in different periods, according to their different distances from the Sun.

But the Sun, though thus eased of that prodigious motion by which the Ancients imagined he revolved daily round our earth, yet is he not a perfectly quiescent body. For, from the phenomena of his maculæ or spots, it evidently appears, that he has a rotation round his axis, like that of the earth by which our natural day is measured, but only slower. For, some of these spots have made their first appearance near the edge or margin of the Sun, from thence they have seemed gradually to pass over the Sun's face to the opposite edge, then disappear; and hence, after an absence of about 14 days, they have reappeared in their first place, and have taken the same course over again; finishing their entire circuit in 27 days 12^h 20^m; which is hence inferred to be the period of the Sun's rotation round his axis: and therefore the periodical time of the Sun's revolution to a fixed star is 25^d 15^h 16^m; because in 27^d 12^h 20^m of the month of May, when the observations were made, the earth describes an angle about the Sun's centre of $26° 22'$, and therefore as the angular motion

$$360° + 26° 22' : 360° :: 27^d 12^h 20^m : 25^d 15^h 16^m.$$

This motion of the spots is from west to east: whence we conclude the motion of the Sun, to which the other is owing, to be from east to west.

Beside this motion round his axis, the Sun, on account of the various attractions of the surrounding planets, is agitated by a small motion round the centre of gravity of the system.—Whether the Sun and stars have any proper motion of their own in the immensity of space, however small, is not absolutely certain. Though some very accurate observers have intimated conjectures of this kind, and have made such a general motion not improbable. See STARS.

As for the apparent annual motion of the SUN *round the earth*; it is easily shewn, by astronomers, that the real annual motion of the earth, about the Sun, will cause such an appearance. A spectator in the Sun would see the earth move from west to east, for the same reason as we see the Sun move from east to west: and all the phenomena resulting from this annual motion in whichsoever of the bodies it be, will appear the same from

from either. And hence arises that apparent motion of the Sun, by which he is seen to advance insensibly towards the eastern stars; in so much that, if any star, near the ecliptic, rise at any time with the Sun; after a few days the Sun will be got more to the east of the star, and the star will rise and set before him

Nature, Properties, Figure, &c, of the SUN.

Those who have maintained that the substance of the Sun is fire, argue in the following manner: The Sun shines, and his rays, collected by concave mirrors, or convex lenses, do burn, consume, and melt the most solid bodies, or else convert them into ashes, or glass: therefore, as the force of the solar rays is diminished, by their divergency, in a duplicate ratio of the distances reciprocally taken; it is evident that their force and effect are the same, when collected by a burning lens, or mirror, as if we were at such distance from the sun, where they were equally dense. The Sun's rays therefore, in the neighbourhood of the Sun, produce the same effects, as might be expected from the most vehement fire: consequently the Sun is of a fiery substance.

Hence it follows, that its surface is probably every where fluid; that being the condition of flame. Indeed, whether the whole body of the Sun be fluid, as some think; or solid, as others; they do not presume to determine: but as there are no other marks, by which to distinguish fire from other bodies, but light, heat, a power of burning, consuming, melting, calcining, and vitrifying; they do not see what should hinder but that the Sun may be a globe of fire, like our fires, invested with flame: and, supposing that the maculæ are formed out of the solar exhalations, they infer that the Sun is not pure fire; but that there are heterogeneous parts mixed along with it.

Philosophers have been much divided in opinion with respect to the nature of fire, light, and heat, and the causes that produce them: and they have given very different accounts of the agency of the Sun, with which, whether we consider them as substances or qualities, they are intimately connected, and on which they seem primarily to depend. Some, among whom we may reckon Sir Isaac Newton, consider the rays of light as composed of small particles, which are emitted from shining bodies, and move with uniform velocities in uniform mediums, but with variable velocities in mediums of variable densities. These particles, say they, act upon the minute constituent parts of bodies, not by impact, but at some indefinitely small distance; they attract and are attracted; and in being reflected or refracted, they excite a vibratory motion in the component particles. This motion increases the distance between the particles, and thus occasions an augmentation of bulk, or an expansion in every dimension, which is the most certain characteristic of fire. This expansion, which is the beginning of a disunion of the parts, being increased by the increasing magnitude of the vibrations proceeding from the continued agency of light, it may easily be apprehended, that the particles will at length vibrate beyond their sphere of mutual attraction, and thus the texture of the body will be altered or destroyed; from solid it may become fluid, as in melted gold; or from being fluid, it may be dispersed in vapour, as in boiling water.

Others, as Boerhaave, represent fire as a substance *sui generis*, unalterable in its nature, and incapable of being produced or destroyed; naturally existing in equal quantities in all places, imperceptible to our senses, and only discoverable by its effects, when, by various causes, it is collected for a time into a less space than that which it would otherwise occupy. The matter of this fire is not in any wise supposed to be derived from the Sun: the solar rays, whether direct or reflected, are of use only as they impel the particles of fire in parallel directions: that parallelism being destroyed, by intercepting the solar rays, the fire instantly assumes its natural state of uniform diffusion. According to this explication, which attributes heat to the matter of fire, when driven in parallel directions, a much greater degree must be given it when the quantity, so collected, is amassed into a focus; and yet the focus of the largest speculum does not heat the air or medium in which it is is found, but only bodies of densities different from that medium.

M de Luc (Lettres Physiques) is of opinion, that the solar rays are the principal cause of heat; but that they heat such bodies only as do not allow them a free passage. In this remark he agrees with Newton; but then he differs totally from him, as well as from Boerhaave, concerning the nature of the rays of the Sun. He does not admit the emanation of any luminous corpuscles from the Sun, or other self-shining substances, but supposes all space to be filled with an ether of great elasticity and small density, and that light consists in the vibrations of this ether, as sound consists in the vibrations of the air. "Upon Newton's supposition, says an excellent writer, the cause by which the particles of light, and the corpuscles constituting other bodies are mutually attracted and repelled, is uncertain. The reason of the uniform diffusion of fire, of its vibration, and repercussion, as stated in Boerhaave's opinion, is equally inexplicable. And in the last mentioned hypothesis, we may add to the other difficulties attending the supposition of an universal ether, the want of a first mover to make the Sun vibrate. Of these several opinions concerning elementary fire, it may be said, as Cicero remarked upon the opinions of philosophers concerning the nature of the soul: *Harum sententiarum quæ vera sit, Deus aliquis viderit; quæ verisimillima, magna questio est.*" Watson's Chem. Ess. vol. 1, pa. 164.

As to the Figure of the SUN; this, like the planets, is not perfectly globular, but spheroidical, being higher about the equator than at the poles. The reason of which is this: the Sun has a motion about his own axis; and therefore the solar matter will have an endeavour to recede from the axis, and that with the greater force as their distances from it, or the circles they move in, are greater: but the equator is the greatest circle; and the rest, towards the poles, continually decrease; therefore the solar matter, though at first in a spherical form, will endeavour to recede from the centre of the equator farther than from the centres of the parallels. Consequently, since the gravity, by which it is retained in its place, is supposed to be uniform throughout the whole Sun, it will really recede from the centre more at the

the equator, than at any of the parallels; and hence the Sun's diameter will be greater through the equator, than through the poles; that is, the Sun's figure is not perfectly spherical, but spheroidical.

Several particulars of the Sun, related by Newton, in his Principia, are as follow:

1. That the density of the Sun's heat, which is proportional to his light, is 7 times as great at Mercury as with us; and therefore our water there would be all carried off, and boil away: for he found by experiments of the thermometer, that a heat but 7 times greater than that of the Sun beams in summer, will serve to make water boil.

2. That the quantity of matter in the Sun is to that in Jupiter, nearly as 1100 to 1; and that the distance of that planet from the Sun, is in the same ratio to the Sun's semidiameter.

3. That the matter in the Sun is to that in Saturn, as 2360 to 1; and the distance of Saturn from the Sun is in a ratio but little less than that of the Sun's semidiameter. And hence, that the common centre of gravity of the Sun and Jupiter is nearly in the superficies of the Sun; of the Sun and Saturn, a little within it.

4. And by the same mode of calculation it will be found, that the common centre of gravity of all the planets, cannot be more than the length of the solar diameter distant from the centre of the Sun. This common centre of gravity he proves is at rest; and therefore though the Sun, by reason of the various positions of the planets, may be moved every way, yet it cannot recede far from the common centre of gravity, and this, he thinks, ought to be accounted the centre of our world. Book 3, prop. 12.

5. By means of the solar spots it hath been discovered, that the Sun revolves round his own axis, without moving considerably out of his place, in about 25 days, and that the axis of this motion is inclined to the ecliptic in an angle of 87° 30′ nearly. The Sun's apparent diameter being sensibly longer in December than in June, the Sun must be proportionably nearer to the earth in winter than in Summer; in the former of which seasons therefore will be the perihelion, in the latter the aphelion: and this is also confirmed by the earth's motion being quicker in December than in June, as it is by about $\frac{1}{15}$ part. For since the earth always describes equal areas in equal times, whenever it moves swifter, it must needs be nearer to the Sun: and for this reason there are about 8 days more from the sun's vernal equinox to the autumnal, than from the autumnal to the vernal.

6. That the Sun's diameter is equal to 100 diameters of the earth; and therefore the body of the Sun must be 1000000 times greater than that of the earth.—Mr. Azout assures us, that he observed, by a very exact method, the Sun's diameter to be no less than 31′ 45″ in his apogee, and not greater than 32′ 45″ in his perigee.

7. According to Newton, in his theory of the moon, the mean apparent diameter of the Sun is 32′ 12″.—The Sun's horizontal parallax is now fixed at 8″$\frac{6}{10}$.

8. If you divide 360 degrees (the whole ecliptic) by the quantity of the solar year, it will give 59′ 8″ &c, which therefore is the medium quantity of the Sun's daily motion: and if this 59′ 8″ be divided by 24, you have the Sun's horary motion equal to 2′ 28″: and if this last be divided by 60, it will give his motion in a minute, &c. And in this way are the tables of the Sun's mean motion constructed, as placed in books of Astronomical tables and calculations.

SUNDAY, the first day of the week; thus called by our idolatrous ancestors, because set apart for the worship of the sun.

It is sometimes called the *Lord's Day*, because kept as a feast in memory of our Lord's resurrection on this day: and also *Sabbath-day*, because substituted under the new law instead of the Sabbath in the old law.

It was Constantine the Great who first made a law for the proper observation of Sunday; and who, according to Eusebius, appointed that it should be regularly celebrated throughout the Roman empire.

SUNDAY *Letter*. See DOMINICAL *Letter*.

SUPERFICIAL, relating to Superficies.

SUPERFICIES, or SURFACE, in Geometry, the outside or exterior face of any body. This is considered as having the two dimensions of length and breadth only, but no thickness; and therefore it makes no part of the substance or solid content or matter of the body.

The terms or bounds or extremities of a Superficies, are lines; and Superficies may be considered as generated by the motions of lines.

Superficies are either rectilinear, curvilinear, plane, concave, or convex. A

Rectilinear SUPERFICIES, is that which is bounded by right lines.

Curvilinear SUPERFICIES, is bounded by curve lines.

Plane SUPERFICIES is that which has no inequality in it, nor risings, nor sinkings, but lies evenly and straight throughout, so that a right line may wholly coincide with it in all parts and directions.

Convex SUPERFICIES, is that which is curved and rises outwards.

Concave SUPERFICIES, is curved and sinks inward.

The measure or quantity of a Surface, is called the *area* of it. And the finding of this measure or area, is sometimes called the *quadrature* of it, meaning the reducing it to an equal square, or to a certain number of smaller squares. For all plane figures, and the Surfaces of all bodies, are measured by squares; as square inches, or square feet, or square yards, &c; that is, squares whose sides are inches, or feet, or yards, &c. Our least superficial measure is the square inch, and other squares are taken from it according to the proportion in the following Table of superficial or square measure.

Table of Superficial or Square Measure.

144	square inches	=	1 square foot
9	square feet	=	1 square yard
30¼	square yards	=	1 square pole
16	square poles	=	1 square chain
10	square chains	=	1 acre
640	acres - -	=	1 square mile.

The Superficial measure of all bodies and figures depends entirely on that of a rectangle; and this is found by drawing or multiplying the length by the breadth of it;

it; as is proved from plane geometry only, in my Mensuration, pt. 2, sect. 1, prob. 1. From the area of the rectangle we obtain that of any oblique parallelogram, which, by geometry, is equal to a rectangle of equal base and altitude; thence a triangle, which is the half of such a parallelogram or rectangle; and hence, by composition, we obtain the Superficies of all other figures whatever, as these may be considered as made up of triangles only.

Beside this way of deriving the Superficies of all figures, which is the most simple and natural, as proceeding on common geometry alone, there are certain other methods; such as the methods of exhaustions, of fluxions, &c. See these articles in their places, as also QUADRATURES.

Line of SUPERFICIES, a line usually found on the sector, and Gunter's scale. The description and use of which, see under SECTOR and GUNTER'S *Scale*.

SUPERPARTICULAR *Proportion*, or *Ratio*, is that in which the greater term exceeds the less by unit or 1. As the ratio of 1 to 2, or 2 to 3, or 3 to 4, &c.

SUPERPARTIENT *Proportion*, or *Ratio*, is when the greater term contains the less term, once, and leaves some number greater than 1 remaining. As the ratio

of 3 to 5, which is equal to that of 1 to $1\frac{2}{3}$;
of 7 to 10, which is equal to that of 1 to $1\frac{3}{7}$; &c.

SUPPLEMENT, of an arch, or angle, in Geometry or Trigonometry, is what it wants of a semicircle, or of 180 degrees; as the *complement* is what it wants of a quadrant, or of 90 degrees. So, the Supplement of 50° is 130°; as the complement of it is 40°.

SURD, in Arithmetic, denotes a number or quantity that is incommensurate to unity; or that is inexpressible in rational numbers by any known way of notation, otherwise than by its radical sign or index.—This is otherwise called an *irrational* or *incommensurable number*, as also an *imperfect power*.

These Surds arise in this manner: when it is proposed to extract a certain root of some number or quantity, which is not a complete power or a true figurate number of that kind; as, if its square root be demanded, and it is not a true square; or if its cube root be required, and it is not a true cube, &c; then it is impossible to assign, either in whole numbers, or in fractions, the exact root of such proposed number. And whenever this happens, it is usual to denote the root by setting before it the proper mark of radicality, which is $\surd$, and placing above this radical sign the number that shews what kind of root is required. Thus, $\sqrt[2]{2}$ or $\sqrt{2}$ signifies the square root of 2, and $\sqrt[3]{10}$ signifies the cube root of 10; which roots, because it is impossible to express them in numbers exactly, are properly called *Surd roots*.

There is also another way of notation, now much in use, by which roots are expressed by fractional indices, without the radical sign: thus, like as x^2, x^3, x^4, &c, denote the square, cube, 4th power, &c, of x; so $x^{\frac{1}{2}}, x^{\frac{1}{3}}, x^{\frac{1}{4}}$, &c, denote the square root, cube root, 4th root, &c, of the same quantity x.—The reason of this is plain enough; for since $\sqrt{x}$ is a geometrical mean proportional between 1 and x, so $\frac{1}{2}$ is an arithmetical mean between 0 and 1; and therefore, as 2 is the index of the square of x, $\frac{1}{2}$ will be the proper index of its square root, &c.

It may be observed that, for convenience, or the sake of brevity, quantities which are not naturally Surds, are often expressed in the form of Surd roots. Thus $\sqrt{4}$, $\sqrt{\frac{9}{4}}$, $\sqrt[3]{27}$, are the same as 2, $\frac{3}{2}$, 3.

Surds are either *simple* or *compound*.

Simple SURDS, are such as are expressed by one single term; as $\sqrt{2}$, or $\sqrt[3]{a}$, &c.

Compound SURDS, are such as consist of two or more simple Surds connected together by the signs + or −; as $\sqrt{3} + \sqrt{2}$, or $\sqrt{3} - \sqrt{2}$, or $\sqrt[3]{5 + \sqrt{2}}$: which last is called an *universal* root, and denotes the cubic root of the sum arising by adding 5 and the root of 2 together.

Of certain Operations by Surds.

1. Such Surds as $\sqrt{2}$, $\sqrt{3}$, $\sqrt{5}$, &c. though they are themselves incommensurable with unity, according to the definition, are commensurable in power with it, because their powers are integers, which are multiples of unity. They may also be sometimes commensurable with one another; as $\sqrt{8}$ and $\sqrt{2}$, which are to one another as 2 to 1, as is found by dividing them by their greatest common measure, which is $\sqrt{2}$, for then those two become $\sqrt{4} = 2$, and 1 the ratio.

2. *To reduce Rational Quantities to the form of any proposed Surd Roots.*—Involve the rational quantity according to the index of the power of the Surd, and then prefix before that power the proposed radical sign.

Thus, $a = \sqrt{a^2} = \sqrt[3]{a^3} = \sqrt[4]{a^4} = \sqrt[n]{a^n}$, &c.
and $4 = \sqrt{16} = \sqrt[3]{64} = \sqrt[4]{256} = \sqrt[n]{4^n}$, &c.

And in this way may a simple Surd fraction, whose radical sign refers to only one of its terms, be changed into another, which shall include both numerator and denominator. Thus, $\frac{\sqrt{2}}{5}$ is reduced to $\sqrt{\frac{2}{25}}$, and $\frac{5}{\sqrt[3]{4}}$ to $\sqrt[3]{\frac{125}{4}}$: thus also the quantity a reduced to the form of $x^{\frac{1}{n}}$ or $\sqrt[n]{x}$, is $\overline{a^n}|^{\frac{1}{n}}$ or $\sqrt[n]{a^n}$. And thus may roots with rational coefficients be reduced so as to be wholly affected by the radical sign; as $a\sqrt[n]{x} = \sqrt[n]{a^n x}$.

3. *To reduce Simple Surds, having different radical signs (which are called heterogeneal Surds) to others that may have one common radical sign, or which are homogeneal: Or to reduce roots of different names to roots of the same name.*—Involve the powers reciprocally, each according to the index of the other, for new powers; and multiply their indices together, for the common index. Otherwise, as Surds may be considered as powers with fractional exponents, reduce these fractional exponents to fractions having the same value and a common denominator.

Thus, by the 1st way,

$\sqrt[n]{a}$ and $\sqrt[m]{x}$ become $\sqrt[mn]{a^m}$ and $\sqrt[mn]{x^n}$;

and,

and, by the 2d way,

$a^{\frac{1}{n}}$ and $x^{\frac{1}{m}}$ become $\overline{a^m}|^{\frac{1}{mn}}$ and $\overline{x^n}|^{\frac{1}{mn}}$.

Also $\sqrt{3}$ and $\sqrt[3]{2}$ are reduced to $\sqrt[6]{27}$ and $\sqrt[6]{4}$, which are equal to them, and have a common radical sign.

4. *To reduce Surds to their most simple expressions, or to the lowest terms possible.*—Divide the Surd by the greatest power, of the same name with that of the root, which you can discover is contained in it, and which will measure or divide it without a remainder; then extract the root of that power, and place it before the quotient or Surd so divided; this will produce a new Surd of the same value with the former, but in more simple terms. Thus, $\sqrt{16a^2x}$, by dividing by $16a^2$, and prefixing its root $4a$, before the quotient $\sqrt{x}$, becomes $4a\sqrt{x}$; in like manner, $\sqrt{12}$ or $\sqrt{4 \times 3}$, becomes $2\sqrt{3}$;

And $\sqrt[3]{ab^3x}$ reduces to $b\sqrt[3]{ax}$.

Also $\sqrt[3]{81} = \sqrt[3]{27 \times 3} = \sqrt[3]{3^3 \times 3} = 3\sqrt[3]{3}$.

And $\sqrt{288} = \sqrt{144 \times 2} = 12\sqrt{2}$.

5. *To Add and Subtract Surds.*—When they are reduced to their lowest terms, if they have the same irrational part, add or subtract their rational coefficients, and to the sum or difference subjoin the common irrational part.

Thus, $\sqrt{75} + \sqrt{48} = 5\sqrt{3} + 4\sqrt{3} = 9\sqrt{3}$;
and $\sqrt{150} - \sqrt{54} = 5\sqrt{6} - 3\sqrt{6} = 2\sqrt{6}$;
also $\sqrt{a^2x} + \sqrt{c^2x} = a\sqrt{x} + c\sqrt{x} = \overline{a+c}.\sqrt{x}$.

Or such Surds may be added and subtracted, by first squaring them (by uniting the square of each part with double their product), and then extracting the root universal of the whole. Thus, for the first example above,

$$\sqrt{75} + \sqrt{48} = \sqrt{75 + 48 + 2\sqrt{75 \times 48}} = \sqrt{123 + 2\sqrt{3600}} = \sqrt{123 + 120} = \sqrt{243} = 9\sqrt{3}.$$

If the quantities cannot be reduced to the same irrational part, they may just be connected by the signs $+$ or $-$.

6. *To Multiply and Divide Surds.*—If the terms have the same radical, they will be multiplied and divided like powers, viz, by adding their indices for multiplication, and subtracting them for division.

Thus,

$\sqrt{a} \times \sqrt[3]{a} = a^{\frac{1}{2}} \times a^{\frac{1}{3}} = a^{\frac{3}{6}} \times a^{\frac{2}{6}} = a^{\frac{5}{6}} = \sqrt[6]{a^5}$;

and $\sqrt{2} \times \sqrt[3]{2} = 2^{\frac{5}{6}} = \sqrt[6]{2^5} = \sqrt[6]{32}$;

also $\sqrt{a} \div \sqrt[3]{a} = a^{\frac{1}{2}} \div a^{\frac{1}{3}} = a^{\frac{1}{6}} = \sqrt[6]{a}$;

and $\sqrt{2} \div \sqrt[3]{2} = 2^{\frac{1}{6}} = \sqrt[6]{2}$.

If the quantities be different, but under the same radical sign; multiply or divide the quantities, and place the radical sign to the product or quotient.

Thus, $\sqrt{2} \times \sqrt{5} = \sqrt{10}$;
and $\sqrt[3]{a^2} \times \sqrt[3]{c} = \sqrt[3]{a^2c}$;
also $\sqrt[3]{20} \div \sqrt[3]{4} = \sqrt[3]{5}$.

But if the Surds have not the same radical sign, reduce them to such as shall have the same radical sign, and proceed as before.

Thus, $\sqrt[m]{a} \times \sqrt[n]{b} = \sqrt[mn]{a^n} \times \sqrt[mn]{b^m} = \sqrt[mn]{a^nb^m}$;
and $\sqrt{2} \times \sqrt[3]{4} = \sqrt[6]{2^3} \times \sqrt[6]{4^2} = \sqrt[6]{8 \times 16} = \sqrt[6]{128}$.

If the Surds have any rational coefficients, their product or quotient must be prefixed.

Thus, $5\sqrt{6} \times 2\sqrt{3} = 10\sqrt{18} = 30\sqrt{2}$;
and $8\sqrt{5} \div 2\sqrt{6} = 4\sqrt{\tfrac{5}{6}}$.

7. *Involution and Evolution of Surds.*——Surds are involved, or raised to any power, by multiplying their indices by the index of the power; and they are evolved or extracted, by dividing their indices by the index of the root.

Thus, the square of $\sqrt[3]{2}$ or of $2^{\frac{1}{3}}$, is $2^{\frac{2}{3}} = \sqrt[3]{4}$;

and the cube of $\sqrt{5}$ or of $5^{\frac{1}{2}}$, is $5^{\frac{3}{2}} = \sqrt{125}$;

also the square root of $\sqrt[3]{4}$ or $4^{\frac{1}{3}}$, is $4^{\frac{1}{6}} = 2^{\frac{1}{3}} = \sqrt[3]{2}$.

Or thus: involve or extract the quantity under the radical sign according to the power or root required, continuing the same radical sign.

So the square of $\sqrt[3]{2}$ is $\sqrt[3]{4}$;
and the square root of $\sqrt[3]{4}$, is $\sqrt[3]{2}$.

Unless the index of the power is equal to the name of the Surd, or a multiple of it, for in that case the power of the Surd becomes rational. Thus, the square of $\sqrt{3}$ is 3, and the cube of $\sqrt[3]{a^2}$ is a^2.

Simple Surds are commensurable in power, and by being multiplied by themselves give, at length, rational quantities: but compound Surds, multiplied by themselves, commonly give irrational products. Yet, in this case, when any compound Surd is proposed, there is another compound Surd, which, multiplied by it, gives a rational product.

Thus, $\sqrt{a} + \sqrt{b}$ multiplied by $\sqrt{a} - \sqrt{b}$ gives $a - b$;
and $\sqrt[3]{a} - \sqrt[3]{b}$ mult. by $\sqrt[3]{a^2} + \sqrt[3]{ab} + \sqrt[3]{b^2}$ gives $a - b$.

The finding of such a Surd as multiplying the proposed Surd gives a rational product, is made easy by three theorems, delivered by Maclaurin, in his Algebra, pa. 109 &c.

This operation is of use in reducing Surd expressions to more simple forms. Thus, suppose a binomial Surd divided by another, as $\sqrt{20} + \sqrt{12}$ by $\sqrt{5} - \sqrt{3}$, the quotient might be expressed by

$\dfrac{\sqrt{20} + \sqrt{12}}{\sqrt{5} - \sqrt{3}} = \dfrac{2\sqrt{5} + 2\sqrt{3}}{\sqrt{5} - \sqrt{3}}$; but this will be expressed in a more simple form, by multiplying both numerator and denominator by such a Surd as makes the product of the denominator become a rational quantity: thus, multiplying them by $\sqrt{5} + \sqrt{3}$, the fraction or quotient becomes

$$2 \times \frac{\sqrt{5} + \sqrt{3}}{\sqrt{5} - \sqrt{3}} \times \frac{\sqrt{5} + \sqrt{3}}{\sqrt{5} + \sqrt{3}} = 2 \times \frac{\overline{\sqrt{5} + \sqrt{3}}|^2}{5 - 3 = 2} = \overline{\sqrt{5} + \sqrt{3}}|^2 = 8 + 2\sqrt{15}.$$

To do this generally, see Maclaurin's Alg. p. 113.

When the square root of a Surd is required, it may be found nearly, by extracting the root of a rational quantity that approximates to its value. Thus, to find the square

square root of $3 + 2\sqrt{2}$; first calculate $\sqrt{2} = 1{\cdot}41421$; hence $3 + 2\sqrt{2} = 5{\cdot}82842$, the root of which is nearly $2{\cdot}41421$.

In like manner we may proceed with any other proposed root. And if the index of the root be very high, a table of logarithms may be used to advantage: thus, to extract the root $\sqrt[7]{5 + \sqrt[13]{17}}$; take the logarithm of 17, divide it by 13, find the number answering to the quotient, add this number to 5, find the log. of the sum, and divide it by 7, and the number answering to this quotient will be nearly equal to $\sqrt[7]{5 + \sqrt[13]{17}}$.

But it is sometimes requisite to express the roots of Surds exactly by other Surds. Thus, in the first example, the square root of $3 + 2\sqrt{2}$ is $1 + \sqrt{2}$, for $\overline{1 + \sqrt{2}}^2 = 1 + 2\sqrt{2} + 2 = 3 + \sqrt{2}$. For the method of performing this, the curious may consult Maclaurin's Algeb. p. 115, where also rules for trinomials &c may be found. See also the article BINOMIAL *Roots*, in this Dictionary.

For extracting the higher roots of a binomial, whose two members when squared are commensurable numbers, we have a rule in Newton's Arith. pa. 59, but without demonstration. This is supplied by Maclaurin, in his Alg. p. 120: as also by Gravesande, in his Matheseos Univers. Elem. p. 211.

It sometimes happens, in the resolution of cubic equations, that binomials of this form $a \pm b\sqrt{-1}$ occur, the cube roots of which must be found; and to these Newton's rule cannot always be applied, because of the impossible or imaginary factor $\sqrt{-1}$; yet if the root be expressible in rational numbers, the rule will often yield to it in a short way, not merely tentative, the trials being confined to known limits. See Maclaurin's Alg. p. 127. It may be farther observed, that such roots, whether expressible in rational numbers or not, may be found by evolving the quantity $a + b\sqrt{-1}$ by Newton's binomial theorem, and summing up the alternate terms. Maclaurin, p. 130.

Those who are desirous of a general and elegant solution of the problem, *to extract any root of an impossible binomial* $a + b\sqrt{-1}$, *or of a possible binomial* $a + \sqrt{b}$, may have recourse to the appendix to Saunderson's Algebra, and to the Philos. Trans. number 451, or Abridg. vol. 8, p. 1. On the management of Surds, see also the numerous authors upon Algebra.

SURDESOLID. See SURSOLID.

SURFACE, in Geometry. See SUPERFICIES.

A *mathematical* SURFACE is the mere exterior face of a body, but is not any part of it, being of no thickness, but only the bare figure or termination of the body.

A *Physical* SURFACE is considered as of some very small thickness.

SURSOLID, or SURDESOLID, in Arithmetic, the 5th power of a number, considered as a root. The number 2, for instance, considered as a root, produces the powers thus:

$2 \quad = 2$ the root or 1st power,
$2 \times 2 = 4$ the square or 2d power,
$2 \times 4 = 8$ the cube or 3d power,
$2 \times 8 = 16$ the biquadratic or 4th power,
$2 \times 16 = 32$ the Sursolid or 5th power.

SURSOLID PROBLEM, is that which cannot be resolved but by curves of a higher kind than the conic sections.

SURVEYING, the art, or act, of measuring land. This comprises the three following parts; viz, taking the dimensions of any tract or piece of ground; the delineating or laying the same down in a map or draught; and finding the superficial content or area of the same; beside the dividing and laying out of lands.

The first of these is what is properly called *Surveying*; the second is called *plotting*, or *protracting*, or *mapping*; and the third *casting up*, or *computing the contents*.

The first again consists of two parts, the making of observations for the angles, and the taking of lineal measures for the distances.

The former of these is performed by some of the following instruments; the theodolite, circumferentor, semicircle, plain-table, or compass, or even by the chain itself: the latter is performed by means either of the chain, or the perambulator. The description and manner of using each of these, see under its respective article or name.

It is useful in Surveying, to take the angles which the bounding lines form with the magnetic needle, in order to check the angles of the figure, and to plot them conveniently afterwards. But, as the difference between the true and magnetic meridian perpetually varies in all places, and at all times; it is impossible to compare two surveys of the same place, taken at distant times, by magnetic instruments, without making due allowance for this variation. See observations on this subject, by Mr. Molineux, Philos. Trans. number 230, p. 625, or Abr. vol. 1, p. 125.

The second branch of Surveying is performed by means of the protractor, and plotting scale. The description of which, see under their proper names.

If the lands in the survey are hilly, and not in any one plane, the measured lines cannot be truly laid down on paper, till they are reduced to one plane, which must be the horizontal one, because angles are taken in that plane. And in this case, when observing distant objects, for their elevation or depression, the following table shews the links or parts to be subtracted from each chain in the hypothenusal line, when the angle is the corresponding number of degrees.

A TABLE *of the links to be subtracted out of every chain in hypothenusal lines, of several degrees of altitude or depression, for reducing them to horizontal.*

		links			links
4°	3′	¼	19°	57′	6
5	44	½	21	34	7
7	1	¾	23	4	8
8	7	1	24	30	9
11	29	2	24	50	10
14	4	3	27	8	11
16	16	4	28	22	12
18	12	5	29	32	13

For

For example, if a station line measure 1250 links, or $12\frac{1}{2}$ chains, on an ascent, or a descent, of 11°; here it is after the rate of almost two links per chain, and it will be exact enough to take only the 12 chains at that rate, which make 24 links in all, to be deducted from 1250, which leaves 1226 links, for the length to be laid down.

Practical surveyors say, it is best to make this deduction at the end of every chain-length while measuring, by drawing the chain forward every time as much as the deduction is; viz, in the present instance, drawing the chain on 2 links at each chain-length.

The third branch of Surveying, namely computing or casting-up, is performed by reducing the several inclosures and divisions into triangles, trapeziums, and parallelograms, but especially the two former; then finding the areas or contents of these several figures, and adding them all together.

The Practice of Surveying.

1. Land is measured with a chain, called Gunter's chain, of 4 poles or 22 yards in length, which consists of 100 equal links, each link being $\frac{22}{100}$ of a yard, or $\frac{66}{100}$ of a foot, or 7·92 inches long, that is nearly 8 inches or $\frac{2}{3}$ of a foot.

An acre of land is equal to 10 square chains, that is, 10 chains in length and 1 chain in breadth.

Or it is 40 × 4 or 160 square poles.
Or it is 220 × 22 or 4840 square yards.
Or it is 1000 × 100 or 100000 square links.

These being all the same quantity.

Also, an acre is divided into 4 parts called roods, and a rood into 40 parts called perches, which are square poles, or the square of a pole of $5\frac{1}{2}$ yards long, or the square of $\frac{1}{4}$ of a chain, or of 25 links, which is 625 square links. So that the divisions of land measure will be thus:

625 sq. links = 1 pole or perch
40 perches = 1 rood
4 roods = 1 acre

The length of lines, measured with a chain, are set down in links as integers, every chain in length being 100 links; and not in chains and decimals. Therefore, after the content is found, it will be in square links; then cut off five of the figures on the right-hand for decimals, and the rest will be acres. Those decimals are then multiplied by 4 for roods, and the decimals of these again by 40 for perches.

Ex. Suppose the length of a rectangular piece of ground be 792 links, and its breadth 385: to find the area in acres, roods, and perches.

```
     792
     385

2. Among the various instruments for surveying, the plain-table is the easiest and most generally useful, especially in crooked difficult places, as in a town among houses, &c. But although the plain-table be the most generally useful instrument, it is not *always* so; there being many cases in which sometimes one instrument is the properest, and sometimes another; nor is that surveyor master of his business who cannot in any case distinguish which is the fittest instrument or method, and use it accordingly: nay, sometimes no instrument at all, but barely the chain itself, is the best method, particularly in regular open fields lying together; and even when you are using the plain-table, it is often of advantage to measure such large open parts with the chain only, and from those measures lay them down upon the table.

The perambulator is used for measuring roads, and other great distances on level ground, and by the sides of rivers. It has a wheel of $8\frac{1}{4}$ feet, or half a pole, in circumference, upon which the machine turns; and the distance measured is pointed out by an index, which is moved round by clock work.

Levels, with telescopic or other sights, are used to find the level between place and place, or how much one place is higher or lower than another.

An offset-staff is a very useful and necessary instrument, for measuring the offsets and other short distances. It is 10 links in length, being divided and marked at each of the 10 links.

Ten small arrows, or rods of iron or wood, are used to mark the end of every chain length, in measuring lines. And sometimes pickets, or staves with flags, are set up as marks or objects of direction.

Various scales are also used in protracting and measuring on the plan or paper; such as plane scales, line of chords, protractor, compasses, reducing scales, parallel and perpendicular rulers, &c. Of plane scales, there should be several sizes, as a chain in 1 inch, a chain in $\frac{3}{4}$ of an inch, a chain in $\frac{1}{2}$ of an inch, &c. And of these, the best for use are those that are laid on the very edges of the ivory scale, to prick off distances by, without compasses.

3. *The Field Book.*

In surveying with the plain-table, a field-book is not used, as every thing is drawn on the table immediately when it is measured. But in surveying with the theodolite, or any other instrument, some sort of a field-book must be used, to write down in it a register or account of all that is done and occurs relative to the survey in hand.

This book every one contrives and rules as he thinks fittest for himself. The following is a specimen of a form that has formerly been much used. It is ruled into 3 columns: the middle, or principal column, is for the stations, angles, bearings, distances measured, &c; and those on the right and left are for the offsets on the right and left, which are set against their corresponding distances in the middle column; as also for such remarks as may occur, and be proper to note for drawing the plan, &c.

Here ⊙ 1 is the first station, where the angle or bearing is 105° 25′. On the left, at 73 links in the distance,

distance or principal line, is an offset of 92; and at 610 an offset of 24 to a cross hedge. On the right, at 0, or the beginning, an offset 25 to the corner of the field; at 248 Brown's boundary hedge commences; at 610 an offset 35; and at 954, the end of the first line, the 0 denotes its terminating in the hedge. And so on for the other stations.

Draw a line under the work, at the end of every station line, to prevent confusion.

Offsets and Remarks on the left.	Stations, Bearings, and Distances.	Offsets and Remarks on the right.
	⊙1	
	105°25′	
	00	25 corner
92	73	
	248	Brown's hedge
cross a hedge 24	610	35
	954	00
	⊙2	
	53°10′	
	00	00
house corner 51	25	21
	120	29 a tree
34	734	40 a stile
	⊙3

	61	35
a brook 30	248	
	639	16 a spring
foot path 16	810	
cross hedge 18	973	20 a pond

But a few skilful surveyers now make use of a different method for the field book, namely, beginning at the bottom of the page and writing upwards; by which they sketch a neat boundary on either hand, as they pass it; an example of which will be given below, with the plan of the ground to accompany it.

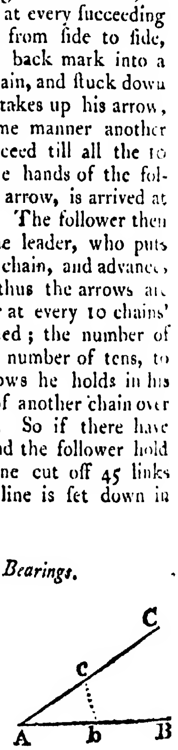
In smaller surveys and measurements, a very good way of setting down the work, is, to draw, by the eye, on a piece of paper, a figure resembling that which is to be measured; and so write the dimensions, as they are found, against the corresponding parts of the figure. And this method may be practised to a considerable extent, even in the larger surveys.

4. *To measure a line on the ground with the chain:* Having provided a chain, with 10 small arrows, or rods, to stick one into the ground, as a mark, at the end of every chain; two persons take hold of the chain, one at each end of it, and all the 10 arrows are taken by one of them who goes foremost, and is called the leader; the other being called the follower, for distinction's sake.

A picket, or station staff, being set up in the direction of the line to be measured, if there do not appear some marks naturally in that direction; the follower stands at the beginning of the line, holding the ring at the end of the chain in his hand, while the leader drags forward the chain by the other end of it, till it is stretched straight, and laid or held level, and the leader directed, by the follower waving his hand, to the right or left, till the follower see him exactly in a line with the mark or direction to be measured to; then both of them stretching the chain straight, and stooping and holding it level, the leader having the head of one of his arrows in the same hand by which he holds the end of the chain, he there sticks one of them down with it, while he holds the chain stretched. This done, he leaves the arrow in the ground, as a mark for the follower to come to, and advances another chain forward, being directed in his position by the follower standing at the arrow, as before; as also by himself now, and at every succeeding chain's length, by moving himself from side to side, till he brings the follower and the back mark into a line. Having then stretched the chain, and stuck down an arrow, as before, the follower takes up his arrow, and they advance again in the same manner another chain-length. And thus they proceed till all the 10 arrows are employed, and are in the hands of the follower; and the leader, without an arrow, is arrived at the end of the 11th chain length. The follower then sends or brings the 10 arrows to the leader, who puts one of them down at the end of his chain, and advances with the chain as before. And thus the arrows are changed from the one to the other at every 10 chains' length, till the whole line is finished; the number of changes of the arrows shews the number of tens, to which the follower adds the arrows he holds in his hand, and the number of links of another chain over to the mark or end of the line. So if there have been 3 changes of the arrows, and the follower hold 6 arrows, and the end of the line cut off 45 links more, the whole length of the line is set down in links thus, 3645.

5. *To take Angles and Bearings.*

Let B and C be two objects, or two pickets set up perpendicular; and let it be required to take their bearings, or the angle formed between them at any station A.



1*st*. *With the Plain Table.* The table being covered with a paper, and fixed on its stand; plant it at the station A, and fix a fine pin, or a point of the compasses, in a proper part of the paper, to represent the point A: Close by the side of this pin lay the fiducial edge of the index, and turn it about, still touching the pin, till one object B can be seen through the sights: then by the fiducial edge of the index draw a line. In the very same manner draw another line in the direction of the other object C. And it is done.

2*d*. *With the Theodolite, &c.* Direct the fixed sights along one of the lines, as AB, by turning the instrument about till you see the mark B through these sights; and there screw the instrument fast. Then turn

turn the moveable index about till, through its ſights, you ſee the other mark C. Then the degrees cut by the index, upon the graduated limb or ring of the inſtrument, ſhew the quantity of the angle.

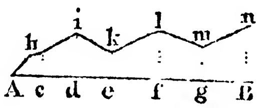
3*d.* *With the Magnetic Needle and Compaſs.* Turn the inſtrument, or compaſs, ſo, that the north end of the needle point to the flower-de-luce. Then direct the ſights to one mark, as B, and note the degrees cut by the needle. Then direct the ſights to the other mark C, and note again the degrees cut by the needle. Then their ſum or difference, as the caſe is, will give the quantity of the angle BAC.

4*th.* *By Meaſurement with the Chain, &c.* Meaſure one chain length, or any other length, along both directions, as to b and c. Then meaſure the diſtance b c, and it is done.—This is eaſily transferred to paper, by making a triangle A b c with theſe three lengths, and then meaſuring the angle A as in Practical Geometry.

6. *To Meaſure the Offsets.*

A h i k l m n being a crooked hedge, or river, &c. From A meaſure in a ſtraight direction along the ſide of it to B. And in meaſuring along this line AB obſerve when you are directly oppoſite any bends or corners of the hedge, as at c d, e, &c; and from thence meaſure the perpendicular offsets, ch, di, &c, with the offset-ſtaff, if they are not very large, otherwiſe with the chain itſelf; and the work is done. And the regiſter, or field-book, may be as follows:

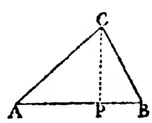
Offs. left.		Baſeline AB	
	o	⊙	A
ch	62	45	Ac
di	84	220	Ad
ek	70	340	Ae
fl	98	510	Af
gm	57	634	Ag
Bn	91	785	AB



7. *To Survey a triangular Field* ABC.

1*ſt.* *By the Chain.*

AP	794
AB	1321
PC	826



Having ſet up marks at the corners, which is to be done in all caſes where there are not marks naturally; meaſure with the chain from A to P, where a perpendicular would fall from the angle C, and there meaſure from P to C; then complete the diſtance AB by meaſuring from P to B; ſetting down each of theſe meaſured diſtances. And thus, having the baſe and perpendicular, the area from them is eaſily found. Or having the place P of the perpendicular, the triangle is eaſily conſtructed.

Or, meaſure all the three ſides with the chain, and note them down. From which the content is eaſily found, or the figure conſtructed.

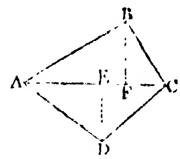
2*d.* *By taking one or more of the Angles.*

Meaſure two ſides AB, AC, and the angle A between them. Or meaſure one ſide AB, and the two adjacent angles A and B. From either of theſe ways the figure is eaſily planned: then by meaſuring the perpendicular CP on the plan, and multiplying it by half AB, you have the content.

8. *To meaſure a Four-ſided Field.*

1*ſt.* *By the Chain.*

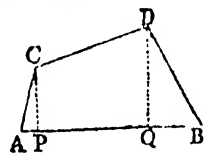
AE	214	210	DE
AF	362	306	BF
AC	592		



Meaſure along either of the diagonals, as AC; and either the two perpendiculars DE, BF, as in the laſt problem; or elſe the ſides AB, BC, CD, DA. From either of which the figure may be planned and computed as before directed.

Otherwiſe by the Chain.

AP	110	352	PC
AQ	745	595	QD
AB	1110		



Meaſure on the longeſt ſide, the diſtances AP, AQ, AB; and the perpendiculars PC, QD.

2*d.* *By taking one or more of the Angles.*

Meaſure the diagonal AC (ſee the firſt fig. above), and the angles CAB, CAD, ACB, ACD.—Or meaſure the four ſides, and any one of the angles as BAD.

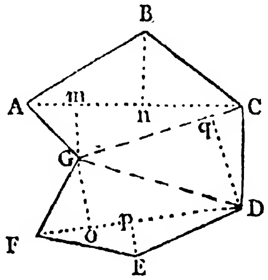
Thus		Or thus	
AC	591	AB	486
CAB	37°20′	BC	394
CAD	41 15	CD	410
ACB	72 25	DA	462
ACD	54 40	BAD	78°35′

9. *To Survey any Field by the Chain only.*

Having ſet up marks at the corners, where neceſſary, of the propoſed field ABCDEFG. Walk over the ground, and conſider how it can beſt be divided into triangles and trapeziums; and meaſure them ſeparately as in the laſt two problems. And in this way it will be proper to divide it into as few ſeparate triangles, and as many trapeziums as may be, by drawing diagonals

nals from corner to corner: and so, as that all the perpendiculars may fall within the figure. Thus, the following figure is divided into the two trapeziums ABCG, GDEF, and the triangle GCD. Then, in the first, beginning at A, measure the diagonal AC, and the two perpendiculars Gm, Bn. Then the base GC and the perpendicular Dq. Lastly the diagonal DF, and the two perpendiculars pE, oG. All which measures write against the corresponding parts of a rough figure drawn to resemble the figure to be surveyed, or set them down in any other form you choose.

Am 135	130 mG
An 410	180 nB
Ac 550	
Cq 152	230 qD
CG 440	
FO 206	120 oG
FP 288	80 pE
FD 520	



Or thus:

Measure all the sides AB, BC, CD, DE, EF, FG, and GA; and the diagonals AC, CG, GD, DF.

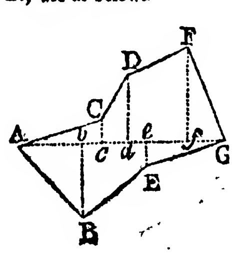
Otherwise,

Many pieces of land may be very well surveyed, by measuring any base line, either within or without them, together with the perpendiculars let fall upon it from every corner of them. For they are by these means divided into several triangles and trapezoids, all whose parallel sides are perpendicular to the base line; and the sum of these triangles and trapeziums will be equal to the figure proposed if the base line fall within it; if not, the sum of the parts which are without being taken from the sum of the whole which are both within and without, will leave the area of the figure proposed.

In pieces that are not very large, it will be sufficiently exact to find the points, in the base line, where the several perpendiculars will fall, by means of the *cross*, and from thence measuring to the corners for the lengths of the perpendiculars.—And it will be most convenient to draw the line so as that all the perpendiculars may fall within the figure.

Thus, in the following figure, beginning at A, and measuring along the line AG, the distances and perpendiculars, on the right and left, are as below.

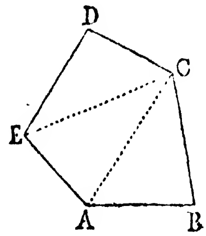
Ab 315	350 bB
Ac 440	70 cC
Ad 585	320 dD
Ae 610	50 eE
Af 990	470 fF
AG 1020	0



10. *To Survey any Field with the Plain Table.*

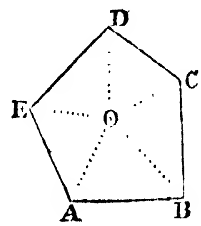
1st. From one Station.

Plant the table at any angle, as C, from whence all the other angles, or marks set up, can be seen; and turn the table about till the needle point to the flower-de-luce: and there screw it fast. Make a point for C on the paper on the table, and lay the edge of the index to C, turning it about there till through the sights you see the mark D; and by the edge of the index draw a dry or obscure line: then measure the distance CD, and lay that distance down on the line CD. Then turn the index about the point C, till the mark E be seen through the sights, by which draw a line, and measure the distance to E, laying it on the line from C to E. In like manner determine the positions of CA and CB, by turning the sights successively to A and B; and lay the lengths of those lines down. Then connect the points with the boundaries of the field, by drawing the black lines CD, DE, EA, AB, BC.



2d. From a Station within the Field.

When all the other parts cannot be seen from one angle, choose some place O within; or even without, if more convenient, from whence the other parts can be seen. Plant the table at O, then fix it with the needle north, and mark the point O upon it. Apply the index successively to O, turning it round with the sights to each angle A, B, C, D, E, drawing dry lines to them by the edge of the index, then measuring the distances OA, OB, &c, and laying them down upon those lines. Lastly draw the boundaries AB, BC, CD, DE, EA.



3d. By going round the Figure.

When the figure is a wood or water, or from some other obstruction you cannot measure lines across it; begin at any point A, and measure round it, either within or without the figure, and draw the directions of all the sides thus: Plant the table at A, turn it with the needle to the north or flower-de-luce, fix it and mark the point A. Apply the index to A, turning it till you can see the point E, there draw a line; and then the point B, and there draw a line: then measure these lines, and lay them down from A to E and B. Next move the table to B, lay the index along the line AB, and turn the table about till you can see the mark A, and screw fast the table; in which position also the needle will again point to the flower-de-luce, as it will do

do indeed at every station when the table is in the right position. Here turn the index about B till through the sights you see the mark C; there draw a line, measure BC, and lay the distance upon that line after you have set down the table at C. Turn it then again into its proper position, and in like manner find the next line CD. And so on quite round by E to A again. Then the proof of the work will be the joining at A: for if the work is all right, the last direction EA on the ground, will pass exactly through the point A on the paper; and the measured distance will also reach exactly to A. If these do not coincide, or nearly so, some error has been committed, and the work must be examined over again.

11. *To Survey a Field with the Theodolite, &c.*

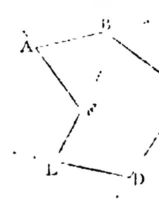
1st. From one Point or Station.

When all the angles can be seen from one point, as the angle C (last fig. but one), place the instrument at C, and turn it about till, through the fixed sights, you see the mark B, and there fix it. Then turn the moveable index about till the mark A is seen through the sights, and note the degrees cut on the instrument. Next turn the index successively to E and D, noting the degrees cut off at each; which gives all the angles BCA, BCF, BCD. Lastly, measure the lines CB, CA, CE, CD; and enter the measures in a field-book, or rather against the corresponding parts of a rough figure drawn by guess to resemble the field.

2d. From a Point within or without.

Plant the instrument at O, (last fig.) and turn it about till the fixed sights point to any object, as A; and there screw it fast. Then turn the moveable index round till the sights point successively to the other points E, D, C, B, noting the degrees cut off at each of them; which gives all the angles round the point O. Lastly, measure the distances OA, OB, OC, OD, OE, noting them down as before, and the work is done.

3d. By going round the Field.



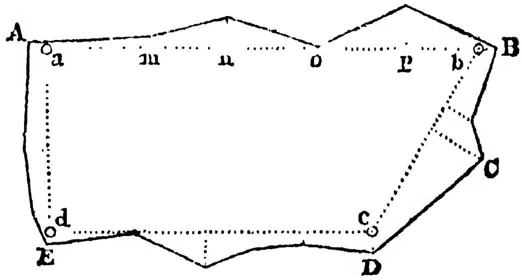
By measuring round, either within or without the field, proceed thus. Having set up marks at B, C, &c. near the corners as usual, plant the instrument at any point A, and turn it till the fixed index be in the direction AB, and there screw it fast: then turn the moveable index to the direction AF; and the degrees cut off will be the angle A. Measure the line AB, and plant the instrument at B, and there in the same manner observe the angle A. Then measure BC, and observe the angle C. Then measure the distance CD, and take the angle D. Then measure DE, and take the angle E. Then measure EF, and take the angle F. And lastly measure the distance FA.

To prove the work; add all the inward angles, A, B, C, &c, together, and when the work is right, their sum will be equal to twice as many right angles as the figure has sides, wanting 4 right angles. And when there is an angle, as F, that bends inwards, and you measure the external angle, which is less than two right angles, subtract it from 4 right angles, or 360 degrees, to give the internal angle greater than a semicircle or 180 degrees.

Otherwise. Instead of observing the internal angles, you may take the external angles, formed without the figure by producing the sides further out. And in this case, when the work is right, their sum altogether will be equal to 360 degrees. But when one of them, as F, runs inwards, subtract it from the sum of the rest, to leave 360 degrees.

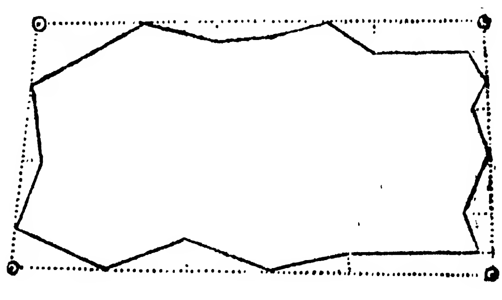
12. *To Survey a Field with crooked Hedges, &c.*

With any of the instruments measure the lengths and positions of imaginary lines running as near the sides of the field as you can; and in going along them measure the offsets in the manner before taught; and you will have the plan on the paper in using the plain table, drawing the crooked hedges through the ends of the offsets; but in surveying with the theodolite, or other instrument, set down the measures properly in a field-book, or memorandum-book, and plan them after returning from the field, by laying down all the lines and angles.



So, in surveying the piece ABCDE, set up marks a, b, c, d, dividing it into as few sides as may be. Then begin at any station a, and measure the lines ab, bc, cd, da, and take their positions, or the angles a, b, c, d; and in going along the lines measure all the offsets, as at m, n, o, p, &c, along every station line.

And this is done either within the field, or without, as may be most convenient. When there are obstructions within, as wood, water, hills, &c; then measure without, as in the figure here below.

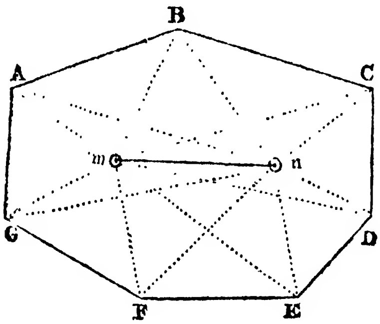


13. *To Survey a Field or any other Thing, by Two Stations.*

This is performed by chooſing two ſtations, from whence all the marks and objects can be ſeen, then meaſuring the diſtance between the ſtations, and at each ſtation taking the angles formed by every object, from the ſtation line or diſtance.

The two ſtations may be taken either within the bounds, or in one of the ſides, or in the direction of two of the objects, or quite at a diſtance, and without the bounds of the objects, or part to be ſurveyed.

In this manner, not only grounds may be ſurveyed, without even entering them, but a map may be taken of the principal parts of a country, or the chief places of a town, or any part of a river or coaſt ſurveyed, or any other inacceſſible objects; by taking two ſtations, on two towers, or two hills, or ſuch like.



When the plain table is uſed; plant it at one ſtation m, draw a line m n on it, along which lay the edge of the index, and turn the table about till the ſights point directly to the other ſtation; and there ſcrew it faſt. Then turn the ſights round m ſucceſſively to all the objects ABC, &c, drawing a dry line by the edge of the index at each, as mA, mB, mC, &c. Then meaſure the diſtance to the other ſtation, there plant the table, and lay that diſtance down on the ſtation line from m to n. Next lay the index by the line nm, and turn the table about till the ſights point to the other ſtation m, and there ſcrew it faſt. Then direct the ſights ſucceſſively to all the objects A, B, C, &c, as before, drawing lines each time, as nA, nB, nC, &c: and their interſection with the former lines will give the places of all the objects, or corners, A, B, C, &c.

When the theodolite, or any other inſtrument for taking angles, is uſed; proceed in the ſame way, meaſuring the ſtation diſtance mn, planting the inſtrument firſt at one ſtation, and then at another; then placing the fixed ſights in the direction mn, and directing the moveable ſights to every object, noting the degrees cut off at each time. Then, theſe obſervations being planned, the interſections of the lines will give the objects as before.

When all the objects, to be ſurveyed, cannot be ſeen from two ſtations; then three ſtations may be uſed, or four, or as many as is neceſſary; meaſuring always the diſtance from one ſtation to another; placing the inſtrument in the ſame poſition at every ſtation, by means deſcribed before; and from each ſtation obſerving or ſetting every object that can be ſeen from it, by taking its direction or angular poſition, till every object be determined by the interſection of two or more lines of direction, the more the better. And thus may very extenſive ſurveys be taken, as of large commons, rivers, coaſts, countries, hilly grounds, and ſuch like.

14. *To Survey a Large Eſtate.*

If the eſtate be very large, and contain a great number of fields, it cannot well be done by ſurveying all the fields ſingly, and then putting them together; nor can it be done by taking all the angles and boundaries that incloſe it. For in theſe caſes, any ſmall errors will be ſo multiplied, as to render it very much diſtorted.

1ſt. Walk over the eſtate two or three times, in order to get a perfect idea of it, and till you can carry the map of it tolerably in your head. And to help your memory, draw an eye draught of it on paper, or at leaſt, of the principal parts of it, to guide you.

2d. Chooſe two or more eminent places in the eſtate, for your ſtations, from whence you can ſee all the principal parts of it: and let theſe ſtations be as far diſtant from one another as poſſible; as the fewer ſtations you have to command the whole, the more exact your work will be: and they will be fitter for your purpoſe, if theſe ſtation lines be in or near the boundaries of the ground, and eſpecially if two or more lines proceed from one ſtation

3d. Take angles, between the ſtations, ſuch as you think neceſſary, and meaſure the diſtances from ſtation to ſtation, always in a right line: theſe things muſt be done, till you get as many angles and lines as are ſufficient for determining all your points of ſtation. And in meaſuring any of theſe ſtation diſtances, mark accurately where theſe lines meet with any hedges, ditches, roads, lanes, paths, rivulets, &c, and where any remarkable object is placed, by meaſuring its diſtance from the ſtation line, and where a perpendicular from it cuts that line; and always mind, in any of theſe obſervations, that you be in a right line, which you will know by taking backſight and foreſight, along your ſtation line. And thus as you go along any main ſtation line, take offſets to the ends of all hedges, and to any pond, houſe, mill, bridge, &c, omitting nothing that is remarkable. And all theſe things muſt be noted down; for theſe are your data, by which the places of ſuch objects are to be determined upon your plan. And be ſure to ſet marks up at the interſections of all hedges with the ſtation line, that you may know where to meaſure from, when you come to ſurvey theſe particular fields, which muſt immediately be done, as ſoon as you have meaſured that ſtation line, whilſt they are freſh in memory. In this way all your ſtation lines are to be meaſured, and the ſituation of all places adjoining to them determined, which is the firſt grand point to be obtained. It will be proper for you to lay down your work upon paper every night, when you go home, that you may ſee how you go on.

4th. As to the inner parts of the eſtate, they muſt be deter-

determined in like manner, by new station lines: for, after the main stations are determined, and every thing adjoining to them, then the estate must be subdivided into two or three parts by new station lines; taking inner stations at proper places, where you can have the best view. Measure these station lines as you did the first, and all their intersections with hedges, and all offsets to such objects as appear. Then you may proceed to survey the adjoining fields, by taking the angles that the sides make with the station line, at the intersections, and measuring the distances to each corner, from the intersections. For every station line will be a basis to all the future operations; the situation of all parts being entirely dependant upon them; and therefore they should be taken ot as great a length as possible; and it is best for them to run along some of the hedges or boundaries of one or more fields, or to pass through some of their angles. All things being determined for these stations, you must take more inner ones, and so continue to divide and subdivide, till at last you come to single fields; repeating the same work for the inner stations, as for the outer ones, till all be done: and close the work as often as you can, and in as few lines as possible. And that you may choose stations the most conveniently, so as to cause the least labour, let the station lines run as far as you can along some hedges, and through as many corners of the fields, and other remarkable points, as you can. And take notice how one field lies by another; that you may not misplace them in the draught.

5th. An estate may be so situated, that the whole cannot be surveyed together; because one part of the estate cannot be seen from another. In this case, you may divide it into three or four parts, and survey the parts separately, as if they were lands belonging to different persons; and at last join them together.

6th. As it is necessary to protract or lay down your work as you proceed in it, you must have a scale of a due length to do it by. To get such a scale, you must measure the whole length of the estate in chains; then you must consider how many inches in length the map is to be; and from these you will know how many chains you must have in an inch; then make your scale, or choose one already made, accordingly.

7th. The trees in every hedge row must be placed in their proper situation, which is soon done by the plain table; but may be done by the eye without an instrument; and being thus taken by guess, in a rough draught, they will be exact enough, being only to look at; except it be such as are at any remarkable places, as at the ends of hedges, at stiles, gates, &c, and these must be measured. But all this need not be done till the draught is finished. And observe in all the hedges, what side the gutter or ditch is on, and consequently to whom the fences belong.

8th. When you have long stations, you ought to have a good instrument to take angles with; and the plain table may very properly be made use of, to take the several small internal parts, and such as cannot be taken from the main stations, as it is a very quick and ready instrument.

15. Instead of the foregoing method, an ingenious friend (Mr. Abraham Crocker), after mentioning the new and improved method of keeping the field book by writing from bottom to top of the pages, observes that "In the former method of measuring a large estate, the accuracy of it depends on the correctness of the instruments used in taking the angles. To avoid the errors incident to such a multitude of angles, other methods have of late years been used by some few skilful surveyors; the most practical, expeditious, and correct, seems to be the following.

"As was advised in the foregoing method, so in this, choose two or more eminences, as grand stations, and measure a principal base line from one station to the other, noting every hedge, brook, or other remarkable object as you pass by it; measuring also such short perpendicular lines to such bends of hedges as may be near at hand. From the extremities of this base line, or from any convenient parts of the same, go off with other lines to some remarkable object situated towards the sides of the estate, without regarding the angles they make with the base line or with one another; still remembering to note every hedge, brook or other object that you pass by. These lines, when laid down by intersections, will with the base line form a grand triangle upon the estate; several of which, if need be, being thus laid down, you may proceed to form other smaller triangles and trapezoids on the sides of the former: and so on, until you finish with the enclosures individually.

"To illustrate this excellent method, let us take AB (in the plan of an estate, fig. 1, pl. 28) for the principal base line. From B go off to the tree at C; noting down, in the field-book, every cross hedge, as you measure on; and from C measure back to the first station at A, noting down every thing as before directed.

"This grand triangle being completed, and laid down on the rough plan paper, the parts, exterior as well as interior, are to be completed by smaller triangles and trapezoids.

"When the whole plan is laid down on paper, the contents of each field might be calculated by the methods laid down below, at article 20.

"In countries where the lands are enclosed with high hedges, and where many lanes pass through an estate, a theodolite may be used to advantage, in measuring the angles of such lands; by which means, a kind of skeleton of the estate may be obtained, and the lane-lines serve as the bases of such triangles and trapezoids as are necessary to fill up the interior parts."

The method of measuring the other cross lines, offsets and interior parts and enclosures, appears in the plan, fig. 1, last referred to.

16. Another ingenious correspondent (Mr. John Rodham of Richmond, Yorkshire) has also communicated the following example of the new method of surveying, accompanied by the field-book, and its corresponding plan. His account of the method is as follows.

The field-book is ruled into three columns. In the middle one are set down the distances on the chain line at which any mark, offset, or other observation is made; and in the right and left hand columns are entered, the offsets and observations made on the right and left hand respectively of the chain line.

It is of great advantage, both for brevity and perspicuity,

ſpicuity, to begin at the bottom of the leaf and write upwards; denoting the croſſing of fences, by lines drawn acroſs the middle column, or only a part of ſuch a line on the right and left oppoſite the figures, to avoid confuſion, and the corners of fields, and other remarkable turns in the fences where offſets are taken to, by lines joining in the manner the fences do, as will be beſt ſeen by comparing the book with the plan annexed, fig. 2, pl. 28.

The marks called, *a*, *b*, *c*, &c, are beſt made in the fields, by making a ſmall hole with a ſpade, and a chip or ſmall bit of wood, with the particular letter upon it, may be put in, to prevent one mark being taken for another, on any return to it. But in general, the name of a mark is very eaſily had by referring in the book to the line it was made in. After the ſmall alphabet is gone through, the capitals may be next, the print letters afterwards, and ſo on, which anſwer the purpoſe of ſo many different letters; or the marks may be numbered.

The letter in the left hand corner at the beginning of every line, is the mark or place meaſured *from;* and, that at the right hand corner at the end, is the mark meaſured *to:* But when it is not convenient to go exactly from a mark, the place meaſured from, is deſcribed *ſuch a diſtance* from *one mark* towards *another;* and where a mark is not meaſured to, the exact place is aſcertained by ſaying, turn to the right or left hand, *ſuch a diſtance* to *ſuch a mark*, it being always underſtood that thoſe diſtances are taken in the chain line.

The characters uſed, are ┌ for *turn to the right hand*, ┐ for turn to the left hand, and ∧ placed over an offſet, to ſhew that it is not taken at right angles with the chain line, but in the line with ſome ſtraight fence; being chiefly uſed when croſſing their directions, and is a better way of obtaining their true places than by offſets at right angles.

When a line is meaſured whoſe poſition is determined, either by former work (as in the caſe of producing a given line or meaſuring from one known place or mark to another) or by itſelf (as in the third ſide of a triangle) it is called a *faſt line*, and a double line acroſs the book is drawn at the concluſion of it; but if its poſition is not determined (as in the ſecond ſide of a triangle) it is called a *looſe line*, and a ſingle line is drawn acroſs the book. When a line becomes determined in poſition, and is afterwards continued, a double line half through the book is drawn.

When a looſe line is meaſured, it becomes abſolutely neceſſary to meaſure ſome line that will determine its poſition. Thus, the firſt line *ab*, being the baſe of a triangle, is always determined; but the poſition of the ſecond ſide *bj*, does not become determined, till the third ſide *jb* is meaſured; then the triangle may be conſtructed, and the poſition of both is determined.

At the beginning of a line, to fix a looſe line to the mark or place meaſured from, the ſign of turning to the right or left hand muſt be added (as at *j* in the third line); otherwiſe a ſtranger, when laying down the work may as eaſily conſtruct the triangle *bjb* on the wrong ſide of the line *ab*, as on the right one: but this error cannot be fallen into, if the ſign above named be carefully obſerved.

In chooſing a line to fix a looſe one, care muſt be taken that it does not make a very acute or obtuſe angle; as in the triangle *pBr*, by the angle at B being very obtuſe, a ſmall deviation from truth, even the breadth of a point at *p* or *r*, would make the error at B when conſtructed very conſiderable; but by conſtructing the triangle *pBq*, ſuch a deviation is of no conſequence.

Where the words *leave off* are written in the field-book, it is to ſignify that the taking of offſets is from thence diſcontinued; and of courſe ſomething is wanting between that and the next offſet.

The field-book above referred to, is engraved on plate 29, in parts, repreſenting ſo many pages, each of which is ſuppoſed to begin at the bottom, and end at top. And the map or plan belonging to it, in fig. 2, pl. 28.

17. *To Survey a County, or Large Tract of Land.*

1ſt. Chooſe two, three, or four eminent places for ſtations; ſuch as the tops of high hills or mountains, towers, or church ſteeples, which may be ſeen from one another; and from which moſt of the towns, and other places of note, may alſo be ſeen. And let them be as far diſtant from one another as poſſible. Upon theſe place raiſe beacons, or long poles, with flags of different colours flying at them; ſo as to be viſible from all the other ſtations.

2d. At all the places, which you would ſet down in the map, plant long poles with flags at them of ſeveral colours, to diſtinguiſh the places from one another: fixing them upon the tops of church ſteeples, or the tops of houſes, or in the centres of leſſer towns.

But you need not have theſe marks at many places at once, as ſuppoſe half a ſcore at a time. For when the angles have been taken, at the two ſtations, to all theſe places, the marks may be moved to new ones; and ſo ſucceſſively to all the places you want. Theſe marks then being ſet up at a convenient number of places, and ſuch as may be ſeen from both ſtations; go to one of theſe ſtations, and with an inſtrument to take angles, ſtanding at that ſtation, take all the angles between the other ſtation, and each of theſe marks, obſerving which is blue, which red, &c, and which hand they lie on; and ſet all down with their colours. Then go to the other ſtation, and take all the angles between the firſt ſtation, and each of the former marks, and ſet them down with the others, each againſt his fellow with the ſame colour. You may, if you can, alſo take the angles at ſome third ſtation, which may ſerve to prove the work, if the three lines interſect in that point, where any mark ſtands. The marks muſt ſtand till the obſervations are finiſhed at both ſtations; and then they muſt be taken down, and ſet up at freſh places. And the ſame operations muſt be performed, at both ſtations, for theſe freſh places; and the like for others. Your inſtrument for taking angles muſt be an exceeding good one, made on purpoſe with teleſcopic ſights; and of three, four, or five feet radius. A circumferentor is reckoned a good inſtrument for this purpoſe.

3d. And though it is not abſolutely neceſſary to meaſure any diſtance, becauſe a ſtationary line being laid down from any ſcale, all the other lines will be proportional

proportional to it; yet it is better to measure some of the lines, to ascertain the distances of places in miles; and to know how many geometrical miles there are in any length; and from thence to make a scale to measure any distance in miles. In measuring any distance, it will not be exact enough to go along the high roads; by reason of their turnings and windings, and hardly ever lying in a right line between the stations, which would cause endless reductions, and create trouble to make it a right line; for which reason it can never be exact. But a better way is to measure in a right line with a chain, between station and station, over hills and dales or level fields, and all obstacles. Only in case of water, woods, towns, rocks, banks, &c, where one cannot pass, such parts of the line must be measured by the methods of inaccessible distances; and besides, allowing for ascents and descents, when we meet with them. And a good compass that shews the bearing of the two stations, will always direct you to go straight, when you do not see the two stations; and in your progress, if you can go straight, you may take offsets to any remarkable places, likewise noting the intersection of the stationary line with all roads, rivers, &c.

4th. And from all the stations, and in the whole progress, be very particular in observing sea coasts, river mouths, towns, castles, houses, churches, windmills, watermills, trees, rocks, sands, roads, bridges, fords, ferries, woods, hills, mountains, rills, brooks, parks, beacons, sluices, floodgates, locks, &c; and in general all things that are remarkable.

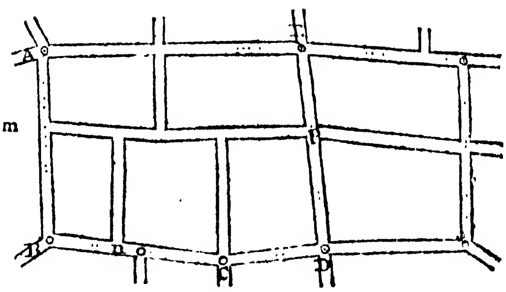
5th. After you have done with the first and main station lines, which command the whole county; you must then take inner stations, at some places already determined; which will divide the whole into several partitions: and from these stations you must determine the places of as many of the remaining towns as you can. And if any remain in that part, you must take more stations, at some places already determined; from which you may determine the rest. And thus proceed through all the parts of the country, taking station after station, till we have determined all we want. And in general the station distances must always pass through such remarkable points as have been determined before, by the former stations.

6th. Lastly, the position of the station line you measure, or the point of the compass it lies on, must be determined by astronomical observation. Hang up a thread and plummet in the sun, over some part of the station line, and observe when the shadow runs along that line, and at that moment take the sun's altitude; then having his declination, and the latitude, the azimuth will be found by spherical trigonometry. And the azimuth is the angle the station line makes with the meridian; and therefore a meridian may easily be drawn through the map: Or a meridian may be drawn through it by hanging up two threads in a line with the pole star, when he is just north, which may be known from astronomical tables. Or thus; observe the star Alioth, or that in the rump of the great bear, being that next the square; or else Cassiopeia's hip; I say, observe by a line and plummet when either of these stars and the pole star come into a perpendicular; and at that time they are due north. Therefore two perpendicular lines being fixed at that moment, towards these two stars, will give the position of the meridian.

18. *To Survey a Town or City.*

This may be done with any of the instruments for taking angles, but best of all with the plain table, where every minute part is drawn while in sight. It is proper also to have a chain of 50 feet long, divided into 50 links, and an offset-staff of 10 feet long.

Begin at the meeting of two or more of the principal streets, through which you can have the longest prospects, to get the longest station lines. There having fixed the instrument, draw lines of direction along those streets, using two men as marks, or poles set in wooden pedestals, or perhaps some remarkable places in the houses at the farther ends, as windows, doors, corners, &c. Measure these lines with the chain, taking offsets with the staff, at all corners of streets, bendings, or windings, and to all remarkable things, as churches, markets, halls, colleges, eminent houses, &c. Then remove the instrument to another station along one of these lines; and there repeat the same process as before. And so on till the whole is finished.



Thus, fix the instrument at A, and draw lines in the direction of all the streets meeting there; and measure AB, noting the street on the left at m. At the second station B, draw the directions of the streets meeting there; measure from B to C, noting the places of the streets at n and o as you pass by them. At the 3d station C, take the direction of all the streets meeting there, and measure CD. At D do the same, and measure DE, noting the place of the cross streets at p. And in this manner go through all the principal streets. This done, proceed to the smaller and intermediate streets; and lastly to the lanes, alleys, courts, yards, and every part that it may be thought proper to represent.

Of Planning, Computing, and Dividing.

19. *To Lay down the Plan of any Survey.*

If the survey was taken with a plain table, you have a rough plan of it already on the paper which covered the

the table. But if the survey was with any other instrument, a plan of it is to be drawn from the measures that were taken in the survey, and first of all a rough plan upon paper.

To do this, you must have a set of proper instruments, for laying down both lines and angles, &c; as scales of various sizes, the more of them, and the more accurate, the better; scales of chords, protractors, perpendicular and parallel rulers, &c. Diagonal scales are best for the lines, because they extend to three figures, or chains and links, which are hundredth parts of chains. And in using the diagonal scale, a pair of compasses must be employed to take off the lengths of the principal lines very accurately. But a scale with a thin edge divided, is much readier for laying down the perpendicular offsets to crooked hedges, and for marking the places of those offsets upon the station line; which is done at only one application of the edge of the scale to that line, and then pricking off all at once the distances along it. Angles are to be laid down either with a good scale of chords, which is perhaps the most accurate way; or with a large protractor, which is much readier when many angles are to be laid down at one point, as they are pricked off all at once round the edge of the protractor.

Very particular directions for laying down all sorts of figures cannot be necessary in this place, to any person who has learned practical geometry, or the construction of figures, and the use of his instruments. It may therefore be sufficient to observe, that all lines and angles must be laid down on the plan in the same order in which they were measured in the field, and in which they are written in the field-book; laying down first the angles for the position of lines, then the lengths of the lines, with the places of the offsets, and then the lengths of the offsets themselves, all with dry or obscure lines; then a black line drawn through the extremities of all the offsets, will be the hedge or bounding line of the field, &c. After the principal bounds and lines are laid down, and made to fit or close properly, proceed next to the smaller objects, till you have entered every thing that ought to appear in the plan, as houses, brooks, trees, hills, gates, stiles, roads, lanes, mills, bridges, woodlands, &c, &c.

The north side of a map or plan is commonly placed uppermost, and a meridian somewhere drawn, with the compass or flower-de-luce pointing north. Also, in a vacant place, a scale of equal parts or chains is drawn, and the title of the map in conspicuous characters, and embellished with a compartment. All hills must be shadowed, to distinguish them in the map. Colour the hedges with different colours; represent hilly grounds by broken hills and valleys; draw single dotted lines for foot-paths, and double ones for horse or carriage roads. Write the name of each field and remarkable place within it, and, if you choose, its content in acres, roods, and perches.

In a very large estate, or a county, draw vertical and horizontal lines through the map, denoting the spaces between them by letters, placed at the top, and bottom, and sides, for readily finding any field or other object, mentioned in a table.

In mapping counties, and estates that have uneven grounds of hills and valleys, reduce all oblique lines, measured up hill and down hill, to horizontal straight lines, if that was not done during the survey, before they were entered in the field-book, by making a proper allowance to shorten them. For which purpose, there is commonly a small table engraven on some of the instruments for Surveying.

20. To Compute the Contents of Fields.

1st. Compute the contents of the figures, whether triangles, or trapeziums, &c, by the proper rules for the several figures laid down in measuring; multiplying the lengths by the breadths, both in links; the product is acres after you have cut off five figures on the right, for decimals; then bring these decimals to roods and perches, by multiplying first by 4, and then by 40. An example of which was given in the description of the chain, art. 1.

2d. In small and separate pieces, it is usual to cast up their contents from the measures of the lines taken in surveying them, without making a correct plan of them.

Thus, in the triangle in art. 7, where we had AP = 794, and AB = 1321
PC = 826

3d. In pieces bounded by very crooked and winding hedges, meaſured by offſets, all the parts between the offſets are moſt accurately meaſured ſeparately as ſmall trapezoids. Thus, for the example to art. 6, where

Ac 45	62 ch

4th. Sometimes ſuch pieces as that above, are computed by finding a mean breadth, by dividing the ſum of the offſets by the number of them, accounting that for one of them where the boundary meets the ſtation line, as at A; then multiply the length AB by that mean breadth.

Thus:

00	785 AB	
62	66 mean breadth	
84		
70	4710	ac r p
98	4710	Content 0 2 2 by this method, which is 10 perches too little.
57		
91	·51810	
	4	
7) 462		
66	2·07240	
	40	
	2·89600	

But this method is always erroneous, except when the offſets ſtand at equal diſtances from one another.

5th. But in larger pieces, and whole eſtates, conſiſting of many fields, it is the common practice to make a rough plan of the whole, and from it compute the contents quite independent of the meaſures of the lines and angles that were taken in Surveying. For then new lines are drawn in the fields in the plan, ſo as to divide them into trapeziums and triangles, the baſes and perpendiculars of which are meaſured on the plan by means of the ſcale from which it was drawn, and ſo multiplied together for the contents. In this way the work is very expeditiouſly done, and ſufficiently correct; for ſuch dimenſions are taken, as afford the moſt eaſy method of calculation; and, among a number of parts, thus taken and applied to a ſcale, it is likely that ſome of the parts will be taken a ſmall matter too little, and others too great; ſo that they will, upon the whole, in all probability, very nearly balance one another. After all the fields, and particular parts, are thus computed ſeparately, and added all together into one ſum, calculate the whole eſtate independent of the fields, by dividing it into large and arbitrary triangles and trapeziums, and add theſe alſo together. Then if this ſum be equal to the former, or nearly ſo, the work is right; but if the ſums have any conſiderable difference, it is wrong, and they muſt be examined, and recomputed, till they nearly agree.

A ſpecimen of dividing into one triangle, or one trapezium, which will do for moſt ſingle fields, may be ſeen in the examples to the laſt article; and a ſpecimen of dividing a large tract into ſeveral ſuch trapeziums and triangles, in article 9, where a piece is ſo divided, and its dimenſions taken and ſet down; and again in articles 15, 16.

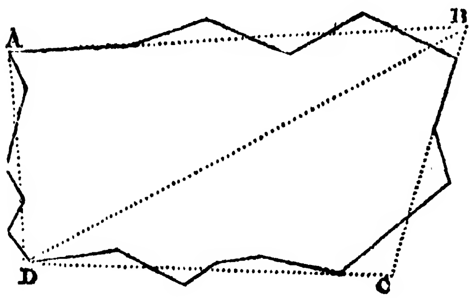
6th. But the chief ſecret in caſting up, conſiſts in finding the contents of pieces bounded by curved, or very irregular lines, or in reducing ſuch crooked ſides of fields or boundaries to ſtraight lines, that ſhall incloſe the ſame or equal area with thoſe crooked ſides, and ſo obtain the area of the curved figure by means of the right-lined one, which will commonly be a trape-

 zium.

gram. Now this reducing the crooked sides to straight ones, is very easily and accurately performed thus: Apply the straight edge of a thin, clear piece of lanthorn-horn to the crooked line, which is to be reduced, in such a manner, that the small parts cut off from the crooked figure by it, may be equal to those which are taken in: which equality of the parts included and excluded, you will presently be able to judge of very nicely by a little practice: then with a pencil draw a line by the straight edge of the horn. Do the same by the other sides of the field or figure. So shall you have a straight-sided figure equal to the curved one; the contents of which, being computed as before directed, will be the content of the curved figure proposed.

Or, instead of the straight edge of the horn, a horse-hair may be applied across the crooked sides in the same manner; and the easiest way of using the hair, is to string a small slender bow with it, either of wire, or cane, or whale-bone, or such like slender springy matter; for, the bow keeping it always stretched, it can be easily and neatly applied with one hand, while the other is at liberty to make two marks by the side of it, to draw the straight line by.

Ex. Thus, let it be required to find the contents of the same figure as in art. 12, to a scale of 4 chains to an inch.



Draw the four dotted straight lines AB, BC, CD, DA, cutting off equal quantities on both sides of them, which they do as near as the eye can judge: so is the crooked figure reduced to an equivalent right-lined one of four sides ABCD. Then draw the diagonal BD, which, by applying a proper scale to it, measures 1256. Also the perpendicular, or nearest distance, from A to this diagonal, measures 456; and the distance of C from it, is 428. Then

456	2) 11·10304
428	5·55152
884	4
1256	2·20608
5024	40
10048	8·24320
10048	
1110304	

And thus the content of the trapezium, and consequently of the irregular figure, to which it is equal, is easily found to be 5 acres, 2 roods, 8 perches.

21. *To Transfer a Plan to another Paper, &c.*

After the rough plan is completed, and a fair one is wanted; this may be done, either on paper or vellum, by any of the following Methods.

First Method.—Lay the rough plan upon the clean paper, and keep them always pressed flat and close together, by weights laid upon them. Then, with the point of a fine pin or pricker, prick through all the corners of the plan to be copied. Take them asunder, and connect the pricked points on the clean paper, with lines; and it is done. This method is only to be practised in plans of such figures as are small and tolerably regular, or bounded by right lines.

Second Method.—Rub the back of the rough plan over with black lead powder; and lay the said black part upon the clean paper, upon which the plan is to be copied, and in the proper position. Then, with the blunt point of some hard substance, as brass, or such like, trace over the lines of the whole plan; pressing the tracer so much as that the black lead under the lines may be transferred to the clean paper; after which take off the rough plan, and trace over the leaden marks with common ink, or with Indian ink, &c.—Or, instead of blacking the rough plan, you may keep constantly a blacked paper to lay between the plans.

Third Method.—Another way of copying plans, is by means of squares. This is performed by dividing both ends and sides of the plan, which is to be copied, into any convenient number of equal parts, and connecting the corresponding points of division with lines; which will divide the plan into a number of small squares. Then divide the paper, upon which the plan is to be copied, into the same number of squares, each equal to the former when the plan is to be copied of the same size, but greater or less than the others, in the proportion in which the plan is to be increased or diminished, when of a different size. Lastly, copy into the clean squares, the parts contained in the corresponding squares of the old plan; and you will have the copy either of the same size, or greater or less in any proportion.

Fourth Method.—A fourth way is by the instrument called a pentagraph, which also copies the plan in any size required.

Fifth Method.—But the neatest method of any is this. Procure a copying frame or glass, made in this manner; namely, a large square of the best window glass, set in a broad frame of wood, which can be raised up to any angle, when the lower side of it rests on a table. Set this frame up to any angle before you, facing a strong light; fix the old plan and clean paper together with several pins quite around, to keep them together, the clean paper being laid uppermost, and upon

upon the face of the plan to be copied. Lay them, with the back of the old plan, upon the glaſs, namely, that part which you intend to begin at to copy firſt; and, by means of the light ſhining through the papers, you will very diſtinctly perceive every line of the plan through the clean paper. In this ſtate then trace all the lines on the paper with a pencil. Having drawn that part which covers the glaſs, ſlide another part over the glaſs, and copy it in the ſame manner. And then another part. And ſo on till the whole be copied.

Then, take them aſunder, and trace all the pencil-lines over with a fine pen and Indian ink, or with common ink.

And thus you may copy the fineſt plan, without injuring it in the leaſt.

When the lines, &c, are copied upon the clean paper or vellum, the next buſineſs is to write ſuch names, remarks, or explanations as may be judged neceſſary; laying down the ſcale for taking the lengths of any parts, a flower-de-luce to point out the direction, and the proper title ornamented with a compartment; and illuſtrating or colouring every part in ſuch manner as ſhall ſeem moſt natural, ſuch as ſhading rivers or brooks with crooked lines, drawing the repreſentations of trees, buſhes, hills, woods, hedges, houſes, gates, roads, &c, in their proper places; running a ſingle dotted line for a foot path, and a double one for a carriage road; and either repreſenting the baſes or the elevations of buildings, &c.

22. *Of the Diviſion of Lands.*

In the diviſion of commons, after the whole is ſurveyed and caſt up, and the proper quantities to be allowed for roads, &c, deducted, divide the net quantity remaining among the ſeveral proprietors, by the rule of Fellowſhip, in proportion to the real value of their eſtates, and you will thereby obtain their proportional quantities of the land. But as this diviſion ſuppoſes the land, which is to be divided, to be all of an equal goodneſs, you muſt obſerve that if the part in which any one's ſhare is to be marked off, be better or worſe than the general mean quality of the land, then you muſt diminiſh or augment the quantity of his ſhare in the ſame proportion.

Or, which comes to the ſame thing, divide the ground among the claimants in the direct ratio of the value of their claims, and the inverſe ratio of the quality of the ground allotted to each; that is, in proportion to the quotients ariſing from the diviſion of the value of each perſon's eſtate, by the number which expreſſes the quality of the ground in his ſhare.

But theſe regular methods cannot always be put in practice; ſo that, in the diviſion of commons, the uſual way is, to meaſure ſeparately all the land that is of different values, and add into two ſums the contents and the values; then, the value of every claimant's ſhare is found, by dividing the whole value among them in proportion to their eſtates; and, laſtly, by the 24th article, a quantity is laid out for each perſon, that ſhall be of the value of his ſhare before found.

23. *It is required to divide any given Quantity of Ground, or its Value, into any given Number of Parts, and in Proportion as any given Numbers.*

Divide the given piece, or its value, as in the rule of Fellowſhip, by dividing the whole content or value by the ſum of the numbers expreſſing the proportions of the ſeveral ſhares, and multiplying the quotient ſeverally by the ſaid proportional numbers for the reſpective ſhares required, when the land is all of the ſame quality. But if the ſhares be of different qualities, then divide the numbers expreſſing the proportions or values of the ſhares, by the numbers which expreſs the qualities of the land in each ſhare; and uſe the quotients inſtead of the former proportional numbers.

Ex. 1. If the total value of a common be 2500 pounds, it is required to determine the values of the ſhares of the three claimants A, B, C, whoſe eſtates are of theſe values, 10000, and 15000, and 25000 pounds.

The eſtates being in proportion as the numbers 2, 3, 5, whoſe ſum is 10, we ſhall have $2500 \div 10 = 250$; which being ſeverally multiplied by 2, 3, 5, the products 500, 750, 1250, are the values of the ſhares required.

Ex. 2. It is required to divide 300 acres of land among A, B, C, D, E, F, G, and H, whoſe claims upon it are reſpectively in proportion as the numbers 1, 2, 3, 5, 8, 10, 15, 20.

The ſum of theſe proportional numbers is 64, by which dividing 300, the quotient is 4 ac. 2 r. 30 p. which being multiplied by each of the numbers, 1, 2, 3, 5, &c, we obtain for the ſeveral ſhares as below:

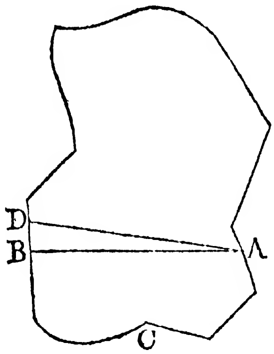
	Ac.	R.	P.
A =	4	2	30
B =	9	1	20
C =	14	0	10
D =	23	1	30
E =	37	2	00
F =	46	3	20
G =	70	1	10
H =	93	3	00
Sum =	300	0	00

Ex. 3. It is required to divide 780 acres among A, B, and C, whoſe eſtates are 1000, 3000, and 4000 pounds a year; the ground in their ſhares being worth 5, 8, and 10 ſhillings the acre reſpectively.

Here their claims are as 1, 3, 4; and the qualities of their land are as 5, 8, 10; therefore their quantities muſt be as $\frac{1}{5}$, $\frac{3}{8}$, $\frac{4}{10}$, or, by reduction, as 8, 15, 16. Now the ſum of theſe numbers is 39; by which dividing the 780 acres, the quotient is 20; which being multiplied ſeverally by the three numbers 8, 15, 16, the three products are 160, 300, 320, for the ſhares of A, B, C, reſpectively.

24. *To Cut off from a Plan a Given Number of Acres, &c, by a Line drawn from any Point in the Side of it.*

Let A be the given point in the annexed plan, from which a line is to be drawn cutting off suppose 5 ac. 2 r. 14 p.



Draw AB cutting off the part ABC as near as can be judged equal to the quantity proposed; and let the true quantity of ABC, when calculated, be only 4 ac. 3 r. 20 p. which is less than 5 ac. 2 r. 14 p. the true quantity, by 0 ac. 2 r. 34 p. or 71250 square links. Then measure AB, which suppose = 1234 links, and divide 71250, by 617 the half of it, and the quotient 115 links will be the altitude of the triangle to be added, and whose base is AB. Therefore if upon the centre B, with the radius 115, an arc be described; and a line be drawn parallel to AB, touching the arc, and cutting BD in D; and if AD be drawn, it will be the line cutting off the required quantity ADCA.

Note. If the first piece had been too much, then D must have been set below B.

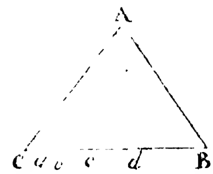
In this manner the several shares of commons, to be divided, may be laid down upon the plan, and transferred from thence to the ground itself.

Also for the greater ease and perfection in this business, the following problems may be added.

25. *From an Angle in a Given Triangle, to draw Lines to the opposite Side, dividing the Triangle into any Number of Parts, which shall be in any assigned Proportion to each other.*

Divide the base into the same number of parts, and in the same proportion, by article 22; then from the several points of division draw lines to the proposed angle, and they will divide the triangle as required.—For, the several parts are triangles of the same altitude, and which therefore are as their bases, which bases are taken in the assigned proportion.

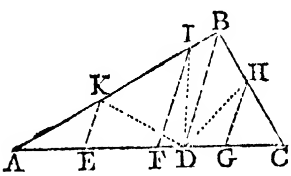
Ex. Let the triangle ABC, of 20 acres, be divided into five parts, which shall be in proportion to the numbers 1, 2, 3, 5, 9; the lines of division to be drawn from A to CB, whose length is 1600 links.



Here $1+2+3+5+9=20$, and $1600 \div 20 = 80$; which being multiplied by each of the proportional numbers, we have 80, 160, 240, 400, and 720. Therefore make $Ca = 80$, $ab = 160$, $bc = 240$, $cd = 400$, and $dB = 720$; then by drawing the lines A*a*, A*b*, A*c*, A*d*, the triangle is divided as required.

26. *From any Point in one side of a Given Triangle, to draw Lines to the other two Sides, dividing the Triangle into any Number of Parts which shall be in any assigned Ratio.*

From the given point D, draw DB to the angle opposite the side AC in which the point is taken; then divide the same side AC into as many parts AE, EF, FG, GC, and in the same proportion with the required parts of the triangle, like as was done in the last problem; and from the points of division draw lines EK, FI, GH, parallel to the line BD, and meeting the other sides of the triangle in K, I, H; lastly, draw KD, ID, HD, so shall ADK, KDI, IDHB, HDC be the parts required.—The example to this will be done exactly as the last.



For, the triangles ADK, KDI, IDB, being of the same height, are as their bases AK, KI, IB; which, by means of the parallels EK, FI, DB, are as AE, EF, FD; in like manner, the triangles CDH, HDB, are to each other as CG, GD: but the two triangles IDB, BDH, having the same base BD, are to each other as the distances of I and H from BD, or as FD to DG; consequently the parts DAK, DKI, DIBH, DHC, are to each other as AE, EF, FG, GC.

Surveying of Harbours.

The method of Surveying harbours, and of forming maps of them, as also of the adjacent coasts, sands, &c, depends on the same principles, and is chiefly conducted like that of common Surveying. The operation is indeed more complicated and laborious; as it is necessary to erect a number of signals, and to mark a variety of objects along the coast, with different bearings from one another, and the several parts of the harbour; and likewise to measure a great number of angles at

at different ſtations, whether on the land or the water. For this purpoſe, the beſt inſtrument is Hadley's quadrant, as all theſe operations may be performed by it, not only with greater eaſe, but alſo with much more preciſion, than can be hoped for by any other means, as it is the only inſtrument in uſe, in which neither the exactneſs of the obſervations, nor the eaſe with which they may be made, are ſenſibly affected by the motion of a veſſel: and hence a ſingle obſerver, in a boat, may generally determine the ſituation of any place at pleaſure, with a ſufficient degree of exactneſs, by taking the angles ſubtended by ſeveral pairs of objects properly choſen upon ſhores round about him; but it will be ſtill better to have two obſervers, or the ſame obſerver at different ſtations, to take the like angles to the ſeveral objects, and alſo to the ſtations. By this means, two angles and one ſide are given, in every triangle, from whence the ſituation of every part of them will be known. By ſuch obſervations, when carefully made with good inſtruments, the ſituation of places may be eaſily determined to 20 or 30 feet, or leſs, upon every 3 or 4 miles. See Philoſ. Tranſ. vol. 55, pa. 70; alſo Mackenzie's Maritime Surveying.

SURVEYING *Croſs*. See CROSS.

SURVEYING *Quadrant*. See QUADRANT.

SURVEYING *Scale*, the ſame with Reducing Scale.

SURVEYING *Wheel*. See PERAMBULATOR.

SURVIVORSHIP, the doctrine of reverſionary payments that depend upon certain contingencies, or contingent circumſtances.

Payments which are not to be made till ſome future period, are termed *reverſions*, to diſtinguiſh them from payments that are to be made immediately.

Reverſions are either *certain* or *contingent*. Of the former ſort, are all ſums or annuities, payable certainly or abſolutely at the expiration of any terms, or on the extinction of any lives. And of the latter ſort, are all ſuch reverſions as depend on any contingency; and particularly the Survivorſhip of any lives beyond or after other lives. An account of the former may be found under the articles Aſſurance, Annuities, and Life annuities. But the latter form the moſt intricate and difficult part of the doctrine of reverſions and life-annuities; and the books in which this ſubject is treated moſt at large, and at the ſame time with the moſt preciſion, are Mr. Simpſon's Select Exerciſes; Dr. Price's Reverſionary Payments; and Mr. Morgan's Annuities and Aſſurances on Lives and Survivorſhips. The whole likewiſe of the 3d volume of Dodſon's Mathematical Repoſitory is on this ſubject; but his inveſtigations are founded on De Moivre's falſe hypotheſis, viz of an equal decrement of life through all its ſtages, and which is explained under Life-annuities: but as this hypotheſis does not agree near enough to fact and experience, the rules deduced from it cannot be ſufficiently correct. For this reaſon, Dr. Price, and alſo the ingenious Mr. Maſeres, curſitor baron of the exchequer (in two volumes lately publiſhed, entitled the Principles of the Doctrine of Life Annuities), have diſcarded the valuations of lives grounded upon it; and the former in particular, in order to obviate all occaſion for uſing them, has ſubſtituted in their ſtead, a great variety of new tables of the probabilities and values of lives, at every age and in every ſituation; calculated, not upon any hypotheſis, but in ſtrict conformity to the beſt obſervations. Theſe tables, added to other new tables of the ſame kind, in Mr. Baron Maſeres's work juſt mentioned, form a complete ſet of tables, by which all queſtions relating to annuities on lives and Survivorſhips, may be anſwered with as much correctneſs as the nature of the ſubject allows.

Rules for calculating correctly, in moſt caſes, the values of reverſions depending on Survivorſhips, may be found in the three treatiſes juſt mentioned. Mr. Morgan, in particular, has gone a good way towards exhauſting this ſubject, as far as any queſtions can include in them any Survivorſhips between two or three lives, either for terms, or the whole duration of the lives.

There is, however, one circumſtance neceſſary to be attended to in calculating ſuch values, to which no regard could be paid till lately. This circumſtance is the ſhorter duration of the lives of males than of females; and the conſequent advantage in favour of females in all caſes of Survivorſhip. In the 4th edition of Dr. Price's Treatiſe on Reverſionary Payments, this fact is not only aſcertained, but ſeparate tables of the duration and values of lives are given for males and females.

SUSPENSION, in Mechanics, as in a balance, are thoſe points in the axis or beam where the weights are applied, or from which they are ſuſpended.

SUTTON's *Quadrant*. See QUADRANT.

SWAN, in Aſtronomy. See CYGNUS.

SWALLOW's-TAIL, in Fortification, is a ſingle Tenaille, which is narrower towards the place than towards the country.

SWING-*Wheel*, in a royal pendulum, is that wheel which drives the pendulum. In a watch, or balance clock, it is called the *crown-wheel*.

SYDEREAL *Day*, or *Year*. See SIDEREAL.

SYMMETRY, the relation of parity, both in reſpect of length, breadth, and height, of the parts neceſſary to compoſe a beautiful whole.

Symmetry ariſes from that proportion which the Greeks call *analogy*, which is the relation of conformity of all the parts of a building, and of the whole, to ſome certain meaſure; upon which depends the nature of Symmetry.

According to Vitruvius, Symmetry conſiſts in the union and conformity of the ſeveral members of a work to their whole, and of the beauty of each of the ſeparate parts to that of the intire work; regard being had to ſome certain meaſure: ſo the body, for inſtance, is framed with Symmetry, by the due relation which the arm, elbow, hand, fingers, &c, have to each other, and to their whole.

SYMPHONY, is a conſonance or concert of ſeveral ſounds agreeable to the ear; whether they be vocal or inſtrumental, or both; called alſo *harmony*.

The Symphony of the Ancients went no farther than to two or more voices or inſtruments ſet to uniſon; for they had no ſuch thing as muſic in parts; as is very well proved by Perrault: at leaſt, if ever they knew ſuch a thing, it muſt have been early loſt.

It is to Guido Aretine, about the year 1022, that moſt writers agree in aſcribing the invention of compoſition: it was he, they ſay, who firſt joined in one harmony ſeveral diſtinct melodies; and brought it even to

the length of 4 parts, viz. bass, tenor, counter-tenor, and treble.

The term Symphony is now applied to instrumental music, both that of pieces designed only for instruments, as sonatas and concertos, and that in which the instruments are accompanied with the voice, as in operas, &c.

A piece is said to be in grand Symphony, when, besides the bass and treble, it has also two other instrumental parts, viz. tenor and 5th of the violin.

SYNCHRONISM, the being or happening of several things together, at or in the same time.

The happening or performing of several things in equal times, as the vibrations of pendulums, &c, is more properly called *isochronism:* though some authors confound the two.

SYNCOPATION, in Music, denotes a striking or breaking of the time; by which the distinctness of the several times or parts of the measure is interrupted.

Syncopation, or Syncope, is more particularly used for the connecting the last note of one measure or bar with the first of the following measure; so as to make only one note of both.

Syncopation is also used when a note of one part ends on the middle of a note of the other part. This is otherwise called *binding.*

SYNODICAL *Month*, is the period or interval of time in which the moon passes from one conjunction with the sun to another. This period is also called a *Lunation*, since in this period the moon puts on all her phases, or appearances, as to increase and decrease. —Kepler found the quantity of the mean Synodical month to be 29 days, 12 hrs, 44 min. 3 sec. 11 thirds.

SYNTHESIS denotes a method of composition, as opposed to analysis.

In the Synthesis, or synthetic method, we pursue the truth by reasons drawn from principles before established, or assumed, and propositions formerly proved; thus proceeding by a regular chain till we come to the conclusion; and hence called also the *direct* method, and *composition*, in opposition to analysis or resolution.

Such is the method in Euclid's Elements, and most demonstrations of the ancient mathematicians, which proceed from definitions and axioms, to prove theorems &c, and from those theorems proved, to demonstrate others. See Analysis.

SYNTHETICAL *Method*, the method by Synthesis, or composition, or the direct method. See Synthesis.

SYPHON. See Siphon.

SYRINGE, in Hydraulics, a small simple machine, serving first to imbibe or suck in a quantity of water, or other fluid, and then to squirt or expel the same with violence in a small jet.

The Syringe is just a small single sucking pump, without a valve, the water ascending in it on the same principle. It consists, like the pump, of a small cylinder, with an embolus or sucker, moving up and down in it by means of a handle, and fitting it very close within. At the lower end is either a small hole, or a smaller tube fixed to it than the body of the instrument, through which the fluid or the water is drawn up, and squirted out again.

Thus, the embolus being first pushed close down, introduce the lower end of the pipe into the fluid, then draw up, by the handle, the sucker, and the fluid will immediately follow, so as to fill the whole tube of the Syringe, and will remain there, even when the pipe is taken out of the fluid; but by thrusting forward the embolus, it will drive the water before it; and, being partly impeded by the smallness of the hole, or pipe, it will hence be expelled in a smart jet or squirt, and to the greater distance, as the sucker is pushed down with the greater force, or the greater velocity.

This ascent of the water the Ancients, who supposed a plenum, attributed to Nature's abhorrence of a vacuum; but the Moderns, more reasonably, as well as more intelligibly, attribute it to the pressure of the atmosphere on the exterior surface of the fluid. For, by drawing up the embolus, the cavity of the cylinder would become a vacuum, or the air left there extremely rarefied; so that being no longer a counterbalance to the air incumbent on the surface of the fluid, this prevails, and forces the water through the little tube, or hole, up into the body of the Syringe.

SYSTEM, in a general Sense, denotes an assemblage or chain of principles and conclusions: or the whole of any doctrine, the several parts of which are bound together, and follow or depend on each other. As a System of astronomy, a System of planets, a System of philosophy, a System of motion, &c.

System, in Astronomy, denotes an hypothesis or a supposition of a certain order and arrangement of the several parts of the universe; by which astronomers explain all the phenomena or appearances of the heavenly bodies, their motions, changes, &c.

This is more peculiarly called the *System of the world*, and sometimes the *Solar System.*

System and hypothesis have much the same signification; unless perhaps hypothesis be a more particular System, and System a more general hypothesis.

Some late authors indeed make another distinction: an hypothesis, say they, is a mere supposition or fiction, founded rather on imagination than reason; while a System is built on the firmest ground, and raised by the severest rules; it is founded on astronomical observations, and physical causes, and confirmed by geometrical demonstrations.

The most celebrated Systems of the world, are the Ptolomaic, the Copernican or Pythagorean, and the Tychonic: the economy of each of which is as follows.

Ptolomaic System is so called from the celebrated astronomer Ptolomy. In this System, the earth is placed at rest, in the centre of the universe, while the heavens are considered as revolving about it, from east to west, and carrying along with them all the heavenly bodies, the stars and planets, in the space of 24 hours.

The principal assertors of this System, are Aristotle, Hipparchus, Ptolomy, and many of the old philosophers, followed by the whole world, for a great number of ages, and long adhered to in many universities, and other places. But the late improvements in philosophy and reasoning, have utterly exploded this erroneous System from the place it so long held in the minds of men.

Copernican System, is that System of the world which

which places the Sun at reſt, in the centre of the world, and the earth and planets all revolving round him, in their ſeveral orbits. See this more particularly explained under the article COPERNICAN *Syſtem.*

Solar or *Planetary* SYSTEM, is uſually confined to narrower bounds; the ſtars, by their immenſe diſtance, and the little relation they ſeem to bear to us, being accounted no part of it. It is highly probable that each fixed ſtar is itſelf a Sun, and the centre of a particular Syſtem, ſurrounded with a company of planets &c, which, in different periods, and at different diſtances, perform their courſes round their reſpective ſun, which enlightens, warms, and cheriſhes them. Hence we have a very magnificent idea of the world, and the immenſity of it. Hence alſo ariſes a kind of Syſtem of Syſtems.

The Planetary Syſtem, deſcribed under the article COPERNICAN, is the moſt ancient in the world. It was firſt of all, as far as we know, introduced into Greece and Italy by Pythagoras; from whom it was called the Pythagorean Syſtem. It was followed by Philolaus, Plato, Archimedes, &c: but it was loſt under the reign of the Peripatetic philoſophy; till happily retrieved about the year 1500 by Nic. Copernicus.

Tychonic SYSTEM, was taught by Tycho, a Dane; who was born An. Dom. 1546. It ſuppoſes that the earth is fixed in the centre of the univerſe or firmament of ſtars, and that all the ſtars and planets revolve round the earth in 24 hours; but it differs from the Ptolomaic Syſtem, as it not only allows a menſtrual motion to the moon round the earth, and that of the ſatellites about Jupiter and Saturn, in their proper periods, but it makes the ſun to be the centre of the orbits of the primary planets Mercury, Venus, Mars, Jupiter, &c, in which they are carried round the ſun in their reſpective years, as the ſun revolves round the earth in a ſolar year; and all theſe planets, together with the ſun, are ſuppoſed to revolve round the earth in 24 hours. This hypotheſis was ſo embarraſſed and perplexed, that very few perſons embraced it. It was afterwards altered by Longomontanus and others, who allowed the diurnal motion of the earth on its own axis, but denied its annual motion round the ſun. This hypotheſis, partly true and partly falſe, is called the *Semi-Tychonic Syſtem.* See the figure and economy of theſe Syſtems, in plates 30, 31, 32, 33.

SYSTEM, in Muſic, denotes a compound interval; or an interval compoſed, or conceived to be compoſed of ſeveral leſs intervals. Such is the octave, &c.

SYSTYLE, in Architecture, the manner of placing columns, where the ſpace between the two fuſts conſiſts of 2 diameters, or 4 modules.

SYZYGY, a term equally uſed for the conjunction and oppoſition of a planet with the ſun.

On the phenomena and circumſtances of the Syzygies, a great part of the lunar theory depends. See MOON. For,

1. It is ſhewn in the phyſical aſtronomy, that the force which diminiſhes the gravity of the moon in the Syzygies, is double that which increaſes it in the quadratures; ſo that, in the Syzygies, the gravity of the moon is diminiſhed by a part which is to the whole gravity, as 1 to 89·36; for in the quadratures, the addition of gravity is to the whole gravity, as 1 to 178·73.

2. In the Syzygies, the diſturbing force is directly as the diſtance of the moon from the earth, and inverſely as the cube of the diſtance of the earth from the ſun. And at the Syzygies, the gravity of the moon towards the earth receding from its centre, is more diminiſhed than according to the inverſe ratio of the ſquare of the diſtance from that centre.—Hence, in the moon's motion from the Syzygies to the quadratures, the gravity of the moon towards the earth is continually increaſed, and the moon is continually retarded in her motion; but in the moon's motion from the quadratures to the Syzygies, her gravity is continually diminiſhed, and the motion in her orbit is accelerated.

3. Farther, in the Syzygies, the moon's orbit, or circuit round the earth, is more convex than in the quadratures; for which reaſon ſhe is leſs diſtant from the earth at the former than the latter.—Alſo, when the moon is in the Syzygies, her apſes go backward, or are retrograde.—Moreover, when the moon is in the Syzygies, the nodes move in antecedentia faſteſt; then ſlower and ſlower, till they become at reſt when the moon is in the quadratures.—Laſtly, when the nodes are come to the Syzygies, the inclination of the plane of the orbit is the leaſt of all.

However, theſe ſeveral irregularities are not equal in each Syzygy, being all ſomewhat greater in the conjunction than in the oppoſition.

T.

TABLE, in Architecture, a ſmooth, ſimple member or ornament, of various forms, but moſt commonly in that of a parallelogram.

TABLE, in Perſpective, is ſometimes uſed for the perſpective plane, or the tranſparent plane upon which the objects are formed in their reſpective appearance.

TABLE *of Pythagoras*, is the ſame as the MULTIPLICATION

CATION Table; which see; as also PYTHAGORAS's Table.

TABLES *of Houses*, among astrologers, are certain Tables, ready drawn up, for the assistance of practitioners in that art, for the erecting or drawing of figures or schemes. See HOUSE.

TABLES, in Mathematics, are systems or series of numbers, calculated to be ready at hand for expediting any sort of calculations in the various branches of mathematics.

Astronomical TABLES, are computations of the motions, places, and other phenomena of the planets, both primary and secondary.

The oldest astronomical Tables, now extant, are those of Ptolomy, found in his Almagest. These however are not now of much use, as they no longer agree with the motions of the heavens.

In 1252, Alphonso XI, king of Castile, undertook the correcting of them, chiefly by the assistance of Isaac Hazen, a learned Jew; and spent 400,000 crowns on the business. Thus arose the *Alphonsine Tables*, to which that prince himself prefixed a preface. But the deficiency of these also was soon perceived by Purbach and Muller, or Regiomontanus; upon which the latter, and after him Walther Warner, applied themselves to celestial observations, for farther improving them; but death, or various difficulties, prevented the effect of these good designs.

Copernicus, in his books of the celestial revolutions, gives other Tables, calculated by himself, partly from his own observations, and partly from the Alphonsine Tables.

From Copernicus's observations and theorems, Erasmus Reinhold afterwards compiled the *Prutenic Tables*, which have been printed several times, and in several places.

Tycho Brahe, even in his youth, became sensible of the deficiency of the Prutenic Tables: which determined him to apply himself with so much vigour to celestial observations. From these he adjusted the motions of the sun and moon; and Longomontanus, from the same observations, made out Tables of the motions of the planets, which he added to the Theories of the same, published in his Astronomia Danica; those being called the *Danish Tables*. And Kepler also, from the same observations, published in 1627 his *Rudolphine Tables*, which are much esteemed.

These were afterwards, viz in 1650, changed into another form, by Maria Cunitia, whose Astronomical Tables, comprehending the effect of Kepler's physical hypothesis, are very easy, satisfying all the phenomena without any mention of logarithms, and with little or no trouble of calculation. So that the Rudolphine calculus is here greatly improved.

Mercator made a like attempt in his Astronomical Institution, published in 1676. And the like did J. Bap. Morini, whose abridgment of the Rudolphine Tables was prefixed to a Latin version of Street's Astronomia Carolina, published in 1705.

Lansbergius indeed endeavoured to discredit the Rudolphine Tables, and framed *Perpetual Tables*, as he calls them, of the heavenly motions. But his attempt was never much regarded by the astronomers; and our countryman Horrox warmly attacked him, in his defence of the Keplerian astronomy.

Since the Rudolphine Tables, many others have been framed, and published: as the *Philolaic Tables* of Bulliald; the *Britannic Tables* of Vincent Wing, calculated on Bulliald's hypothesis; the *Britannic Tables* of John Newton; the French ones of the Count Pagan; the *Caroline Tables* of Street, all calculated on Ward's hypothesis; and the *Novalmagestic Tables* of Riccioli. Among these, however, the Philolaic and Caroline Tables are esteemed the best; insomuch that Mr. Whiston, by the advice of Mr. Flamsteed, thought fit to subjoin the Caroline Tables to his astronomical lectures.

The *Ludovician Tables*, published in 1702, by De la Hire, were constructed wholly from his own observations, and without the assistance of any hypothesis; which, before the invention of the micrometer telescope and the pendulum clock, was held impossible.

Dr. Halley also long laboured to perfect another set of Tables; which were printed in 1719, but not published till 1752.

M. Monnier, in 1746, published, in his Institutions Astronomiques, Tables of the motions of the sun and moon, with the satellites, as also of refractions, and the places of the fixed stars. La Hire also published Tables of the planets, and La Caille Tables of the sun: Gael Morris published Tables of the sun and moon, and Mayer constructed Tables of the moon, which were published by the Board of Longitude. Tables of the same have also been computed by Charles Mason, from the principles of the Newtonian philosophy, which are found to be very accurate, and are employed in computing the Nautical Ephemeris. Many other sets of astronomical Tables have also been published by various persons and academies; and divers sets of them may be found in the modern books of astronomy, navigation, &c, of which those are esteemed the best and most complete, that are printed in Lalande's Astronomy. For an account of several, and especially of those published annually under the direction of the Commissioners of Longitude, see ALMANAC, EPHEMERIS, and LONGITUDE.

For TABLES *of the Stars*, see CATALOGUE.

TABLES of *Sines*, *Tangents*, and *Secants*, used in trigonometry, &c, are usually called CANONS. See SINE.

TABLES *of Logarithms*, *Rhumbs*, *&c*, used in geometry, navigation, &c, see LOGARITHM, and RHUMB.

TABLES, *Loxodromic*, and *of Difference of Latitude and Departure*, are Tables used in computing the way and reckoning of a ship on a voyage, and are published in most books of navigation.

TACQUET (ANDREW), a Jesuit of Antwerp, who died in 1660. He was a most laborious and voluminous writer in mathematics. His works were collected, and printed at Antwerp in one large volume in folio, 1669.

TACTION, in Geometry, the same as tangency, or touching. See TANGENT.

TALUS, or TALUD, in Architecture, the inclination or slope of a work; as of the outside of a wall, when its thickness is diminished by degrees, as it rises in height, to make it the firmer.

Talus, in Fortification, means also the slope of a work, whether of earth or masonry.

The *Exterior Talus* of a work, is its slope on the side outwards or towards the country; which is always made as little as possible, to prevent the enemy's escalade, unless the earth be bad, for then it is necessary to allow a considerable Talus for its parapet, and sometimes to support the earth with a slight wall, called a revetement.

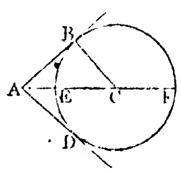
The *Interior Talus* of a work, is its slope on the inside, towards the place. This is larger than the former, and it has, at the angles of the gorge, and sometimes in the middle of the curtains, ramps, or sloping roads for mounting upon the terreplain of the rampart.

Superior Talus *of the Parapet*, is a slope on the top of the parapet, that allows of the soldiers defending the covert-way with small-shot, which they could not do if it were level.

TAMBOUR, in Architecture, a term applied to the Corinthian and Composite capitals, as bearing some resemblance to a tambour or drum.

TAMUZ, in Chronology, the 4th month of the Jewish ecclesiastical year, answering to part of our June and July. The 17th day of this month is observed by the Jews as a fast, in memory of the destruction of Jerusalem by Nebuchadnezzar, in the 11th year of Zedekiah, and the 588th before Christ.

TANGENT, in Geometry, is a line that touches a curve, &c, that is, which meets it in a point without cutting it there, though it be produced both ways; as the Tangent AB of the circle BD. The point B, where the Tangent touches the curve, is called the *point of contact*.



The direction of a curve at the point of contact, is the same as the direction of the Tangent.

It is demonstrated in Geometry;

1. That a Tangent to a circle, as AB, is perpendicular to the radius BC drawn to the point of contact.

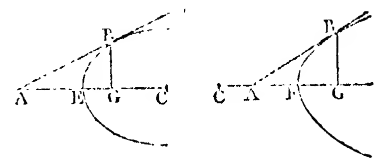
2. The Tangent AB is a mean proportional between AF and AE, the whole secant and the external part of it; and the same for any other secant drawn from the same point A.

3. The two Tangents AB and AD, drawn from the same point A, are always equal to one another. And therefore also, if a number of Tangents be drawn to different points of the curve quite around, and an equal length BA be set off upon each of them from the points of contact, the locus of all the points A will be a circle having the same centre C.

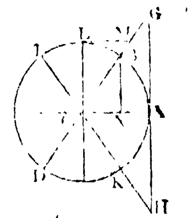
4. The angle of contact ABE, formed at the point of contact, between the Tangent AB and the arc BE, is less than any rectilineal angle.

5. The Tangent of an arc is the right line that limits the position of all the secants that can pass through the point of contact; though strictly speaking it is not one of the secants, but only the limit of them.

6. As a right line is the Tangent of a circle, when it touches the circle so closely, that no right line can be drawn through the point of contact between it and the arc, or within the angle of contact that is formed by them; so, in general, when any right line touches an arc of any curve, in such a manner, that no right line can be drawn through the point of contact, between the right line and the arc, or within the angle of contact that is formed by them, then is that line the Tangent of the curve at the said point; as AB.



7. In all the conic sections; if C be the centre of the figure, and BG an ordinate drawn from the point of contact and perpendicular to the axis; then is CG : CE : : CE : CA, or the semiaxis CE is a mean proportional between CG and CA.



Tangent, in Trigonometry. A Tangent *of an arc*, is a right line drawn touching one extremity of the arc, and limited by a secant or line drawn through the centre and the other extremity of the arc.

So, AG is the Tangent of the arc AB, or of the arc ABD; and AH is the Tangent of the arc AI, or of the arc AIDK.

The same are also the Tangents of the angles that are subtended or measured by the arcs.

Hence, 1. The Tangents in the 1st and 3d quadrants are positive, in the 2d and 4th negative, or drawn the contrary way. But of 0 or 180° the semicircle, the Tangent is 0 or nothing; while those of 90° or a quadrant, and 270° or 3 quadrants, are both infinite; the former infinitely positive, and the latter infinitely negative. That is,

Between 0 and 90°, or bet. 180° and 270°, the Tangents are positive.
Bet. 90° and 180°, or bet. 270° and 360°, the Tangents are negative.

2. The Tangent of an arc and the Tangent of its supplement, are equal, but of contrary affections, the one being positive, and the other negative;

as of a and $180° - a$, where a is any arc.

Also $180° + a$ and a } have the same Tangent, and of the same affection.

Or $180° + a$ and $180° - a$ } have the same Tangent, but of different affections.

3. The Tangent of an arc is a 4th proportional to the cosine the sine and the radius; that is, CN : NB : : CA : AG. Hence, a canon of sines being made or given, the canon of Tangents is easily constructed from them.

Co-Tangent, contracted from complement-tangent, is the Tangent of the complement of the arc or angle, or of what it wants of a quadrant or 90°. So LM is the Cotangent of the arc AB, being the Tangent of its complement BL.

The Tangent is reciprocally as the cotangent; or the Tangent

Tangent and cotangent are reciprocally proportional with the radius. That is Tang. is as $\frac{1}{\text{cotan.}}$, or Tang. : radius :: radius : cotan. And the rectangle of the Tangent and cotangent is equal to the square of the radius; that is, Tan. $\times$ cot. $=$ radius^2.

Artificial TANGENTS, or *logarithmic* TANGENTS, are the logarithms of the tangents of arcs; so called, in contradistinction from the natural Tangents, or the Tangents expressed by the natural numbers.

Line of TANGENTS, is a line usually placed on the sector, and Gunter's scale; the description and uses of which see under the article SECTOR.

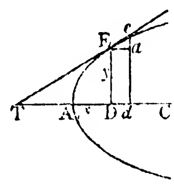
Sub-TANGENT, a line lying beneath the Tangent, being the part of the axis intercepted by the Tangent and the ordinate to the point of contact; as the line AG in the 2d and 3d figures above.

Method of TANGENTS, is a method of determining the quantity of the Tangent and subtangent of any algebraic curve; the equation of the curve being given.

This method is one of the great results of the doctrine of fluxions. It is of great use in Geometry; because that in determining the Tangents of curves, we determine at the same time the quadrature of the curvilinear spaces: on which account it deserves to be here particularly treated on.

To Draw the Tangent, or to find the Subtangent, of a curve.

If AE be any curve, and E any point in it, to which it is required to draw a Tangent TE. Draw the ordinate DE: then if we can determine the subtangent TD, by joining the points T and E, the line TE will be the Tangent fought.



Let *dae* be another ordinate indefinitely near to DE, meeting the curve, or Tangent produced, in e; and let Ea be parallel to the axis AD. Then is the elementary triangle Eae similar to the triangle TDE;

and therefore - ea : aE :: ED : DS ;
but - - - - - - - ea : aE :: flux. ED : flux. AD;
therefore - - - - flux. ED : flux. AD :: DE : DT;

that is - - - - - $\dot{y} : \dot{x} :: y : \frac{y\dot{x}}{\dot{y}} =$ DT,

which is therefore the value of the subtangent sought; where x is the abscis AD, and y the ordinate DE.

Hence we have this general rule: By means of the given equation of the curve, find the value either of $\dot{x}$ or $\dot{y}$, or of $\frac{\dot{x}}{\dot{y}}$, which value substitute for it in the expression DT $= \frac{y\dot{x}}{\dot{y}}$, and, when reduced to its simplest terms, it will be the value of the subtangent sought. This we may illustrate in the following examples.

Ex. 1. The equation defining a circle is $2ax - xx = y^2$, where a is the radius; and the fluxion of this is $2a\dot{x} - 2x\dot{x} = 2y\dot{y}$; hence $\frac{\dot{x}}{\dot{y}} = \frac{y}{a-x}$; this multiplied by y, gives $\frac{y\dot{x}}{\dot{y}} = \frac{y^2}{a-x} = \frac{\text{DE}^2}{\text{CD}} =$ the subtangent TD, or CD : DE :: DE : TD, which is a property of the circle we also know from common geometry.

Ex. 2. The equation defining the common parabola is $ax = y^2$, a being the parameter, and x and y the abscis and ordinate in all cases. The fluxion of this is $a\dot{x} = 2y\dot{y}$; hence $\frac{\dot{x}}{\dot{y}} = \frac{2y}{a}$; conseq. $\frac{y\dot{x}}{\dot{y}} = \frac{2y^2}{a} = \frac{2ax}{a} = 2x =$ TD; that is, the subtangent TD is double the abscis AD, or TA is $=$ AD, which is a well-known property of the parabola.

Ex. 3. The equation defining an ellipsis is $c^2.\overline{2ax-x^2} = a^2y^2$, where a and c are the semiaxes. The fluxion of it is $c^2.2a\dot{x} - 2x\dot{x} = 2a^2y\dot{y}$; hence
$\frac{y\dot{x}}{\dot{y}} = \frac{a^2y^2}{c^2(a-x)} = \frac{c^2(2ax-x^2)}{c^2(a-x)} = \frac{2a-x}{a-x}x =$ TD the subtangent; or by adding CD which is $= a-x$, it becomes CT $= \frac{2ax-x^2}{a-x} + a - x = \frac{a^2}{a-x} = \frac{\text{CA}^2}{\text{CD}}$, or CD : CA :: CA : CT, a well-known property of the ellipse.

Ex. 4. The equation defining the hyperbola is $c^2.\overline{2ax + x^2} = a^2y^2$, which is similar to that for the ellipse, having only $+ x^2$ for $- x^2$; hence the conclusion is exactly similar also, viz,

$\frac{2a+x}{a+x}x$ or $\frac{2ax+xx}{a+x} =$ TD, which taken from CD or $a+x$, gives CT $= \frac{\text{CA}^2}{\text{CD}}$, or CD : CA :: CA : CT.

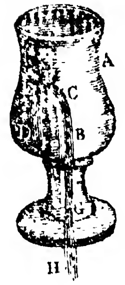
And so on, for the Tangents to other curves.

The Inverse Method of TANGENTS. This is the reverse of the foregoing, and consists in finding the nature of the curve that has a given subtangent. The method of solution is to put the given subtangent equal to the general expression $\frac{y\dot{x}}{\dot{y}}$, which serves for all sorts of curves; then the equation reduced, and the fluents taken, will give the fluential equation of the curve sought.

Ex. 1. To find the curve line whose subtangent is $= \frac{2y^2}{a}$. Here $\frac{2y^2}{a} = \frac{y\dot{x}}{\dot{y}}$; hence $2y\dot{y} = a\dot{x}$, and the fluents of this give $y^2 = ax$, the equation to a parabola, which therefore is the curve sought.

Ex. 2. To find the curve whose subtangent is $= \frac{yy}{2a-x}$, or a third proportional to $2a - x$ and y. Here $\frac{yy}{2a-x} = \frac{y\dot{x}}{\dot{y}}$; hence $y\dot{y} = 2a\dot{x} - x\dot{x}$, the fluents of which give $y^2 = ax - x^2$, the equation to a circle, which therefore is the curve sought.

TANTALUS's *Cup*, in Hydraulics, is a cup, as A, with a hole in the bottom, and the longer leg of a fyphon BCED cemented into the hole; fo that the end D of the fhorter leg DE may always touch the bottom of the cup within. Then, if water be poured into this cup, it will rife in the fhorter leg by its upward preffure, extruding the air before it through the longer leg, and when the cup is filled above the bend of the fyphon at E, the preffure of the water in the cup will force it over the bend; from whence it will defcend in the longer leg EB, and through the bottom at G, till the cup be quite emptied. The legs of this fyphon are almoft clofe together, and it is fometimes concealed by a fmall hollow ftatue, or figure of a man placed over it; the bend E being within the neck of the figure as high as the chin. So that poor thirfty Tantalus ftands up to the chin in water, according to the fable, imagining it will rife a little higher, as more water is poured in, and he may drink; but inftead of that, when the water comes up to his chin, it immediately begins to defcend, and therefore, as he cannot ftoop to follow it, he is left as much tormented with thirft as ever. Ferguson's Lect. p. 72, 4to.



TARRANTIUS (Lucius), furnamed *Firmanus*, becaufe he was a native of Firmum, a town in Italy, flourifhed at the fame time with Cicero, and was one of his friends. He was a mathematical philofopher, and therefore was thought to have great fkill in judicial aftrology. He was particularly famous by two horofcopes which he drew, the one the horofcope of Romulus, and the other of Rome. Plutarch fays, "Varro, who was the moft learned of the Romans in hiftory, had a particular friend named Tarrantius, who, out of curiofity, applied himfelf to draw horofcopes, by means of aftronomical tables, and was efteemed the moft eminent in his time." Hiftorians controvert fome particular circumftances of his calculations; but all agree in conferring on him the honorary title *Prince of aftrologers*.

TARTAGLIA, or Tartalea (Nicholas), a noted mathematician who was born at Brefcia in Italy, probably towards the conclufion of the 15th century, as we find he was a confiderable mafter or preceptor in mathematics in the year 1521, when the firft of his collection of queftions and anfwers was written, which he afterwards publifhed in the year 1546, under the title of *Quefiti et Inventioni diverfe*, at Venice, where he then refided as a public lecturer on mathematics, he having removed to this place about the year 1534. This work confifts of 9 chapters, containing anfwers to a number of queftions on all the different branches of mathematics and philofophy then in vogue. The laft or 9th of thefe, contains the queftions in Algebra, among which are thofe celebrated letters and communications between Tartalea and Cardan, by which our author put the latter in poffeffion of the rules for cubic equations, which he firft difcovered in the year 1530.

But the firft work of Tartalea's that was publifhed, was his *Nova Scientia inventa*, in 4to, at Venice in 1537. This is a treatife on the theory and practice of gunnery, and the firft of the kind, he being the firft writer on the flight and path of balls and fhells. This work was tranflated into Englifh, by Lucar, and printed at London in 1588, in folio, with many notes and additions by the tranflator.

Tartalea publifhed at Venice, in folio, 1543, the whole books of Euclid, accompanied with many curious notes and commentaries.

But the laft and chief work of Tartalea, was his *Trattato di Numeri et Mifure*, in folio, 1556 and 1560. This is an univerfal treatife on arithmetic, algebra, geometry, menfuration, &c. It contains many other curious particulars of the difputes between our author and Cardan, which ended only with the death of Tartalea, before the laft part of this work was publifhed, or about the year 1558.

For many other circumftances concerning Tartalea and his writings, fee the article Algebra, vol. 1, pa. 73.

TATIUS (Achilles), an ancient Greek writer of Alexandria; but the age he lived in is uncertain. According to Suidas, who calls him Statius, he was at firft a Heathen, then a Chriftian, and afterwards a bifhop. He wrote a book upon the Sphere, which feems to have been nothing more than a commentary upon Aratus. Part of it is extant, and was tranflated into Latin by father Petavius, under the title of *Ifagoges in Phænomena Arati*. He wrote alfo, *Of the Loves of Clitophon and Leucippe*, in 8 books. He is well fpoken of by Photius.

TAURUS, *the Bull*, in Aftronomy, one of the 12 figns in the zodiac, and the fecond in order.

The Greeks fabled that this was the bull which carried Europa fafe acrofs the feas to Crete; and that Jupiter, in reward for fo fignal a fervice, placed the creature, whofe form he had affumed on that occafion, among the ftars, and that this is the conftellation formed of it. But it is probable that the Egyptians, or Babylonians, or whoever invented the conftellations of the zodiac, placed this figure in that part of it which the fun entered about the time of the bringing forth of calves; like as they placed the ram in the firft part of fpring, as the lambs appear before them, and the two kids (for that was the original figure of the fign Gemini), afterward, to denote the time of the goats bringing forth their young.

In the conftellation Taurus there are fome remarkable ftars that have names; as Aldebaran in the fouth or right eye of the bull, the clufter called the Pleiades in the neck, and the clufter called Hyades in the face.

The ftars in the conftellation Taurus, in Ptolomy's catalogue are 44, in Tycho's catalogue 43, in Hevelius's catalogue 51, and in the Britannic catalogue 141.

TEBET, or Thevet, the 4th month of the civil year of the Hebrews, and the 10th of their ecclefiaftical year. It anfwered to part of our December and January, and had only 29 days.

TEETH, of various forts of machines, as of mill wheels, &c. Thefe are often called cogs by the workmen; and by working in the pinions, rounds, or trundles, the wheels are made to turn one another.

Mr. Emerfon (in his Mechanics, prop. 25), treats of the theory of Teeth, and fhews that they ought to

 have

have the figure of epicycloids, for properly working in one another. Camus too (in his Cours de Mathematique, tom. 2, p. 349, &c, Edit. 1767) treats more fully on the fame fubject; and demonftrates that the Teeth of the two wheels fhould have the figures of epicycloids, but that the generating circles of thefe epicycloids fhould have their diameters only the half of what Mr. Emerfon makes them.

Mr. Emerfon obferves, that the Teeth ought not to act upon one another before they arrive at the line which joins their centres. And though the inner or under fides of the Teeth may be of any form; yet it is better to make them both fides alike, which will ferve to make the wheels turn backwards. Alfo a part may be cut away on the back of every Tooth, to make way for thofe of the other wheel. And the more Teeth that work together, the better; at leaft one Tooth fhould always begin before the other hath done working. The Teeth ought to be difpofed in fuch manner as not to trouble or hinder one another, before they begin to work; and there fhould be a convenient length, depth and thicknefs given to them, as well for ftrength, as that they may more eafily difengage themfelves.

TELEGRAPH, a machine brought into ufe by the French nation, in the year 1793, contrived to communicate words or fignals from one perfon to another at a great diftance, in a very fmall fpace of time.

The Telegraph it feems was originally the invention of William Amontons, an ingenious philofopher, born in Normandy in the year 1663. See his life in this Dictionary, vol. 1, pa. 105; where it is related that he pointed out a method to acquaint people at a great diftance, and in a very little time, with whatever one pleafed. This method was as follows: let perfons be placed in feveral ftations, at fuch diftances from each other, that, by the help of a telefcope, a man in one ftation may fee a fignal made by the next before him: this perfon immediately repeats the fame fignal to the third man; and this again to a fourth, and fo on through all the ftations to the laft.

This, with confiderable improvements, it feems has lately been brought into ufe by the French, and called a Telegraph. It is faid they have availed themfelves of this contrivance to good purpofe, in the prefent war; and from the utility of the invention, it has alfo juft been brought into ufe in this country.

The following account of this curious inftrument is copied from Barrere's report in the fitting of the French Convention of Auguft 15, 1794.—"The new-invented telegraphic language of fignals is an artful contrivance to tranfmit thoughts, in a peculiar language, from one diftance to another, by means of machines, which are placed at different diftances, of from 12 to 15 miles from one another, fo that the expreffion reaches a very diftant place in the fpace of a few minutes. Laft year an experiment of this invention was tried in the prefence of feveral Commiffioners of the Convention. From the favourable report which the latter made of the efficacy of the contrivance, the Committee of Public Welfare tried every effort to eftablifh, by this means, a correfpondence between Paris and the frontier places, beginning with Lifle. Almoft a whole twelvemonth has been fpent in collecting the neceffary inftruments for the machines, and to teach the people employed how to ufe them. At prefent, the telegraphic language of fignals is prepared in fuch a manner, that a correfpondence may be conducted with Lifle upon every fubject, and that every thing, nay even proper names, may be expreffed; an anfwer may be received, and the correfpondence thus be renewed feveral times a day. The machines are the invention of Citizen Chappe, and were conftructed under his own eye; he alfo directs their eftablifhment at Paris. They have the advantage of refifting the changes in the atmofphere, and the inclemencies of the feafons. The only thing which can interrupt their effect is, if the weather is fo very bad and turbid that the objects and fignals cannot be diftinguifhed. By this invention, remotenefs and diftance almoft difappear; and all the communications of correfpondence are effected with the rapidity of the twinkling of an eye. The operations of Government can be very much facilitated by this contrivance, and the unity of the Republic can be the more confolidated by the fpeedy communication with all its parts. The greateft advantage which can be derived from this correfpondence is, that, if one choofes, its object fhall only be known to certain individuals, or to one individual alone, or to the extremities of any diftance; fo that the Committee of Public Welfare may now correfpond with the Reprefentative of the People at Lifle without any other perfons getting acquainted with the object of the correfpondence. Hence it follows that, were Lifle even befieged, we fhould know every thing at Paris that might happen in that place, and could fend thither the Decrees of the Convention without the enemy's being able to difcover or to prevent it."—The defcription and figure of the French machine, as given in fome Englifh prints, are as follow.

Explanation of the Machine (Telegraph) placed on the Mountain of Bellville, near Paris, for the purpofe of communicating Intelligence.

AA is a beam or maft of wood, placed upright on a rifing ground (fig. 3, pl. 28) which is about 15 or 16 feet high. BB is a beam or balance, moving upon the centre AA. This balance-beam may be placed vertically, or horizontally, or any how inclined, by means of ftrong cords, which are fixed to the wheel D, on the edge of which is a double groove, to receive the two chords. This balance is about 11 or 12 feet long, and 9 inches broad, having at the ends two pieces of wood CC, which likewife turn upon angles by means of four other cords that pafs through the axis of the main balance, otherwife the balance would derange the cords; the pieces C are each about 3 feet long, and may be placed either to the right or left, ftraight or fquare with the balance-beam. By means of thefe three, the combination of movement is faid to be very extenfive, remarkably fimple, and eafy to perform. Below is a fmall wooden gouge or hut, in which a perfon is employed to obferve the movements of the machine. In the mountain neareft to this, another perfon is to repeat thefe movements, and a third to write them down. The time taken up for each movement is 20 feconds; of which the motion alone is 4 feconds, the other 16 the machine is ftationary. The ftations of this machine are about 3 or 4 leagues diftance; and there is an obfervatory near the Committee of Public

Safety to obſerve the motions of the laſt, which is at Bellville. The ſigns are ſometimes made in words, and ſometimes in letters; when in words, a ſmall flag is hoiſted, and, as the alphabet may be changed at pleaſure, it is only the correſponding perſon who knows the meaning of the ſigns. In general, news are given every day, about 11 or 12 o'clock; but the people in the wooden gouge obſerve from time to time, and, as ſoon as a certain ſignal is given and anſwered, they begin, from one end to the other, to move the machine. It is painted of a dark brown colour.

Such is the account given of the French invention. Various improved contrivances have been ſince made in England, and a pamphlet has lately been publiſhed, giving an account of ſome of them, by the Rev. J. Gamble, under the title of, *Obſervations and Telegraphic Experiments*, from whence the following remarks are extracted.

The object propoſed is, to obtain an intelligible figurative language, which may be diſtinguiſhed at a diſtance, and by which the obvious delay in the diſpatch of orders or information by meſſenger may be avoided.

On firſt reflection we find the practical modes of ſuch diſtant communication muſt be confined to Sound and Viſion. Each of which is in a great degree ſubject to the ſtate of the atmoſphere: as, independent of the wind's direction, it is known that the air is ſometimes ſo far deprived of its elaſticity, or whatever other quality the conveyance of ſound depends on, that the heavieſt ordnance is ſcarce heard farther than the ſhot flies; it is alſo well known, that in thick hazy weather the largeſt objects become totally obſcured at a ſhort diſtance. No inſtrument therefore deſigned for the purpoſe can be perfect. We can only endeavour to diminiſh theſe irremediable defects as much as may be.

It ſeems the Romans had a method in their walled cities, either by a hollow formed in the maſonry, or by tubes affixed to it, ſo to confine and augment ſound as to convey information to any part they wiſhed; and in lofty houſes it is now ſometimes the cuſtom to have a pipe, by way of ſpeaking trumpet, to give orders from the upper apartments to the lower: by this mode of confining ſound its volume may be carried to a very great diſtance; but beyond a certain extent the ſound, loſing articulation, would only convey alarm, not give directions.

Every city among the antients had its watch-towers; and the caſtra ſtativa of the Romans, had always ſome ſpot, elevated either by nature or art, from whence ſignals were given to the troops cantoned or foraging in the neighbourhood. But I believe they had not arrived to greater refinement than that on ſeeing a certain ſignal they were immediately to repair to their appointed ſtations.

A beacon or bonfire made of the firſt inflammable materials that offered, as the moſt obvious, is perhaps the moſt antient mode of general alarm; and by being previouſly concerted, the number or point where the fires appeared might have its particular intelligence affixed. The ſame obſervations may be referred to the throwing up of rockets, whoſe number or point from whence thrown may have its affixed ſignification.

Flags or enſigns with their various devices are of earlieſt invention, eſpecially at ſea; where, from the firſt idea, which moſt probably was that of a vane to ſhew the direction of the wind, they have been long adopted as the diſtinguiſhing mark of nations, and are now ſo neatly combined by the ingenuity of a great naval commander, that by his ſyſtem every requiſite order and queſtion is received and anſwered by the moſt diſtant ſhips of a fleet.

To the adopting this or a ſimilar mode in land ſervice, the following are objections: That in the latter caſe, the variety of matter neceſſary to be conveyed, is ſo infinitely greater, that the combinations would become too complicated. And if the perſon for whom the information is intended ſhould be in the direction of the wind, the flag would then preſent a ſtraight line only, and at a little diſtance be ſcarce viſible. The Romans were ſo well aware of this inconvenience of flags, that many of their ſtandards were ſolid, and the name manipulus denotes the rudeſt of their modes, which was a truſs of hay fixed on a pole.

The principle of water always keeping its own level has been ſuggeſted, as a mode of conveying intelligence, by Mr. Daniel Brent, of Rotherhithe, and put in practice on a ſmall ſcale. As for example, ſuppoſe a pipe AB to reach from London to Dover, and to have a per-

pendicular tube connected to each extremity, as AC and BD. Then, if the pipe be conſtantly filled with water to a certain height, as AE, it will alſo riſe to its level in the oppoſite perpendicular tube BF; and if one inch of water be added in the tube AC, it will almoſt inſtantly produce a ſimilar elevation of the tube BD; ſo that by correſponding letters being adapted to the tubes AC and BD, at different heights, intelligence might be conveyed. But the method is liable to ſuch objections, that it is not likely it can ever be adopted to facilitate the object of very diſtant communication.

Full as many, if not greater objections, will perhaps operate againſt every mode of electricity being uſed as the vehicle of information.—And the requiſite magnitude of painted or illuminated letters offers an unſurmountable obſtacle; beſides, in them one object would be loſt, that of the language being figurative.

As to the French machine, it is evident that to every angular change of the greater beam or of the leſſer end arms, a different letter or figure may be annexed. But where the whole difference conſiſts in the variation of the angle of the greater or leſſer pieces, much error may be expected, from the inaccuracy either of the operator or the obſerver: beſides other inconveniences ariſing from the great magnitude of the machinery.

Another idea is perfectly numerical; which is to raiſe and depreſs a flag or curtain a certain number of times for each letter, according to a previouſly concerted ſyſtem: as, ſuppoſe one elevation to mean A, two to mean B, and ſo on through the alphabet. But in this caſe, the leaſt inaccuracy in giving or noting the number

number changes the letter; and beſides, the laſt letters of the alphabet would be a tedious operation.

Another method that has been propoſed, is an ingenious combination of the magnetical experiment of Comus, and the teleſcopic micrometer. But as this is only an imperfect idea of Mr. Garnet's very ingenious machine, deſcribed in the latter part of this article, no farther notice need be taken of it here.

Mr. Gamble then propoſes one on a new idea of his own. The principle of it is ſimply that of a Venetian blind, or rather what are called the lever boards of a brewhouſe, which, when horizontal, preſent ſo ſmall a ſurface to the diſtant obſerver, as to be loſt to his view, but are capable of being in an inſtant converted into a ſcreen of a magnitude adapted to the required diſtance of viſion.—Let AB and CD (fig. 4. pl. 28), two upright poſts fixed in the ground, and joined by the braces BD and EF, be conſidered as the frame work for 9 lever boards working upon centres in EB and DF, and opening in three diviſions by iron rods connected with each three of the lever boards. Let *abcd* and *efgh* be two leſſer frames fixed to the great one, having alſo three lever boards in each, and moving by iron rods, in the ſame manner as the others. If all theſe rods be brought ſo near the ground as to be in the management of the operator, he will then have five, of what may be called, keys to play on. Now as each of the handles *ik'mn* commands three lever boards, by raiſing any one of them, and fixing it in its place by a catch or hook, it will give a different appearance to the machine; and by the proper variation of theſe five movements, there will be more than 25 of what may be called mutations, in each of which the machine exhibits a different appearance, and to which any letter or figure may be annexed at pleaſure.

Should it be required to give intelligence in more than one direction, the whole machine may be eaſily made to turn to different points on a ſtrong centre, after the manner of a ſingle-poſt windmill.—To uſe this machine by night, another frame muſt be connected with the back part of the Telegraph, for raiſing five lamps, of different colours, behind the openings of the lever boards; theſe lamps by night anſwer for the openings by day.

M. Gamble gives alſo particular directions for placing and uſing the machine, and for writing down the ſeveral figures or movements.

I ſhall now conclude this article with a ſhort idea of Mr. John Garnet's moſt ſimple and ingenious contrivance. This is merely a bar or plank turning upon a centre, like the ſail of a windmill, and being moved into any poſition, the diſtant obſerver turns the tube of a teleſcope into the ſame poſition, by bringing a fixed wire within it to coincide with or parallel to the bar, which is a thing extremely eaſy to do. The centre of motion of the bar has a ſmall circle about it, with letters and figures around the circumference, and an index moving round with the bar, pointing to any letter or mark that the operator wiſhes to ſet the bar to, or to communicate to the obſerver. The eye end of the teleſcope without has a like index and circle, with the correſponding letters or other marks. The conſequence is obvious: the teleſcope being turned round till its wire cover or become parallel to the bar, the index of the former neceſſarily points out the ſame letter or mark in its circle, as that of the latter, and the communication of ſentiment is immediate and perfect. The uſe of this machine is ſo eaſy, that I have ſeen it put into the hands of two common labouring men, who had never ſeen it before, and they have immediately held a quick and diſtant converſation together.

The more particular deſcription and figure of this machine, take as follows. ABDE (fig. 5, pl. 28), is the Telegraph, on whoſe centre of gravity C, about which it revolves, is a fixed pin, which goes through a hole or ſocket in the firm upright poſt G, and on the oppoſite ſide of which is fixed an index CI. Concentric to C, on the ſame poſt, is fixed a wooden or braſs circle, of 6 or 8 inches diameter, divided into 48 equal parts, 24 of which repreſent the letters of the alphabet, and between the letters, numbers. So that the index, by means of the arm AB, may be moved to any letter or number. The length of the arm ſhould be 2½ or 3 feet for every mile of diſtance. Two revolving lamps of different colours ſuſpended occaſionally at A and B, the ends of the arm, would ſerve equally at night.

Let *ss* (fig. 6, pl. 28) repreſent the ſection of the outward tube of a teleſcope perpendicular to its axis, and *xx* the like ſection of the ſliding or adjuſting tube, on which is fixed an index II. On the part of the outward tube next to the obſerver, there is fixed a circle of letters and numbers, ſimilarly divided and ſituated to the circle in figure 3; then the index II, by means of the ſliding or adjuſting tube, may be turned to any letter or number.—Now there being a croſs hair, or fine ſilver wire *fg*, fixed in the focus of the eye glaſs, in the ſame direction as the index II; ſo that when the arm AB (fig. 5) of the Telegraph is viewed at a diſtance through the teleſcope, the croſs hair may be turned, by means of the ſliding tube, to the ſame direction of the arm AB; then the index II (fig. 6) will point to the ſame letter or number on its own circle, as the index I (fig. 5) points to on the Telegraphic circle.

If, inſtead of uſing the letters and numbers to form words at length, they be uſed as ſignals, three motions of the arm will give above a hundred thouſand different ſignals.

TELESCOPE, an optical inſtrument which ſerves for diſcovering and viewing diſtant objects, either directly by glaſſes, or by reflection, by means of ſpecula, or mirrors. Accordingly,

Teleſcopes are either refracting or reflecting; the former conſiſting of different lenſes, through which the objects are ſeen by rays refracted through them to the eye; and the latter of ſpecula, from which the rays are reflected and paſſed to the eye. The lens or glaſs turned towards the object, is called the *object-glaſs*; and that next the eye, the *eye-glaſs*; and when the Teleſcope conſiſts of more than two lenſes, all but that next the object are called *eye-glaſſes*.

The invention of the Teleſcope is one of the nobleſt and moſt uſeful theſe ages have to boaſt of: by means of it, the wonders of the heavens are diſcovered to us, and aſtronomy is brought to a degree of perfection which former ages could have no idea of.

The

The diſcovery indeed was owing rather to chance than deſign; ſo that it is the good fortune of the diſcoverer, rather than his ſkill or ability, we are indebted to: on this account it concerns us the leſs to know, who it was that firſt hit upon this admirable invention. Be that as it may, it is certain it muſt have been caſual, ſince the theory it depends upon was not then known.

John Baptiſta Porta, a Neapolitan, according to Wolfius, firſt made a Teleſcope, which he infers from this paſſage in the *Magia Naturalis* of that author, printed in 1560: "If you do but know how to join "the two (viz, the concave and convex glaſſes) rightly "together, you will ſee both remote and near objects, "much larger than they otherwiſe appear, and withal "very diſtinct. In this we have been of good help "to many of our friends, who either ſaw remote "things dimly, or near ones confuſedly; and have "made them ſee every thing perfectly."

But it is certain, that Porta did not underſtand his own invention, and therefore neither troubled himſelf to bring it to a greater perfection, nor ever applied it to celeſtial obſervation. Beſides, the account given by Porta of his concave and convex lenſes, is ſo dark and indiſtinct, that Kepler, who examined it by deſire of the emperor Rudolph, declared to that prince, that it was perfectly unintelligible.

Thirty years afterwards, or in 1590, a Teleſcope 16 inches long was made, and preſented to prince Maurice of Naſſau, by a ſpectacle maker of Middleburg: but authors are divided about his name. Sirturus, in a treatiſe on the Teleſcope, printed in 1618, will have it to be John Lipperſheim: and Borelli, in a volume expreſsly on the inventor of the Teleſcope, publiſhed in 1655, ſhews that it was Zacharias Janſen, or, as Wolfius writes it, Hanſen.

Now the invention of Lipperſheim is fixed by ſome in the year 1609, and by others in 1605: Fontana, in his *Novæ Obſervationes Cæleſtium et Terreſtrium Rerum*, printed at Naples in 1646, claims the invention in the year 1608. But Borelli's account of the diſcovery of Teleſcopes is ſo circumſtantial, and ſo well authenticated, as to render it very probable that Janſen was the original inventor.

In 1620, James Metius of Alemaer, brother of Adrian Metius who was profeſſor of mathematics at Franeker, came with Drebel to Middleburg, and there bought Teleſcopes of Janſen's children, who had made them public; and yet this Adr. Metius has given his brother the honour of the invention, in which too he is miſtakenly followed by Deſcartes.

But none of theſe artificers made Teleſcopes of above a foot and a half: Simon Marius in Germany, and Galileo in Italy, it is ſaid, firſt made long ones fit for celeſtial obſervations; though, from the recently diſcovered aſtronomical papers of the celebrated Harriot, author of the Algebra, it appears that he muſt have made uſe of Teleſcopes in viewing the ſolar maculæ, which he did quite as early as they were obſerved by Galileo. Whether Harriot made his own Teleſcopes, or whether he had them from Holland, does not appear: it ſeems however that Galileo's were made by himſelf; for Le Roſſi relates, that Galileo, being then at Venice, was told of a ſort of optic glaſs made in Holland, which brought objects nearer: upon which, ſetting himſelf to think how it ſhould be, he ground two pieces of glaſs into form as well as he could, and fitted them to the two ends of an organ-pipe; and with theſe he ſhewed at once all the wonders of the invention to the Venetians, on the top of the tower of St. Mark. The ſame author adds, that from this time Galileo devoted himſelf wholly to the improving and perfecting the Teleſcope; and that he hence almoſt deſerved all the honour uſually done him, of being reputed the inventor of the inſtrument, and of its being from him called *Galileo's tube*. Galileo himſelf, in his *Nuncius Sidereus*, publiſhed in 1610, acknowledges that he firſt heard of the inſtrument from a German; and that, being merely informed of its effects, firſt by common report, and a few days after by letter from a French gentleman, James Badovere, at Paris, he himſelf diſcovered the conſtruction by conſidering the nature of refraction. He adds in his *Saggiatore*, that he was at Venice when he heard of the effects of prince Maurice's inſtrument, but nothing of its conſtruction; that the firſt night after his return to Padua, he ſolved the problem, and made his inſtrument the next day, and ſoon after preſented it to the Doge of Venice, who, in honour of his grand invention, gave him the ducal letters, which ſettled him for life in his lectureſhip, at Padua, and doubled his ſalary, which then became treble of what any of his predeceſſors had enjoyed before. And thus Galileo may be conſidered as an inventor of the Teleſcope, though not the firſt inventor.

F. Mabillon indeed relates, in his travels through Italy, that in a monaſtery of his own order, he ſaw a manuſcript copy of the works of Commeſtor, written by one Conradus, who lived in the 13th century; in the 3d page of which was ſeen a portrait of Ptolomy, viewing the ſtars through a tube of 4 joints or draws: but that father does not ſay that the tube had glaſſes in it. Indeed it is more than probable, that ſuch tubes were then uſed for no other purpoſe but to defend and direct the ſight, or to render it more diſtinct, by ſingling out the particular object looked at, and ſhutting out all the foreign rays reflected from others, whoſe proximity might have rendered the image leſs preciſe. And this conjecture is verified by experience; for we have often obſerved that without a tube, by only looking through the hand, or even the fingers, or a pin-hole in a paper, the objects appear more clear and diſtinct than otherwiſe.

Be this as it may, it is certain that the optical principles, upon which Teleſcopes are founded, are contained in Euclid, and were well known to the ancient geometricians; and it has been for want of attention to them, that the world was ſo long without that admirable invention; as doubtleſs there are many others lying hid in the ſame principles, only waiting for reflection or accident to bring them forth.

To the foregoing abſtract of the hiſtory of the invention of the Teleſcope, it may be proper to add ſome particulars relating to the claims of our own celebrated countryman, friar Bacon, who died in 1294. Mr. W. Molyneux, in his Dioptrica Nova, pa. 256, declares his opinion, that Bacon did perfectly well underſtand all ſorts of optic glaſſes, and knew likewiſe the way

way of combining them, so as to compose some such instrument as our Telescope: and his son, Samuel Molyneux, asserts more positively, that the invention of Telescopes, in its first original, was certainly put in practice by an Englishman, friar Bacon; although its first application to astronomical purposes may probably be ascribed to Galileo. The passages to which Mr. Molyneux refers, in support of Bacon's claims, occur in his Opus Majus, pa. 348 and 357 of Jebb's edit. 1773. The first is as follows: *Si vero non sint corpora plana, per quæ visus videt, sed sphæria, tunc est magna diversitas; nam vel concavitas corporis est versus oculum vel convexitas:* whence it is inferred, that he knew what a concave and a convex glass was. The second is comprised in a whole chapter, where he says, *De visione fracta majora sunt; nam de facili patet per canones supra dictos, quod maxima possunt apparere minima, et e contra, et longe distantia videbuntur propinquissime, et e converso. Nam possumus sic figurare perspicua, et taliter ea ordinare respectu nostri visus et rerum, quod frangentur radii, et flectentur quorsumcunque voluerimus, ut sub quocunque angulo voluerimus, videbimus rem prope vel longe, &c. Sic etiam faceremus solem et lunam et stellas descendere secundum apparentiam hic inferius, &c:* that is, Greater things than these may be performed by refracted vision; for it is easy to understand by the canons above mentioned, that the greatest things may appear exceeding small, and the contrary; also that the most remote objects may appear just at hand, and the converse; for we can give such figures to transparent bodies, and dispose them in such order with respect to the eye and the objects, that the rays shall be refracted and bent towards any place we please; so that we shall see the object near at hand or at a distance, under any angle we please, &c. So that thus the sun, moon, and stars may be made to descend hither in appearance, &c. Mr. Molyneux has also cited another passage out of Bacon's Epistle ad Parisiensem, of the Secrets of Art and Nature, cap. 5, to this purpose, *Possunt etiam sic figurari perspicua, ut longissime posita appareant propinqua, et è contrario; ita quod ex incredibili distantia legeremus literas minutissimas, et numeraremus res quantumquo parvas, et stellas faceremus apparere quo vellemus:* that is, Glasses, or diaphanous bodies may be so formed, that the most remote objects may appear just at hand, and the contrary; so that we may read the smallest letters at an incredible distance, and may number things though never so small, and may make the stars appear as near as we please.

Moreover, Doctor Jebb, in the dedication of his edition of the Opus Majus, produces a passage from a manuscript, to shew that Bacon actually applied Telescopes to astronomical purposes: *Sed longe magis quam hæc,* says he, *oporteret homines haberi, qui bene, immo optime, scirent perspectivam et instrumenta ejus—quia instrumenta astronomia non vadunt nisi per visionem secundum leges istius scientiæ.*

From these passages, it is not unreasonable to conclude, that Bacon had actually combined glasses so as to have produced the effects which he mentions, though he did not complete the construction of Telescopes. Dr. Smith, however, to whose judgment particular deference is due, is of opinion that the celebrated friar wrote hypothetically, without having made any actual trial of the things he mentions: to which purpose he observes, that this author does not assert one single trial or observation upon the sun or moon, or any thing else, though he mentions them both: on the other hand, he imagines some effects of Telescopes that cannot possibly be performed by them. He adds, that persons unexperienced in looking through Telescopes expect, in viewing any object, as for instance the face of a man, at the distance of one hundred yards, through a Telescope that magnifies one hundred times, that it will appear much larger than when they are close to it: this he is satisfied was Bacon's notion of the matter; and hence he concludes that he had never looked through a Telescope.

It is remarkable that there is a passage in Thomas Digges's Stratioticos, pa. 359, where he affirms that his father, Leonard Digges, among other curious practices, had a method of discovering, by perspective glasses set at due angles, all objects pretty far distant that the sun shone upon, which lay in the country round about; and that this was by the help of a manuscript book of Roger Bacon of Oxford, who he conceived was the only man besides his father (since Archimedes) who knew it. This is the more remarkable, because the Stratioticos was first printed in 1579, more than 30 years before Metius or Galileo made their discovery of those glasses; and therefore it has hence been thought that Roger Bacon was the first inventor of Telescopes, and Leonard Digges the next reviver of them. But from what Thomas Digges says of this matter, it would seem that the instrument of Bacon, and of his father, was something of the nature of a camera obscura, or, if it were a Telescope, that it was of the reflecting kind; although the term *perspective* glass seems to favour a contrary opinion.

There is also another passage to the same effect in the preface to the Pantometria of Leonard Digges, but published by his son Thomas Digges, some time before the Stratioticos, and a second time in the year 1591. The passage runs thus: *My father by his continuall painfull practises, assisted with demonstrations mathematical, was able, and sundrie times hath by Proportional Glasses duely situate in convenient angles, not only discovered things farre off, read letters, numbered peeces of money with the very coyne and superscription thereof, cast by some of his freends of purpose upon downes in open fields, but also seven myles off declared what hath beene doone at that instant in private places: He hath also sundrie times by the sunne beames fixed* (should be *fired*) *powder, and discharge ordinance halfe a mile and more distante,* &c.

But to whomsoever we ascribe the honour of first inventing the Telescope, the rationale of this admirable instrument, depending on the refraction of light in passing through mediums of different forms, was first explained by the celebrated Kepler, who also pointed out methods of constructing others, of superior powers, and more commodious application, than that first used: though something of the same kind, it is said, was also done by Maurolycus, whose treatise De Lumine et Umbra was published in 1575.

The Principal Effects of TELESCOPES, depend upon this plain maxim, viz, that objects appear larger in proportion to the angles which they subtend at the eye;

eye; and the effect is the same, whether the pencils of rays, by which objects are visible to us, come directly from the objects themselves, or from any place nearer to the eye, where they may have been united, so as to form an image of the object; because they issue again from those points in certain directions, in the same manner as they did from the corresponding points in the objects themselves. In fact therefore, all that is effected by a Telescope, is first to make such an image of a distant object, by means of a lens or mirror, and then to give the eye some assistance for viewing that image as near as possible; so that the angle, which it shall subtend at the eye, may be very large, compared with the angle which the object itself would subtend in the same situation. This is done by means of an eye-glass, which so refracts the pencils of rays, as that they may afterwards be brought to their several foci, by the natural humours of the eye. But if the eye had been so formed as to be able to see the image, with sufficient distinctness, at the same distance, without an eye-glass, it would appear to him as much magnified, as it does to another person who makes use of a glass for that purpose, though he would not in all cases have so large a field of view.

Although no image be actually formed by the foci of the pencil without the eye, yet if, by the help of an eye-glass, the pencils of rays shall enter the pupil, just as they would have done from any place without the eye, the visual angle will be the same as if an image had been actually formed in that place. Priestley's History of Light &c, pa. 69, &c.

As to the Grinding of Telescopic Glasses, the first persons who distinguished themselves in that way, were two Italians, Eustachio Divini at Rome, and Campani at Bologna, whose fame was much superior to that of Divini, or that of any other person of his time; though Divini himself pretended, that in all the trials that were made with their glasses, his of a great focal distance performed better than those of Campani, and that his rival was not willing to try them fairly, viz, with equal eye-glasses. It is however generally supposed, that Campani really excelled Divini, both in the goodness and the focal length of his object-glasses.

It was with Campani's Telescopes that Cassini discovered the nearest satellites of Saturn. They were made at the express desire of Lewis XIV, and were of 86, 100, and 136, Paris feet focal length.

Campani's laboratory was purchased, after his death, by pope Benedict XIV, who made a present of it to the academy at Bologna called the Institute; and by the account which Fougeroux has given, we learn that (except a machine which Campani constructed, to work the basons on which he ground his glasses) the goodness of his lenses depended upon the clearness of his glass, his Venetian tripoli, the paper with which he polished his glasses, and his great skill and address as a workman. It does not appear that he made many lenses of a very great focal distance. Accordingly Dr. Hook, who probably speaks with the partiality of an Englishman, says that some glasses, made by Divini and Campani, of 36 and 50 feet focal distance, did not excel Telescopes of 12 or 15 feet made in England. He adds, that Sir Paul Neilli made Telescopes of 36 feet, pretty good, and one of 50, but not of proportionable goodness.

Afterwards, Mr. Reive first, and then Mr. Cox, who were the most celebrated in England, as grinders of optic glasses, made some good Telescopes of 50 and 60 feet focal distance; and Mr. Cox made one of 100, but how good Dr. Hook could not assert. Borelli also in Italy, made object-glasses of a great focal length, one of which he presented to the Royal Society. But, with respect to the focal length of Telescopes, these and all others were far exceeded by those of Auzout, who made one object-glass of 600 feet focus; but he was never able to manage it, so as to make any use of it. And Hartsoeker, it is said, made some of a still greater focal length. Philos. Trans. Abr. vol. i, p. 193. Hook's Exper. by Derham, p. 261. Priestley as above, p. 211. See GRINDING.

Telescopes are of several kinds, distinguished by the number and form of their lenses, or glasses, and denominated from their particular uses &c: such are the *terrestrial* or *land Telescope*, the *celestial* or *astronomical Telescope*; to which may be added, the *Galilean* or *Dutch Telescope*, the *reflecting Telescope*, the *refracting Telescope*, the *aërial Telescope*, *achromatic Telescope*, &c.

Galileo's, or the *Dutch Telescope*, is one consisting of a convex object-glass, and a concave eye-glass.

This is the most ancient form of any, being the only kind made by the inventors, Galileo, &c. or known, before Huygens. The first Telescope, constructed by Galileo, magnified only 3 times; but he soon made another, which magnified 18 times: and afterwards, with great trouble and expence, he constructed one that magnified 33 times; with which he discovered the satellites of Jupiter, and the spots of the sun. The construction, properties, &c, of it, are as follow:

Construction of Galileo's, or the *Dutch* TELESCOPE. In a tube prepared for the purpose, at one end is fitted a convex object lens, either a plain convex, or convex on both sides, but a segment of a very large sphere: at the other end is fitted an eye glass, concave on both sides, and the segment of a less sphere, so disposed as to be at the distance of the virtual focus before the image of the convex lens.

Let AB (fig. 10, pl. 23) be a distant object, from every point of which pencils of rays issue, and falling upon the convex glass DE, tend to their foci at FSG. But a concave lens HI (the focus of which is at FG) being interposed, the converging rays of each pencil are made parallel when they reach the pupil; so that by the refractive humours of the eye, they can easily be brought to a focus on the retina at PRQ. Also the pencils themselves diverging, as if they came from X, MXO is the angle under which the image will appear, which is much larger than the angle under which the object itself would have appeared. Such then is the Telescope that was at first discovered and used by philosophers: the great inconvenience of which is, that the field of view, which depends, not on the breadth of the eye-glass, as in the astronomical Telescope, but upon the breadth of the pupil of the eye, is exceedingly small: for since the pencils of the rays enter the eye very much diverging from one another, but few of them can be intercepted by the pupil; and this inconvenience increases with the magnifying power of the Telescope, so that philosophers may now well wonder at

at the patience and address with which Galileo and others, with such an instrument, made the discoveries they did. And yet no other Telescope was thought of for many years after the discovery. Descartes, who wrote 30 years after, mentions no other as actually constructed, though Kepler had suggested some. Hence,

1. In an instrument thus framed, all people, except myopes, or short-sighted persons, must see objects distinctly in an erect situation, and increased in the ratio of the distance of the virtual focus of the eye-glass, to the distance of the focus of the object glass.

2. But for myopes to see objects distinctly through such an instrument, the eye-glass must be set nearer the object-glass, so that the rays of each pencil may not emerge parallel, but may fall diverging upon the eye; in which case the apparent magnitude will be altered a little, though scarce sensibly.

3. Since the focus of a plano-convex object lens, and the vertical focus of a plano-concave eye-lens, are at the distance of the diameter; and the focus of an object glass convex on both sides, and the vertical focus of an eye-glass concave on both sides, are at the distance of a semidiameter; if the object-glass be plano-convex, and the eye-glass plano-concave, the Telescope will increase the diameter of the object, in the ratio of the diameter of the concavity to that of the convexity: if the object-glass be convex on both sides, and the eye-glass concave on both sides, it will magnify in the ratio of the semidiameter of the concavity to that of the convexity: if the object-glass be plano-convex, and the eye-glass concave on both sides, the semidiameter of the object will be increased in the ratio of the diameter of the convexity to the semidiameter of the concavity: and lastly, if the object-glass be convex on both sides, and the eye-glass plano-concave, the increase will be in the ratio of the diameter of the concavity to the semidiameter of the convexity.

4. Since the ratio of the semidiameters is the same as that of the diameters, Telescopes magnify the object in the same manner, whether the object-glass be plano-convex, and the eye-glass plano-concave; or whether the one be convex on both sides, and the other concave on both.

5. Since the semidiameter of the concavity has a less ratio to the diameter of the convexity than its diameter has, a Telescope magnifies more if the object-glass be plano-convex, than if it be convex on both sides. The case is the same if the eye-glass be concave on both sides, and not plano-concave.

6. The greater the diameter of the object-glass, and the less that of the eye-glass, the less ratio has the diameter of the object, viewed with the naked eye, to its semidiameter when viewed with a Telescope, and consequently the more is the object magnified by it.

7. Since a Telescope exhibits so much a less part of the object, as it increases its diameter more, for this reason, mathematicians were determined to look out for another Telescope, after having clearly found the imperfection of the first, which was discovered by chance. Nor were their endeavours vain, as appears from the astronomical Telescope described below.

If the semidiameter of the eye-glass have too small a ratio to that of the object-glass, an object through the Telescope will not appear sufficiently clear, because the great divergency of the rays will occasion the several pencils representing the several points of the object on the retina, to consist of too few rays.

It is also found that equal object-lenses will not bear the same eye-lenses, if they be differently transparent, or if there be a difference in their polish; a less transparent object-glass, or one less accurately ground, requiring a more spherical eye-glass than another more transparent, &c.

Hevelius recommends an object-glass convex on both sides, whose diameter is 4 feet; and an eye-glass concave on both sides, whose diameter is $4\frac{1}{2}$ tenths of a foot. An object-glass, equally convex on both sides, whose diameter is 5 feet, he observes, will require an eye-glass of $5\frac{1}{2}$ tenths; and adds, that the same eye-glass will also serve an object-glass of 8 or 10 feet.

Hence, as the distance between the object-glass and eye-glass is the difference between the distance of the vertical focus of the eye-glass, and the distance of the focus of the object glass; the length of the telescope is had by subtracting that from this. That is, the length of the Telescope is the difference between the diameters of the object-glass and eye-glass, if the former be plano-convex, and the latter plano-concave, or the difference between the semidiameters of the object-glass and eye-glass, if the former be convex on both sides, and the latter concave on both; or the difference between the semidiameter of the object-glass and the diameter of the eye-glass, if the former be convex on both sides, and the latter plano concave; or lastly the difference between the diameter of the object-glass and the semidiameter of the eye-glass, if the former be plano-convex, and the latter concave on both sides. Thus, for instance, if the diameter of an object-glass, convex on both sides, be 4 feet, and that of an eye glass, concave on both sides, be $4\frac{1}{2}$ tenths of a foot; then the length of the Telescope will be 1 foot and $7\frac{3}{4}$ tenths.

Astronomical TELESCOPE; this is one that consists of an object-glass, and an eye-glass, both convex. It is so called from being wholly used in astronomical observations.

It was Kepler who first suggested the idea of this Telescope; having explained the rationale, and pointed out the advantages of it in his Catoptrics, in 1611. But the first person who actually made an instrument of this construction, was father Scheiner, who has given a description of it in his Rosa Ursina, published in 1630. To this purpose he says, If you insert two similar convex lenses in a tube, and place your eye at a convenient distance, you will see all terrestrial objects, inverted indeed, but magnified and very distinct, with a considerable extent of view. He afterwards subjoined an account of a Telescope of a different construction, with two convex eye-glasses, which again reverses the images, and makes them appear in their natural position. Father Reita however soon after proposed a better construction, using three eye-glasses instead of two.

Construction of the Astronomical TELESCOPE. The tube being prepared, an object-glass, either plano-con-

vex, or convex on both ſides, but a ſegment of a large ſphere, is fitted in at one end; and an eye-glaſs, convex on both ſides, which is the ſegment of a ſmall ſphere, is fitted into the other end; at the common diſtance of the foci.

Thus the rays of each pencil iſſuing from every point of the object ABC, (fig. 3 pl. 30) paſſing through the object-glaſs DEF, become converging, and meet in their foci at IHG, where an image of the object will be formed. If then another convex lens KM, of a ſhorter focal length, be ſo placed, as that its focus ſhall be in IHG, the rays of each pencil, after paſſing through it, will become nearly parallel, ſo as to meet upon the retina, and form an enlarged image of the object at RST. If the proceſs of the rays be traced, it will preſently be perceived that this image muſt be inverted. For the pencil that iſſues from A, has its focus in G, and again in R, on the ſame ſide with A. But as there is always one inverſion in ſimple viſion, this want of inverſion produces juſt the reverſe of the natural appearance. The field of view in this Teleſcope will be large, becauſe all the pencils that can be received on the ſurface of the lens KM, being converging after paſſing through it, are thrown into the pupil of the eye, placed in the common interſection of the pencils at P.

Theory of the Aſtronomical TELESCOPE.—An eye placed near the focus of the eye-glaſs, of ſuch a Teleſcope, will ſee objects diſtinctly, but inverted, and magnified in the ratio of the diſtance of the focus of the eye-glaſs to the diſtance of the focus of the object-glaſs.

If the ſphere of concavity in the eye glaſs of the Galilean Teleſcope, be equal to the ſphere of convexity in the eye-glaſs of another Teleſcope, their magnifying power will be the ſame. The concave glaſs however being placed between the object-glaſs and its focus, the Galilean Teleſcope will be ſhorter than the other, by twice the focal length of the eye-glaſs. Conſequently, if the length of the Teleſcopes be the ſame; the Galilean will have the greater magnifying power. Viſion is alſo more diſtinct in theſe Teleſcopes, owing in part perhaps to there being no intermediate image between the eye and the object. Beſides, the eye-glaſs being very thin in the centre, the rays will be leſs liable to be diſtorted by irregularities in the ſubſtance of the glaſs. Whatever be the cauſe, we can ſometimes ſee Jupiter's ſatellites very clearly in a Galilean Teleſcope, of 20 inches or 2 feet long, when one of 4 or 5 feet, of the common ſort, will hardly make them viſible.

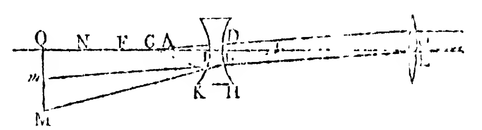
As the aſtronomical Teleſcope exhibits objects inverted, it ſerves commodiouſly enough for obſerving the ſtars, as it is not material whether *they* be ſeen erect or inverted; but for terreſtrial objects it is much leſs proper, as the inverting often prevents them from being known. But if a plane well-poliſhed metal ſpeculum, of an oval figure, and about an inch long, and inclined to the axis in an angle of 45°, be placed behind the eye-glaſs; then the eye, conveniently placed, will ſee the image, hence reflected, in the ſame magnitude as before, but in an erect ſituation; and therefore, by the addition of ſuch a ſpeculum, the aſtronomical Teleſcope is thus rendered fit to obſerve terreſtrial objects.

Since the focus of the glaſs convex on both ſides is diſtant from the glaſs itſelf a ſemidiameter, and that of a plano-convex glaſs, a diameter; if the object-glaſs be convex on both ſides, the Teleſcope will magnify the ſemidiameter of the object, in the ratio of the diameter of the eye-glaſs to the diameter of the object-glaſs; but if the object-glaſs be a plano-convex, in the ratio of the ſemidiameter of the eye-glaſs to the diameter of the object-glaſs. And therefore a Teleſcope magnifies more if the object-glaſs be a plano-convex, than if convex on both ſides. And for the ſame reaſon, a Teleſcope magnifies more when the eye-glaſs is convex on both ſides, than when it is plano-convex.

A Teleſcope magnifies the more, as the object glaſs is a ſegment of a great ſphere, and the eye-glaſs of a leſs one. And yet the eye-glaſs muſt not be too ſmall in reſpect of the object-glaſs; for if it be, it will not refract rays enough to the eye from each point of the object; nor will it ſeparate ſufficiently thoſe that come from different points; by which means the viſion will be rendered obſcure and confuſed.—De Chales obſerves, that an object-lens of 2½ feet will require an eye-glaſs of 1½ tenth of a foot; and an object-glaſs of 8 or 10 feet, an eye-glaſs of 4 tenths; in which he is confirmed by Euſtachio Divini.

To ſhorten the Aſtronomical TELESCOPE; that is, to conſtruct a Teleſcope ſo, as that, though ſhorter than the common one, it ſhall magnify as much.

Having provided a drawing tube, fit in it an object-lens EO which is a ſegment of a moderate ſphere;



let the firſt eye-glaſs BD be concave on both ſides, and ſo placed in the tube, as that the focus of the object-glaſs A may be behind it, but nearer to the centre of the concavity G: then will the image be thrown in Q, ſo as that GA : GI : : AB : QI. Laſtly, fit in another object-glaſs, convex on both ſides, and a ſegment of a ſmaller ſphere, ſo as that its focus may be in Q.

This Teleſcope will magnify the diameter of the object more than if the object-glaſs were to repreſent its image at the ſame diſtance IQ; and conſequently a ſhorter Teleſcope, conſtructed this way, is equivalent to a longer in the common way. See Wolfius Elem. Math. vol. 3, p. 245.

Sir Iſaac Newton furniſhes us with another method of conſtructing the Teleſcope, in his catoptrical or reflecting Teleſcope, the conſtruction of which is given below. See *Achromatic* TELESCOPE.

Aërial TELESCOPE, a kind of aſtronomical Teleſcope, the lenſes of which are uſed without a tube. In ſtrictneſs however, the aërial Teleſcope is rather a particular manner of mounting and managing long

Telescopes for celestial observation in the night-time, by which the trouble of long unwieldy tubes is saved, than a particular kind of Telescope; and the contrivance was one of Huygens's. This invention was successfully practised by the inventor himself and others, particularly with us by Dr. Pound and Dr. Bradley, with an object-glass of 123 feet focal distance, and an apparatus belonging to it, made and presented by Huygens to the Royal Society, and described in his Astroscopia Compendiaria Tubi Optici Molimine Liberata, printed at the Hague in 1684.

The principal parts of this Telescope may be comprehended from a view of fig. 4, pl. 30, where AB is a long pole, or a mast, or a high tree, &c, in a groove of which slides a piece that carries a small tube LK in which is fixed an object glass; which tube is connected by a fine line, with another small tube OQ, which contains the eye-glass, &c.

La Hire contrived a little machine for managing the object-glass which is described Mem. de l'Acad. 1715. See Smith's Optics, book 3, chap. 10.

Hartsoeker, who made Telescopes of a very considerable focal length, contrived a method of using them without a tube, by fixing them to the top of a tree, a high wall, or the roof of a house. Miscel. Berol. vol. 1, p. 261.

Huygens's great Telescope, with which Saturn's true face, and one of his satellites were first discovered, consists of an object-glass of 12 feet, and an eye-glass of a little more than 3 inches; though he frequently used a Telescope of 23 feet long, with two eye-glasses joined together, each $1\frac{1}{2}$ inch diameter; so that the two were equal to one of 3 inches.

The same author observes, that an object-glass of 30 feet requires an eye-glass of $3\frac{3}{10}$ inches; and has given a table of proportions for constructing astronomical Telescopes, an abridgment of which is as follows:

Dist. of Foc. of Obj. Glass.	Diameter of Apert.	Dist. of Foc. of Eye-glass.	Power or Magnitude of Diam.
Feet.	Inches and Decim.	Inches and Decim.	
1	0·55	0·61	20
2	0·77	0·85	28
3	0·95	1·05	34
4	1·09	1·20	40
5	1·23	1·35	44
6	1·34	1·47	49
7	1·45	1·60	53
8	1·55	1·71	56
9	1·64	1·80	60
10	1·73	1·90	63
15	2·12	2·33	77
20	2·45	2·70	89
25	2·74	3·01	100
30	3·00	3·30	109
40	3·46	3·81	120
50	3·87	4·26	141
60	4·24	4·66	154
70	4·58	5·04	166
80	4·90	5·39	178
90	5·20	5·72	189
100	5·49	6·03	200
120	6·00	6·60	218
140	6·48	7·12	235
160	6·93	7·62	252
180	7·35	8·09	267
200	7·75	8·53	281
220	8·12	8·93	295
240	8·48	9·33	308
260	8·83	9·71	321
280	9·16	10·08	333
300	9·49	10·44	345
400	10·95	12·05	400
500	12·25	13·47	445
600	13·42	14·76	488

Dr. Smith (Rem. p. 78) observes, that the magnifying powers of this table are not so great as Huygens himself intended, or as the best object-glasses now made will admit of. For the author, in his Astroscopia Compendiaria, mentions an object-glass of 34 feet focal distance, which, in astronomical observations, bore an eye-glass of $2\frac{1}{4}$ inches focal distance, and consequently magnified 163 times. According to this standard, a Telescope of 35 feet ought to magnify 166 times, and of 1 foot 28 times; whereas the table allows but 118 times to the former, and but 20 to the latter. Now $\frac{166}{118}$ or $\frac{28}{20} \doteq 1{\cdot}4$; by which if we multiply the numbers in the given column of magnifying powers, we shall gain a new column, shewing how much those object-glasses ought to magnify if wrought up to the perfection of this standard.

The new apertures and eye glasses must also be taken in the same proportions to one another, as the old ones have in the table; or the eye-glasses may be found by dividing the length of each Telescope by its magnifying power. And thus a new table may be easily made for this or any other more perfect standard when offered.

The rule for computing this table depends on the following theorem, viz, that in refracting Telescopes of different lengths, a given object will appear equally bright and equally distinct, when their linear apertures and the focal distances of their eye-glasses are severally in a subduplicate ratio of their lengths, or focal distances of their object-glasses; and then also the breadth of their apertures will be in the subduplicate ratio of their lengths.

The rule is this: Multiply the number of feet in the focal distance of any proposed object-glass by 3000, and the square-root of the product will give the breadth of its aperture in centesms, or 100th parts of an inch; that

that is, $\sqrt{3000F}$ is the breadth of the aperture in centesms of an inch, where F is the focal distance of the object-glass in feet. Also, the same breadth of the aperture increased by the 10th part of itself, gives the focal distance of the eye-glass in centesms of an inch. And the magnifying powers are as the breadths of the apertures.

If, in different Telescopes, the ratio between the object-glass and eye-glass be the same, the object will be magnified the same in both. Hence some may conclude the making of large Telescopes a needless trouble. But it must be remembered, that an eye-glass may be in a less ratio to a greater object-glass than to a smaller: thus, for example, in Huygens's Telescope of 25 feet, the eye-glass is 3 inches: now, keeping this proportion in a Telescope of 50 feet, the eye glass should be 6 inches; but the table shews that $4\frac{1}{2}$ are sufficient. Hence, from the same table it appears, that a Telescope of 50 feet magnifies in the ratio of 1 to 141; whereas that of 25 feet only magnifies in the ratio of 1 to 100.

Since the distance of the lens is equal to the aggregate of the distances of the foci of the object and eye-glasses; and since the focus of a glass convex on each side is a semidiameter's distance from the lens, and that of a plano-convex at a diameter's distance from the same; the length of a Telescope is equal to the aggregate of the semidiameters of the lenses, if the object-glass be convex on both sides; and to the sum of the semidiameter of the eye-glass and the whole diameter of the object glass, if the object-glass be a plano-convex.

But as the diameter of the eye-glass is very small in respect of that of the object-glass, the length of the Telescope is usually estimated from the distance of the object-glass; i. e. from its semidiameter if it be convex on both sides, or its whole diameter if plano-convex. Thus, a Telescope is said to be 12 feet, if the semidiameter of the object-glass, convex on both sides, be 12 feet, &c.

Since myopes see near objects best; for them, the eye-glass is to be removed nearer to the object-glass, that the rays refracted through it may be the more diverging.

To take in the larger field at one view, some make use of two eye-glasses, the foremost of which is a segment of a larger sphere than that behind; to this it must be added, that if two lenses be joined immediately together, so as the one may touch the other, the focus is removed to double the distance which that of one of them would be at.

Land Telescope, or *Day* Telescope, is one adapted for viewing objects in the day-time, on or about the earth. This contains more than two lenses, usually it has a convex object-glass, and three convex eye-glasses; exhibiting objects erect, yet different from that of Galileo.

In this Telescope, after the rays have passed the first eye-glass HI (fig. 2, pl. 30), as in the former construction, instead of being there received by the eye, they pass on to another equally convex lens, situated at twice its focal distance from the other, so that the rays of each pencil, being parallel in that whole interval, those pencils cross one another in the common focus, and the rays constituting them are transmitted parallel to the second eye-glass LM; after which the rays of each pencil converge to other foci at NO, where a second image of the object is formed, but inverted with respect to the former image in EF. This image then being viewed by a third eye-glass QR, is painted upon the retina at XYZ, exactly as before, only in a contrary position.

Father Reita was the author of this construction; which is effected by fitting in at one end of a tube an object-glass, which is either convex on both sides, or plano-convex, and a segment of a large sphere; to this add three eye glasses, all convex on both sides, and segments of equal spheres; disposing them in such a manner as that the distance between any two may be the aggregate of the distances of their foci. Then will an eye applied to the last lens, at the distance of its focus, see objects very distinctly, erect, and magnified in the ratio of the distance of the focus of one eye-glass, to the distance of the focus of the object-glass.

Hence, 1. An astronomical Telescope is easily converted into a Land Telescope, by using three eye-glasses for one; and the Land Telescope, on the contrary, into an astronomical one, by taking away two eye-glasses, the faculty of magnifying still remaining the same.

2. Since the distance of the eye-glasses is very small, the length of the Telescope is much the same as if you only used one.

3. The length of the Telescope is found by adding five times the semidiamer of the eye-glasses, to the diameter of the object-glass when this is a plano-convex, or to its semidiameter when convex on both sides.

Huygens first observed, both in the astronomical and Land Telescope, that it contributes considerably to the perfection of the instrument, to have a ring of wood or metal, with an aperture, a little less than the breadth of the eye-glass, fixed in the place where the image is found to radiate upon the lens next the eye: by means of which, the colours, which are apt to disturb the clearness and distinctness of the object, are prevented, and the whole compass taken in at one view, perfectly defined.

Some make Land Telescopes of three lenses, which yet represent objects erect, and magnified as much as the former. But such Telescopes are subject to very great inconveniences, both as the objects in them are tinged with false colours, and as they are distorted about the margin.

Some again use five lenses, and even more; but as some parts of the rays are intercepted in passing every lens, objects are thus exhibited dim and feeble.

Telescopes of this kind, longer than 20 feet, will be of hardly any use in observing terrestrial objects, on account of the continual motion of the particles of the atmosphere, which these powerful Telescopes render visible, and give a tremulous motion to the objects themselves.

The great length of dioptric Telescopes, adapted to any important astronomical purpose, rendered them extremely inconvenient for use; as it was necessary to increase their length in no less a proportion than the duplicate

duplicate of the increase of their magnifying power: so that, in order to magnify twice as much as before, with the same light and distinctness, the Telescope required to be lengthened 4 times; and to magnify thrice as much, 9 times the length, and so on. This unwieldiness of refracting Telescopes, possessing any considerable magnifying power, was one cause, why the attention of astronomers, &c, was directed to the discovery and construction of reflecting Telescopes. And indeed a refracting Telescope, even of 1000 feet focus, supposing it possible to make use of such an instrument, could not be made to magnify with distinctness more than 1000 times; whereas a reflecting Telescope, of 9 or 10 feet, will magnify 12 hundred times. The perfection of refracting Telescopes, it is well known, is very much limited by the aberration of the rays of light from the geometrical focus: and this arises from two different causes, viz, from the different degrees of refrangibility of light, and from the figure of the sphere, which is not of a proper curvature for collecting the rays in a single point. Till the time of Newton, no optician had imagined that the object glasses of Telescopes were subject to any other error beside that which arose from their spherical figure, and therefore all their efforts were directed to the construction of them, with other kinds of curvature: but that author had no sooner demonstrated the different refrangibility of the rays of light, than he discovered in this circumstance a new and a much greater cause of error in Telescopes. Thus, since the pencils of each kind of light have their foci in different places, some nearer and some farther from the lens, it is evident that the whole beam cannot be brought into any one point, but that it will be drawn the nearest to a point in the middle place between the focus of the most and least refrangible rays; so that the focus will be a circular space of a considerable diameter. Newton shews that this space is about the 55th part of the aperture of the Telescope, and that the focus of the most refrangible rays is nearer to the object-glass than the focus of the least refrangible ones, by about the $27\frac{1}{2}$ part of the distance between the object-glass, and the focus of the mean refrangible rays. But he says, that if the rays flow from a lucid point, as far from the lens on one side as their foci are on the other, the focus of the most refrangible rays will be nearer to the lens than that of the least refrangible, by more than the 14th part of the whole distance. Hence, he concludes, that if all the rays of light were equally refrangible, the error in Telescopes, arising from the spherical figure of the glass, would be many hundred times less than it now is; because the error arising from the spherical figure of the glass, is to that arising from the different refrangibility of the rays of light, as 1 to 5449. See Aberration.

Upon the whole he observes, that it is a wonder that Telescopes represent objects so distinctly as they do. The reason of which is, that the dispersed rays are not scattered uniformly over all the circular space above-mentioned, but are infinitely more dense in the centre than in any other part of the circle; and that in the way from the centre to the circumference they grow continually rarer and rarer, till at the circumference they become infinitely rare: for which reason, these dispersed rays are not copious enough to be visible, except about the centre of the circle. He also mentions another argument to prove, that the different refrangibility of the rays of light is the true cause of the imperfection of Telescopes. For the dispersions of the rays arising from the spherical figures of object-glasses, are as the cubes of their apertures; and therefore, to cause Telescopes of different lengths to magnify with equal distinctness, the apertures of the object-glasses, and the charges or magnifying powers ought to be as the cubes of the square roots of their lengths, which does not answer to experience. But the errors of the rays, arising from the different refrangibility, are as the apertures of the object-glasses; and thence, to make Telescopes of different lengths to magnify with equal distinctness, their apertures and charges ought to be as the square roots of their lengths; and this answers to experience.

Were it not for this different refrangibility of the rays, Telescopes might be brought to a sufficient degree of perfection, by composing the object-glass of two glasses with water between them. For by this means, the refractions on the concave sides of the glasses will very much correct the errors of the refractions on the convex sides, so far as they arise from their spherical figure: but on account of the different refrangibility of different kinds of rays, Newton did not see any other means of improving Telescopes by refraction only, except by increasing their length. Newton's Optics, pa. 73, 83, 89, 3d edition.

This important desideratum in the construction of dioptric Telescopes, has been since discovered by the ingenious Mr. Dollond; an account of which is given below.

Achromatic Telescope, is a name given to the refracting Telescope, invented by Mr. John Dollond, and so contrived as to remedy the aberration arising from colours, or the different refrangibility of the rays of light. See Achromatic.

The principles of Mr. Dollond's discovery and construction, have been already explained under the articles Aberration, and Achromatic. The improvement made by Mr. Dollond in his Telescopes, by making two object-glasses of crown-glass, and one of flint, which was tried with success when concave eye-glasses were used, was completed by his son Peter Dollond; who, conceiving that the same method might be practised with success with convex eye-glasses, found, after a few trials, that it might be done. Accordingly he finished an object-glass of 5 feet focal length, with an aperture of $3\frac{3}{4}$ inches, composed of two convex lenses of crown-glass, and one concave of white flint glass. But apprehending afterward that the apertures might be admitted still larger, he completed one of $3\frac{1}{2}$ feet focal length, with the same aperture of $3\frac{3}{4}$ inches. Philos. Trans. vol. 55, p. 56.

But beside the obligation we are under to Mr. Dollond, for correcting the aberration of the rays of light in the focus of object-glasses, arising from their different refrangibility, he made another considerable improvement in Telescopes, viz, by correcting, in a great measure, both this kind of aberration, and also that which arises from the spherical form of lenses, by an expedient of a very different nature, viz, increasing the

the number of eye-glasses. If any person, says he, would have the visual angle of a Telescope to contain 20 degrees, the extreme pencils of the field must be bent or refracted in an angle of 10 degrees; which, if it be performed by one eye-glass, will cause an aberration from the figure, in proportion to the cube of that angle: but if two glasses be so proportioned and situated, as that the refraction may be equally divided between them, they will each of them produce a refraction equal to half the required angle; and therefore, the aberration being in this case proportional to double the cube of half the angle, will be but a 4th part of that which is in proportion to the cube of the whole angle; because twice the cube of 1 is but $\frac{1}{4}$ of the cube of 2: so that the aberration from the figure, where two eye-glasses are rightly proportioned, is but a 4th part of what it must unavoidably be, where the whole is performed by a single eye-glass. By the same way of reasoning, when the refraction is divided among three glasses, the aberration will be found to be but the 9th part of what would be produced from a single glass; because 3 times the cube of 1 is but the 9th part of the cube of 3. Whence it appears, that by increasing the number of eye-glasses, the indistinctness, near the borders of the field of a Telescope, may be very much diminished, though not entirely taken away.

The method of correcting the errors arising from the different refrangibility of light, is of a different consideration from the former: for, whereas the errors from the figure can only be diminished in a certain proportion to the number of glasses, in this they may be entirely corrected, by the addition of only one glass; as we find in the astronomical Telescope, that two eye-glasses, rightly proportioned, will cause the edges of objects to appear free from colours quite to the borders of the field. Also, in the day telescope, where no more than two eye glasses are absolutely necessary for erecting the object, we find, by the addition of a third rightly situated, that the colours, which would otherwise confuse the image, are entirely removed: but this must be understood with some limitation; for though the different colours, which the extreme pencils must necessarily be divided into by the edges of the eye-glasses, may in this manner be brought to the eye in a direction parallel to each other, so as, by its humours, to be converged to a point in the retina, yet if the glasses exceed a certain length, the colours may be spread too wide to be capable of being admitted through the pupil or aperture of the eye; which is the reason that, in long Telescopes, constructed in the common way, with three eye-glasses, the field is always very much contracted.

These considerations first set Mr. Dollond upon contriving how to enlarge the field, by increasing the number of eye-glasses, without any hindrance to the distinctness or brightness of the image: and though others had been about the same work before, yet observing that the five-glass Telescopes, sold in the shops, would admit of farther improvement, he endeavoured to construct one with the same number of glasses in a better manner; which so far answered his expectations, as to be allowed by the best judges to be a considerable improvement on the former. Encouraged by this success, he resolved to try if he could not make some farther enlargement of the field, by the addition of another glass, and by placing and proportioning the glasses in such a manner, as to correct the aberrations as much as possible, without any detriment to the distinctness: and at last he obtained as large a field as is convenient or necessary, and that even in the longest Telescopes that can be made. These Telescopes, with 6 glasses, having been well received both at home and abroad, the author has settled the date of the invention in a letter addressed to Mr. Short, and read at the Royal Society, March 1, 1753. Philos. Trans. vol. 48, art. 14.

Of the Achromatic Telescopes, invented by Mr. Dollond, there are several different sizes, from one foot to 8 feet in length, made and sold by his sons P. and J. Dollond. In the 17-inch improved Achromatic Telescope, the object-glass is composed of three glasses, viz, two convex of crown-glass, and one concave of white flint-glass: the focal distance of this combined object-glass is about 17 inches, and the diameter of the aperture 2 inches. There are 4 eye-glasses contained in the tube, to be used for land objects; the magnifying power with these is near 50 times; and they are adjusted to different sights, and to different distances of the object, by turning a finger screw at the end of the outer tube. There is another tube, containing two eye-glasses that magnify about 70 times, for astronomical purposes. The Telescope may be directed to any object by turning two screws in the stand on which it is fixed, the one giving a vertical motion, and the other a horizontal one. The stand may be inclosed in the inside of the brass tube.

The object-glass of the $2\frac{1}{2}$ and $3\frac{1}{2}$ feet Telescopes is composed of two glasses, one convex of crown glass, and the other concave of white flint glass; and the diameters of their apertures are 2 inches and $2\frac{3}{4}$ inches. Each of them is furnished with two tubes; one for land objects, containing four eye-glasses, and another with two eye-glasses for astronomical uses. They are adjusted by buttons on the outside of the wooden tube; and the vertical and horizontal motions are given by joints in the stands. The magnifying power of the least of these Telescopes, with the eye glass for land objects, is near 50 times, and with those for astronomical purposes, 80 times; and that of the greatest for land objects is near 70 times, but for astronomical observations 80 and 130 times; for this has two tubes, either of which may be used as occasion requires. This Telescope is also moved by a screw and rackwork, and the screw is turned by means of a Hook's joint.

These opticians also construct an Achromatic pocket perspective glass, or Galilean Telescope; so contrived, that all the different parts are put together and contained in one piece $4\frac{1}{2}$ inches long. This small Telescope is furnished with 4 concave eye-glasses, the magnifying powers of which are 6, 12, 18, and 28 times. With the greatest power of this Telescope, the satellites of Jupiter and the ring of Saturn may be easily seen. They have also contrived an Achromatic Telescope, the sliding tubes of which are made of very thin brass, which pass through springs or tubes; the outside tube being either of mahogany or brass. These Telescopes, which from their convenience for gentlemen in the army are called military Telescopes, have 4 convex eye-glasses,

glasses, whose surfaces and focal lengths are so proportioned, as to render the field of view very large. They are of 4 different lengths and sizes, usually called one foot, 2, 3, and 4 feet: the first is 14 inches when in use, and 5 inches when shut up, having the aperture of the object-glass $1\frac{1}{10}$ inch, and magnifying 22 times: the second 28 inches for use, 9 inches shut up, the aperture $1\frac{4}{10}$ inch, and magnifying 35 times; the third 40 inches, and 10 inches shut, with the aperture 2 inches, and magnifying 45 times; and the fourth 52 inches, and 14 inches shut, with the aperture $2\frac{1}{4}$ inches, and magnifying 55 times.

Mr. Euler, who, in a memoir of the Academy of Berlin for the year 1757, p. 323, had calculated the effects of all possible combinations of lenses in Telescopes and microscopes, published another long memoir on the subject of these Telescopes, shewing with precision of what advantages they are naturally capable. See Miscel. Taurin. vol. 3, par. 2, pag. 92.

Mr. Caleb Smith, having paid much attention to the subject of shortening and improving Telescopes, thought he had found it possible to rectify the errors which arise from the different degrees of refrangibility, on the principle that the sines of refraction of rays differently refrangible, are to one another in a given proportion, when their sines of incidence are equal; and the method he proposed for this purpose, was to make the specula of glass, instead of metal, the two surfaces having different degrees of concavity. But it does not appear that this scheme was ever carried into practice. See Philos. Trans. number 456, pa. 326, or Abr. vol. 8, pa. 113.

The ingenious Mr. Ramsden has lately described a new construction of eye-glasses for such Telescopes as may be applied to mathematical instruments. The construction which he proposes, is that of two plano-convex lenses, both of them placed between the eye and the observed image formed by the object-glass of the instrument, and thus correcting not only the aberration arising from the spherical figure of the lenses, but also that arising from the different refrangibility of light. For a more particular account of this construction, its principle, and its effects, see Philos. Trans. vol. 73, art. 5.

A construction, similar at least in its principle to that above, is ascribed, in the Synopsis Optica Honorati Fabri, to Eustachio Divini, who placed two equal narrow plano-convex lenses, instead of one eye lens, to his Telescopes, which touched at their vertices; the focus of the object-glass coinciding with the centre of the plano-convex lens next it. And this, it is said, was done at once both to make the rays that come parallel from the object fall parallel upon the eye, to exclude the colours of the rainbow from it, to augment the angle of sight, the field of view, the brightness of the object, &c. This was also known to Huygens, who sometimes made use of the same construction, and gives the theory of it in his Dioptrics. See Hugenii Opera Varia, vol. 4, ed. 1728.

Telescope, *Reflecting*, or *Catoptric*, or *Catadioptric*, is a Telescope which, instead of lenses, consists chiefly of mirrors, and exhibits remote objects by reflection instead of refraction.

A brief account of the history of the invention of this important and useful Telescope, is as follows. The ingenious Mr. James Gregory, of Aberdeen, has been commonly considered as the first inventor of this Telescope.—But it seems the first thought of a reflector had been suggested by Mersenne, about 20 years before the date of Gregory's invention: a hint to this purpose occurs in the 7th proposition of his Catoptrics, which was printed in 1651; and it appears from the 3d and 29th letters of Descartes, in vol. 2 of his Letters, which it is said were written in 1639, though they were not published till the year 1666, that Mersenne proposed a Telescope with specula to Descartes in that correspondence; though indeed in a manner so very unsatisfactory, that Descartes, who had given particular attention to the improvement of the Telescope, was so far from approving the proposal, that he endeavoured to convince Mersenne of its fallacy. This point has been largely discussed by Le Roi in the Encyclopedia, art. Telescope, and by Montucla in his Hist. des Mathem. tom. 2, p. 643.

Whether Gregory had seen Mersenne's treatise on optics and catoptrics, and whether he availed himself of the hint there suggested, or not, perhaps cannot now be determined. He was led however to the invention by seeking to correct two imperfections in the common Telescope: the first of these was its too great length, which made it troublesome to manage: and the second was the incorrectness of the image. It had been already demonstrated, that a pencil of rays could not be collected in a single point by a spherical lens; and also, that the image transmitted by such a lens would be in some degree incurvated. These inconveniences he thought might be obviated by substituting for the object-glass a metallic speculum, of a parabolical figure, to receive the image, and to reflect it towards a small speculum of the same metal; this again was to return the image to an eye-glass placed behind the great speculum, which was, for that purpose, to be perforated in its centre. This construction he published in 1663, in his Optica Promota. But as Gregory, according to his own account, possessed no mechanical skill, and could not find a workman capable of realizing his invention, after some fruitless trials, he was obliged to give up the thoughts of bringing Telescopes of this kind into use.

Sir Isaac Newton however interposed, to save this excellent invention from perishing, and to bring it forward to maturity. Having applied himself to the improvement of the Telescope, and imagining that Gregory's specula were neither very necessary, nor likely to be executed, he began with prosecuting the views of Descartes; who aimed at making a more perfect image of an object, by grinding lenses, not to the figure of a sphere, but to that formed from one of the conic sections. But, in the year 1666, having discovered the different refrangibility of the rays of light, and finding that the errors of Telescopes, arising from that cause alone, were much more considerable than such as were occasioned by the spherical figure of lenses, he was constrained to turn his thoughts to reflectors. The plague however interrupted his progress in this business; so that it was towards the end of 1668, or in the beginning of 1669, when, despairing of perfecting Telescopes by means of refracted light,

and returning to the construction of reflectors, he set about making his own specula, and early in the year 1672 completed two small reflecting Telescopes. In these he ground the large speculum into a spherical concave, being unable to accomplish the parabolic form proposed by Gregory; but though he then despaired of performing that work by geometrical rules, yet (as he writes in a letter that accompanied one of these instruments, which he presented to the Royal Society) he doubted not but that the thing might in some measure be accomplished by mechanical devices. With a perseverance equal to his ingenuity, he, in a great measure, overcame another difficulty, which was to find a metallic substance that would be of a proper hardness, have the fewest pores, and receive the smoothest polish: this difficulty he deemed almost insurmountable, when he considered that every irregularity in a reflecting surface would make the rays of light deviate 5 or 6 times more out of their due course, than the like irregularities in a refracting surface. After repeated trials, he at last found a composition that answered in some degree, leaving it to those who should come after him to find a better. These difficulties have accordingly been since obviated by other artists, particularly by Dr. Mudge, the rev. Mr. Edwards, and Dr. Herschel, &c. Newton having succeeded so far, he communicated to the Royal Society a full and satisfactory account of the construction and performance of his Telescope. The Society, by their secretary Mr. Oldenburgh, transmitted an account of the discovery to Mr. Huygens, celebrated as a distinguished improver of the refractor; who not only replied to the Society in terms expressing his high approbation of the invention, but drew up a favourable account of the new Telescope, which he caused to be published in the Journal des Sçavans of the year 1672, and by this mode of communication it was soon known over Europe. See Huygenii Opera Varia, tom. 4.

Notwithstanding the excellence and utility of this contrivance, and the honourable manner in which it was announced to the world, it seems to have been greatly neglected for nearly half a century. Indeed when Newton had published an account of his Telescopes in the Philos. Transf. M. Cassegrain, a Frenchman, in the Journal des Sçavans of 1672, claimed the honour of a similar invention, and said, that, before he heard of Newton's improvement, he had hit upon a better construction, by using a small convex mirror instead of the reflecting prism. This Telescope, which was the Gregorian one disguised, the large mirror being perforated, and which it is said was never executed by the author, is much shorter than the Newtonian; and the convex mirror, by dispersing the rays, serves greatly to increase the image made by the large concave mirror.

Newton made many objections to Cassegrain's construction, but several of them equally affect that of Gregory, which has been found to answer remarkably well in the hands of good artists.

Dr. Smith took the pains to make many calculations of the magnifying power, both of Newton's and Cassegrain's Telescopes, in order to their farther improvement, which may be seen in his Optics, Rem. p. 97.

Mr. Short, it is also said, made several Telescopes on the plan of Cassegrain.

Dr. Hook constructed a Reflecting Telescope (mentioned by Dr. Birch in his Hist. of the Royal Soc. vol. 3, p. 122) in which the great mirror was perforated, so that the spectator looked directly towards the object, and it was produced before the Royal Society in 1674. On this occasion it was said that this construction was first proposed by Mersenne, and afterwards repeated by Gregory, but that it never had been actually executed before it was done by Hook. A description of this instrument may be seen in Hook's Experiments, by Derham, p. 269.

The Society also made an unsuccessful attempt, by employing an artificer to imitate the Newtonian construction; however, about half a century after the invention of Newton, a Reflecting Telescope was produced to the world, of the Newtonian construction, which the venerable author, ere yet he had finished his very distinguished course, had the satisfaction to find executed in such a manner, as left no room to fear that the invention would longer continue in obscurity. This effectual service to science was accomplished by Mr. John Hadley, who, in the year 1723, presented to the Royal Society a Telescope, which he had constructed upon Newton's plan. The two Telescopes which Newton had made, were but 6 inches long, were held in the hand for viewing objects, and in power were compared to a 6-feet refractor: but the radius of the sphere, to which the principal speculum of Hadley's was ground, was 10 feet $5\frac{1}{4}$ inches, and consequently its focal length was $62\frac{5}{8}$ inches. In the Philos. Transf. Abr. vol. 6, p. 133, may be seen a drawing and description of this Telescope, and also of a very ingenious but complex apparatus, by which it was managed. One of these Telescopes, in which the focal length of the large mirror was not quite $5\frac{1}{4}$ feet, was compared with the celebrated Huygenian Telescope, which had the focal length of its object-glass 123 feet; and it was found that the former would bear such a charge, as to make it magnify the object as many times as the latter with its due charge; and that it represented objects as distinctly, though not altogether so clear and bright. With this Reflecting Telescope might be seen whatever had been hitherto discovered by the Huygenian, particularly the transits of Jupiter's satellites, and their shades over the disk of Jupiter, the black list in Saturn's ring, and the edge of the shade of Saturn cast upon his ring. Five satellites of Saturn were also observed with this Telescope, and it afforded other observations on Jupiter and Saturn, which confirmed the good opinion which had been conceived of it by Pound and Bradley.

Mr. Hadley, after finishing two Telescopes of the Newtonian construction, applied himself to make them in the Gregorian form, in which the large mirror is perforated. This scheme he completed in the year 1726.

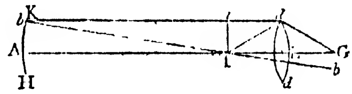
Dr. Smith prefers the Newtonian construction to that of Gregory; but if long experience be admitted as a final judge in such matters, the superiority must be adjudged to the latter; as it is now, and has been for many years past, the only instrument in request.

Mr. Hadley spared no pains, after having completed his construction, to instruct Mr. Molyneux and Dr. Bradley; and when these gentlemen had made a good proficiency in the art, being desirous that these Telescopes should become more public, they liberally communicated to some of the chief instrument makers of London, the knowledge they had acquired from him: and thus, as it is reasonable to imagine, reflectors were completed by other and better methods than even those in which they had been instructed. Mr. James Short in particular signalized himself as early as the year 1734, by his work in this way. He at first made his specula of glass; but finding that the light reflected from the best glass specula was much less than the light reflected from metallic ones, and that glass was very liable to change its form by its own weight, he applied himself to improve metallic specula; and, by giving particular attention to the curvature of them, he was able to give them greater apertures than other workmen could do; and by a more accurate adjustment of the specula, &c, he greatly improved the whole instrument. By some which he made, in which the larger mirror was 15 inches focal distance, he and some other persons were able to read in the Philos. Trans. at the distance of 500 feet; and they several times saw the five satellites of Saturn together, which greatly surprised Mr. Maclaurin, who gave this account of it, till he found that Cassini had sometimes seen them all with a 17 feet refractor. Short's Telescopes were all of the Gregorian construction. It is supposed that he discovered a method of giving the parabolic figure to his great speculum; a degree of perfection which Gregory and Newton despaired of attaining, and which Hadley it seems had never attempted in either of his Telescopes. However, the secret of working that configuration, whatever it was, it seems died with that ingenious artist. Though lately in some degree discovered by Dr. Mudge and others.

On the History of Reflecting Telescopes, see Dr. David Gregory's Elem. of Catopt. and Dioptr. Appendix by Desaguliers: Smith's Optics, book 3, c. 2, Rem. on art. 489: and Sir John Pringle's excellent Discourse on the Invention &c of the Reflecting Telescope.

Construction of the Reflecting Telescope of the Newtonian form.—Let ABCD (fig. 2, pl. 32) be a large tube, open at AD, and closed at BC, and its length at least equal to the distance of the focus from the metallic spherical concave speculum GH placed at the end BC. The rays EG, FH, &c, proceeding from a remote object PR, intersect one another somewhere before they enter the tube, so that EG and *eg* are those that come from the lower part of the object, and *fh* FH from its upper part: these rays, after falling on the speculum GH, will be reflected so as to converge and meet in *mn*, where they will form a perfect image of the object. But as this image cannot be seen by the spectator, they are intercepted by a small plane metallic speculum KK, intersecting the axis at an angle of 45°, by which the rays tending to *m*, *n*, will be reflected towards a hole LL in the side of the tube, and the image of the object will be thus formed in *q*S; which image will be less distinct, because some of the rays which would otherwise fall on the concave speculum GH, are intercepted by the plane speculum: it will nevertheless appear pretty distinct, because the aperture AD of the tube, and the speculum GH, are large. In the lateral hole LL is fixed a convex lens, whose focus is at S*q*; and therefore this lens will refract the rays that proceed from any point of the image, so as at their exit they will appear parallel, and those that proceed from the extreme points S, *q*, will converge after refraction, and form an angle at O, where the eye is placed; which will see the image S*q*, as if it were an object, through the lens LL: consequently the object will appear enlarged, inverted, bright, and distinct. In LL may be placed lenses of different convexities, which, by being moved nearer to the image and farther from it, will represent the object more or less magnified, if the surface of the speculum GH be of a figure truly spherical. If, instead of one lens LL, three lenses be disposed in the same manner with the three eye-glasses of the refracting Telescope, the object will appear erect, but less distinct than when it is observed with one lens. On account of the position of the eye in this Telescope, it is extremely difficult to direct the instrument towards any object: Huygens therefore first thought of adding to it a small refracting Telescope, having its axis parallel to that of the reflector: this is called a *finder* or *director*. The Newtonian Telescope is also furnished with a suitable apparatus for the commodious use of it.

To determine the magnifying power of this Telescope, it is to be considered that the plane speculum KK is of no use in this respect: let us then suppose that one ray proceeding from the object coincides with the axis GLIA of the lens and speculum; let *bb* be



another ray proceeding from the lower extremity of the object, and passing through the focus I of the speculum KH; this will be reflected in the direction *bid*, parallel to the axis GLA, and falling on the lens *d*L*d*, will be refracted to G, so that GL will be equal to LI, and $dG = dI$. To the naked eye the object would appear under the angle $Ibi = bIA$; but by means of the Telescope it appears under the angle $dGL = dIL = Idi$: and the angle Idi is to the angle Ibi as bI to Id; consequently the apparent magnitude by the Telescope, is to that with the naked eye, as the distance of the focus of the speculum from the speculum, to the distance of the focus of the lens from the lens.

Construction of the Gregorian Reflecting Telescope.—Let TYYT (fig. 3, pl. 32) be a brass tube, in which L*ld*D is a metallic concave speculum, perforated in the middle at X; and EF a less concave mirror, so fixed by the arm or strong wire RT, which is moveable by means of a long screw on the outside of the tube, as to be moved nearer to, or farther from the larger speculum L*ld*D; its axis being kept in the same line with that of the great one. Let AB represent a very remote object, from each part of which issue pencils of rays, as *cd*, CD, from A the upper extremity of the object,

object, and IL, il, from the lower part B; the rays IL, CD, from the extremities, crossing one another before they enter the tube. These rays, falling upon the larger mirror LD, are reflected from it into the focus KH, where they form an inverted image of the object AB, as in the Newtonian Telescope. From this image the rays, issuing as from an object, fall upon the small mirror EF, the centre of which is at c, so that after reflection they would meet in their foci at QQ, and there form an erect image. But since an eye at that place could see but a small part of an object, in order to bring rays from more distant parts of it into the pupil, they are intercepted by the plano-convex lens MN, by which means a smaller erect image is formed at PV, which is viewed through the meniscus SS, by an eye at O. This meniscus both makes the rays of each pencil parallel, and magnifies the image PV. At the place of this image all the foreign rays are intercepted by the perforated partition ZZ. For the same reason the hole near the eye O is very narrow. When nearer objects are viewed by this Telescope, the small speculum EF is removed to a greater distance from the larger LD, so that the second image may be always formed in PV: and this distance is to be adjusted (by means of the screw on the outside of the great tube) according to the form of the eye of the spectator. It is also necessary that the axis of the Telescope should pass through the middle of the speculum EF, and its centre, the centre of the speculum LL, and the middle of the hole X, the centres of the lenses MN, SS, and the hole near O. As the hole X in the speculum LL can reflect none of the rays issuing from the object, that part of the image which corresponds to the middle of the object, must appear to the observer more dark and confused than the extreme parts of it. Besides, the speculum EF will also intercept many rays proceeding from the object; and therefore, unless the aperture TT be large, the object must appear in some degree obscure.

The magnifying power of this Telescope is estimated in the following manner. Let LD be the larger mirror (fig. 3, pl 31), having its focus at G, and aperture in A; and FF the small mirror with the focus of parallel rays in I, and the axis of both the specula and lenses MN, SS, be in the right line DIGAOK. Let bb be a ray of light coming from the lower extremity of a very distant visible object, passing through the focus G, and falling upon the point b of the speculum LD; which, after being reflected from b to F in a direction parallel to the axis of the mirror DAK, is reflected by the speculum F so as to pass through the focus I in the direction FIN to N, at the extremity of the lens MN, by which it would have been refracted to K; but by the interposition of another lens SS is brought to O, so that the eye in O sees half the object under the angle TOS. The angle GbF, or AGb, under which the object is viewed by the naked eye, is to SOT under which it is viewed by the Telescope, in the ratio of GbF to $IFi = n\text{IN}$, of $n\text{IN}$ to $\text{NK}n$, and of $\text{NK}n$ to SOT.

$$\text{But } GbF : IFi :: DI : GA,$$
$$\text{and } n\text{IN} : n\text{KN} :: n\text{K} : n\text{I},$$
$$\text{and } n\text{KN} : \text{SOT} :: \text{TO} : \text{TK};$$

theref. $GbF : \text{SOT} :: \text{DI} \times n\text{K} \times \text{TO} : \text{GA} \times n\text{I} \times \text{TK}$. Musschenbroek's Introd. vol. 2, p. 819.

In Reflecting Telescopes of different lengths, a given object will appear equally bright and equally distinct, when their linear apertures, and also their linear breadths, are as the 4th roots of the cubes of their lengths; and consequently when the focal distances of their eye-glasses are also as the 4th roots of their lengths. See the demonstration of this proposition in Smith's Optics, art. 361.

Hence he has deduced a rule, by which he has computed the following table for Telescopes of different lengths, taking, for a standard, the middle eye-glass and aperture of Hadley's Reflecting Telescope, described in Philos. Trans. number 376 and 378: the focal distances and linear apertures being given in 1000th parts of an inch.

Table for Telescopes of different Lengths.

Length of the Tel. or focal dist of the conc.	Focal dist of the Eye-glass.	Linear amplifying or magnifying power.	Linear aperture of the concave metal.
feet	inches	- - -	inches
½	0·167	36	0·864

Mr. Hadley's Telescope, above mentioned, magnified 228 or 230 times; but we are informed that an object-metal of $3\frac{1}{4}$ feet focal distance was wrought by Mr. Hauksbee to so great a perfection, as to magnify 226 times, and therefore it was scarcely inferior to Hadley's of $5\frac{1}{4}$ feet. If Hauksbee's Telescope be taken for a new standard, it follows that a speculum of one foot focal distance ought to magnify 93 times, whereas the above table allows it but 60. Now $\frac{93}{60} = 1·55$, and the given column of magnifying powers multiplied by this number, gives a new column, shewing how much the object-metals ought to magnify if wrought up to the perfection of Hauksbee's. And thus a new table may be easily made for this or any other more perfect standard, taking also the new eye-glasses and apertures in the same ratio to one another as the old ones have in this table. Smith's Optics, Rem. p. 79.

The magnifying power of any Telescope may be easily found by experiment, viz, by looking with one eye through the Telescope upon an object of known dimensions, and at a given distance, and throwing the image upon another object seen with the naked eye. Dr. Smith has given a particular account of the process, Rem. p. 79.

But the easiest method of all, is to measure the diameter of the aperture of the object-glass, and that of the little image of it, which is formed at the place of the eye. For the proportion between these gives the ratio of the magnifying power, provided no part of the original pencil be intercepted by the bad construction of the Telescope. For in all cases the magnifying power of Telescopes, or microscopes, is measured by the proportion of the diameter of the original pencil, to that of the pencil which enters the eye. Priestley's Hist. of Light, p. 747.

But the most considerable, and indeed truly astonishing magnifying powers, that have ever been used, are those of Dr. Herschel's Reflecting Telescopes. Some account of these, and of the discoveries made by them, has been already introduced under the article Star. For his method of ascertaining them, see Philos. Trans. vol. 72, pa. 173 &c. See also several of the other late volumes of the Philos. Trans.

Dr. Herschel observes, that though opticians have proved, that two eye-glasses will give a more correct image than one, he has always (from experience) persisted in refusing the assistance of a second glass, which is sure to introduce errors greater than those he would correct. "Let us resign, says he, the double eye-glass to those who view objects merely for entertainment, and who must have an exorbitant field of view. To a philosopher, this is an unpardonable indulgence. I have tried both the single and double eye-glass of equal powers, and always found that the single eye-glass had much the superiority in point of light and distinctness. With the double eye-glass I could not see the belts in Saturn, which I very plainly saw with the single one. I would however except all those cases where a large field is absolutely necessary, and where power joined to distinctness is not the sole object of our view." Philos. Trans. vol. 72, p. 95.

Mr. Green of Deptford has lately added both to the reflecting and refracting Telescope an apparatus, which fits it for the purposes of surveying, levelling, measuring angles and distances, &c. See his Description and Use of the improved Reflecting and Refracting Telescopes, and Scale of Surveying &c, 1778.— Mr. Ramsden too has lately adapted Telescopes to the like purpose of measuring distances from one station, &c.

Meridian TELESCOPE, is one that is fixed at right angles to an axis, and turned about it in the plane of the meridian; and is otherwise called a *transit instrument.*—The common use of it is to correct the motion of a clock or watch, by daily observing the exact time when the sun or a star comes to the meridian. It serves also for a variety of other uses. The transverse axis is placed horizontal by a spirit level. For the farther description and method of fixing this instrument by means of its levels &c, see Smith's Optics, p. 321. See also TRANSIT *Instrument.*

TELESCOPICAL *Stars*, are such as are not visible to the naked eye, being only discernible by means of a telescope. See STAR.

All stars less than those of the 6th magnitude, are Telescopic to an ordinary eye.

TEMPERAMENT, in Music, usually denotes a rectifying or amending the false or imperfect concords, by transferring to them part of the beauty of the perfect ones.

TENACITY, in Natural Philosophy, is that quality of bodies by which they sustain a considerable pressure or force without breaking; and is the opposite quality to fragility or brittleness. Mem. Acad. Berlin. 1745, p. 47.

TENAILLE, in Fortification, a kind of outwork, consisting of two parallel sides, with a front, having a re-entering angle. In fact, that angle, and the faces which compose it, are the Tenaille.

The Tenaille is of two kinds, *simple* and *double.*

Simple or *Single* TENAILLE, is a large outwork, consisting of two faces or sides, including a re-entering angle.

Double, or *Flanked* TENAILLE, is a large outwork, consisting of two simple Tenailles, or three saliant and two re-entering angles.

The great defects of Tenailles are, that they take up too much room, and on that account are advantageous to the enemy; that the re-entering angle is not defended; the height of the parapet preventing the seeing down into it, so that the enemy can lodge there under cover; and the sides are not sufficiently flanked. For these reasons, Tenailles are now mostly excluded out of fortification by the best engineers, and never made but where time does not serve to form a hornwork.

TENAILLE *of the Place*, is the front of the place, comprehended between the points of two neighbouring bastions; including the curtain, the two flanks raised on the curtain, and the two sides of the bastions which face one another. So that the Tenaille, in this sense, is the same with what is otherwise called the *face of a fortress.*

TENAILLE *of the Ditch*, is a low work raised before the curtain, in the middle of the foss or ditch; the parapet of which is only 2 or 3 feet higher than the level ground of the ravelin.

The use of Tenailles in general, is to defend the bottom of the ditch by a grazing fire, and likewise the level ground of the ravelin, which cannot be so conveniently defended from any other place. The first sort do not defend the ditch so well as the others, because they are too oblique a defence; but as they are not subject to be enfiladed, Vauban has generally preferred them in the fortifying of places. Those of the second sort defend the ditch much better than the first, and add a low flank to those of the bastions; but as these flanks are liable to be enfiladed, they have not been much used. This defect however might be remedied, by making them so as to be covered by the extremities of the parapets of the opposite ravelins, or by some other work. And the same thing may be said of the third sort as of the second.

The *Ram's-horn* is a curved Tenaille, raised in the foss before the flanks, and presenting its convexity to the

the covered way. This work seems preferable to either of the other Tenailles, both on account of its simplicity, and the defence for which it is constructed.

TENAILLONS, in Fortification, are works constructed on each side of the ravelin, much like the lunettes. They differ, as one of the faces of a Tenaillon is in the direction of the ravelin, whereas that of the lunette is perpendicular to it.

TENOR, in Music, the first mean or middle part, or that which is the ordinary pitch, or Tenor, of the voice, when not either raised to the treble, or lowered to the bass.

TENSION, the state of a thing tight, or stretched. Thus, animals sustain and move themselves by the Tension of their muscles and nerves. A chord, or string, gives an acuter or deeper sound, as it is in a greater or less degree of Tension, that is, more or less stretched or tightened.

TERM, in Geometry, is the extreme of any magnitude, or that which bounds and limits its extent. So the Terms of a line, are points; of a superficies, lines; of a solid, superficies.

TERMS, of an equation, or of any quantity, in Algebra, are the several names or members of which it is composed, separated from one another by the signs + or −. So, the quantity $ax + 2bc - 3ax^2$, consists of the three Terms ax and $2bc$ and $3ax^2$.

In an equation, the Terms are the parts which contain the several powers of the same unknown letter or quantity: for if the same unknown quantity be found in several members in the same degree or power, they shall pass but for one Term, which is called a compound one, in distinction from a simple or single Term. Thus, in the equation $x^3 + \overline{a - 3b} \cdot x^2 - acx = b^3$, the four terms are x^3 and $\overline{a - 3b} \cdot x^2$ and acx and b^3; of which the second Term $\overline{a - 3b} \cdot x^2$ is compound, and the other three are simple Terms.

TERMS, of a Product, or of a Fraction, or of a Ratio, or of a Proportion, &c, are the several quantities employed in forming or composing them. Thus, the Terms

of the product ab, are a and b;
of the fraction $\frac{5}{8}$, are 5 and 8;
of the ratio 6 to 7, are 6 and 7;
of the proportion $a : b :: 5 : 9$, are a, b, 5, 9.

TERMS are also used for the several times or seasons of the year in which the public colleges or universities, or courts of law, are open, or sit. Such are the Oxford and Cambridge Terms; also the Terms for the courts of King's-Bench, Common Pleas, and the Exchequer, which are the high courts of common law. But the high court of Parliament, the Chancery, and inferior courts, do not observe the Terms.—The rest of the year, out of Term-time, is called *vacation*.

There are four law Terms in the year; viz,

Hilary-Term, which, at London, begins the 23d day of January, and ends the 12th of February.

Easter-Term, which begins the 3d Wednesday after Easter-day, and ends on the Monday next after Ascension-day.

Trinity-Term, which begins the Friday next after Trinity-Sunday, and ends the 4th Wednesday after Trinity-Sunday.

Michaelmas-Term, which begins the 6th of November, and ends the 28th of November.

All these terms have also their returns, the days of which are expressed in the following table or synopsis.

Table of the Law Terms, and their Returns.

Term	Begin.	1st Return	2d Return	3d Return	4th Return	5th Return	End.
Hilary	January 23	January 20	January 27	February 3	February 9	- - - -	February 12
Easter	3 Wed. af. East.	2 Wks. af. East	3 Wks. af. East.	4 Wks. af. East.	5 Wks. af. East.	Ascens. day	Mond. af. Ascens.
Trinity	Frid. af. Trin. S.	Trinity Mond.	1 Wk. af. Trin.	2 Wks. af. Trin.	3 Wks. af. Trin	- - - -	4th Wed. af. Trin. S.
Mich.	November 6	November 3	November 12	November 18	November 25	- - - -	November 28

N. B. When the beginning or ending of any of these Terms happens on a Sunday, it is held on the Monday after.

Oxford TERMS. These are four; which begin and end as below:

Terms	Begin.	End.
Lent Term	January 14	Sat. bef. Palm-Sund.
Easter Term	Wed. af. Low-Sund	Thurs. bef. Whitsun.
Trinity Term	Wed. af. Trin. Sund.	Sat. after the Act
Michaelmas T.	October 10	December 17

N. B. The *Act* is 1st Monday after the 6th of July. —When the day of the beginning or ending happens on a Sunday, the Terms begin or end the day after.

Cambridge-TERMS. These are three, as below:

Terms	Begin.	End.
Lent Term	January 13	Frid. bef. Palm-Sund.
Easter Term	Wed. aft. Low-Sund.	Frid. aft. Commence.
Michaelmas T.	October 10	December 16

N. B. The *Commencement* is the 1st Tuesday in July. —There is no difference on account of the beginning or ending being Sunday.

Scottish

Scottish TERMS. In Scotland, *Candlemas Term* begins January 23d, and ends February the 12th. *Whitsuntide-Term* begins May 25th, and ends June 15th. *Lammas-Term* begins July the 20th, and ends August the 8th. *Martinmas-Term* begins November the 3d, and ends November the 29th.

Irish TERMS. In Ireland the Terms are the same as at London, except *Michaelmas-Term*, which begins October the 13th, and adjourns to November the 3d, and thence to the 6th.

TERMINATOR, in Astronomy, a name sometimes given to the circle of illumination, from its property of terminating the boundaries of light and darkness.

TERRA, in Geography. See EARTH.

TERRA-*firma*, in Geography, is sometimes used for a continent, in contradistinction to islands. Thus, Asia, the Indies, and South America, are usually distinguished into Terra-firmas and islands.

TERRAQUEOUS, in Geography, an epithet given to our globe or earth, considered as consisting of land and water, which together constitute one mass.

TERRE-PLEIN, or TERRE-PLAIN, in Fortification, the top, platform, or horizontal surface of the rampart, upon which the cannon are placed, and where the defenders perform their office. It is so called, because it lies level, having only a little slope outwardly to counteract the recoil of the cannon. Its breadth is from 24 to 30 feet; being terminated by the parapet on the outer side, and inwardly by the inner talus.

TERRELLA, or little earth, is a magnet turned of a spherical figure, and placed so as that its poles, equator, &c, do exactly correspond with those of the world. It was so first called by Gilbert, as being a just representation of the great magnetic globe we inhabit. Such a Terrella, it was supposed, if nicely poised, and hung in a meridian like a globe, would be turned round like the earth in 24 hours by the magnetic particles pervading it; but experience has shewn that this is a mistake.

TERRESTRIAL, something relating to the earth. As Terrestrial globe, Terrestrial line, &c.

TERTIAN, denotes an old measure, containing 84 gallons, so called because it is the 3d part of a tun.

TERTIATE, in Gunnery. To Tertiate a great gun, is to examine the thickness of the metal at the muzzle, by which to judge of the strength of the piece, and whether it be sufficiently fortified or not.

TETRACHORD, in Music, called by the moderns a *fourth*, is a concord or interval of four tones.—The Tetrachord of the ancients, was a rank of four strings, accounting the Tetrachord for one tone, as it is often taken in music.

TETRADIAPASON, or *quadruple diapason*, is a musical chord, otherwise called a quadruple eighth, or a nine and-twentieth.

TETRAEDRON, or TETRAHEDRON, in Geometry, is one of the five Platonic or regular bodies or solids, comprehended under four equilateral and equal triangles. Or it is a triangular pyramid of four equal and equilateral faces.

It is demonstrated in geometry, that the side of a Tetraedron is to the diameter of its circumscribing sphere, as $\sqrt{2}$ to $\sqrt{3}$; consequently they are incommensurable.

If a denote the linear edge or side of a Tetraedron, b its whole superficies, c its solidity, r the radius of its inscribed sphere, and R the radius of its circumscribing sphere; then the general relation among all these is expressed by the following equations, viz,

$$a = 2r\sqrt{6} = \tfrac{2}{3}R\sqrt{6} = \sqrt{\tfrac{1}{3}b\sqrt{3}} = \sqrt[3]{6c\sqrt{2}}.$$
$$b = 24r^2\sqrt{3} = \tfrac{8}{3}R^2\sqrt{3} = a^2\sqrt{3} = 6\sqrt[3]{c^2\sqrt{3}}.$$
$$c = 8r^3\sqrt{3} = \tfrac{8}{27}R^3\sqrt{3} = \tfrac{1}{12}a^3\sqrt{2} = \tfrac{1}{18}b\sqrt{2b\sqrt{3}}.$$
$$R = 3r = \tfrac{1}{4}a\sqrt{6} = \tfrac{1}{4}\sqrt{2b\sqrt{3}} = \tfrac{3}{2}\sqrt[3]{\tfrac{1}{3}c\sqrt{3}}.$$
$$r = \tfrac{1}{3}R = \tfrac{1}{12}a\sqrt{6} = \tfrac{1}{12}\sqrt{2b\sqrt{3}} = \tfrac{1}{2}\sqrt[3]{\tfrac{1}{3}c\sqrt{3}}.$$

See my Mensuration, pa. 248 &c, 2d ed. See also the articles REGULAR and BODIES.

TETRAGON, in Geometry, a quadrangle, or a figure having 4 angles. Such as a square, a parallelogram, a rhombus, and a trapezium. It sometimes also means peculiarly a square.

TETRAGON, in Astrology, denotes an aspect of two planets with regard to the earth, when they are distant from each other a 4th part of a circle, or 90 degrees. The Tetragon is expressed by the character □, and is otherwise called a square or quartile aspect.

TETRAGONIAS, a meteor, whose head is of a quadrangular figure, and its tail or train is long, thick, and uniform. It does not differ much from the meteor called *Trabs* or beam.

TETRAGONISM, a term which some authors use to express the quadrature of the circle, because the quadrature is the finding a square equal to it.

TETRASPASTON, in Mechanics, a machine in which are four pulleys.

TETRASTYLE, in the Ancient Architecture, a building, and particularly a temple, with four columns in front.

THALES, a celebrated Greek philosopher, and the first of the seven wisemen of Greece, was born at Miletum, about 640 years before Christ. After acquiring the usual learning of his own country, he travelled into Egypt and several parts of Asia, to learn astronomy, geometry, mystical divinity, natural knowledge or philosophy, &c. In Egypt he met for some time great favour from the king, Amasis; but he lost it again, by the freedom of his remarks on the conduct of kings, which it is said occasioned his return to his own country, where he communicated the knowledge he had acquired to many disciples, among the principal of whom were Anaximander, Anaximenes, and Pythagoras, and was the author of the Ionian sect of philosophers. He always however lived very retired, and refused the proffered favours of many great men. He was often visited by Solon; and it is said he took great pleasure in the conversation of Thrasybulus, whose excellent wit made him forget that he was Tyrant of Miletum.

Laertius, and several other writers, agree, that he was the father of the Greek philosophy; being the first that made any researches into natural knowledge, and mathematics. His doctrine was, that water was the principle of which all the bodies in the universe are composed; that the world was the work of God; and that God sees the most secret thoughts in the heart of man. He said, that in order to live well, we ought to abstain from what we find fault with in others: that

bodily

bodily felicity consists in health; and that of the mind in knowledge. That the most ancient of beings is God, because he is uncreated: that nothing is more beautiful than the world, because it is the work of God; nothing more extensive than space, quicker than spirit, stronger than necessity, wiser than time. He used to observe, that we ought never to say that to any one which may be turned to our prejudice; and that we should live with our friends as with persons that may become our enemies.

In Geometry, it has been said, he was a considerable inventor, as well as an improver; particularly in triangles. And all the writers agree, that he was the first, even in Egypt, who took the height of the pyramids by the shadow.

His knowledge and improvements in astronomy were very considerable. He divided the celestial sphere into five circles or zones, the arctic and antarctic circles, the two tropical circles, and the equator. He observed the apparent diameter of the sun, which he made equal to half a degree; and formed the constellation of the Little Bear. He observed the nature and course of eclipses, and calculated them exactly; one in particular, memorably recorded by Herodotus, as it happened on a day of battle between the Medes and Lydians, which, Laertius says, he had foretold to the Ionians. And the same author informs us, that he divided the year into 365 days. Plutarch not only confirms his general knowledge of eclipses, but that his doctrine was, that an eclipse of the sun is occasioned by the intervention of the moon, and that an eclipse of the moon is caused by the intervention of the earth.

His morals were as just, as his mathematics well grounded, and his judgment in civil affairs equal to either. He was very averse to tyranny, and esteemed monarchy little better in any shape.—Diogenes Laertius relates, that walking to contemplate the stars, he fell into a ditch; on which a good old woman, that attended him, exclaimed, "How canst thou know what is doing in the heavens, when thou seest not what is at thy feet?"—He went to visit Crœsus, who was marching a powerful army into Cappadocia, and enabled him to pass the river Halys without making a bridge. Thales died soon after, at above 90 years of age, it is said, at the Olympic games, where, oppressed with heat, thirst, and a load of years, he, in public view, sunk into the arms of his friends.

Concerning his writings, it remains doubtful whether he left any behind him; at least none have come down to us. Augustine mentions some books of Natural Philosophy; Simplicius, some written on Nautic Astrology; Laertius, two treatises on the Tropics and Equinoxes; and Suidas, a treatise on Meteors, written in verse.

THAMMUZ, in Chronology, the 10th month of the year of the Jews, containing 29 days, and answering to our June.

THEMIS, in Astronomy, a name given by some to the 3d satellite of Jupiter.

THEODOLITE, an instrument much used in surveying, for taking angles, distances, altitudes, &c.

This instrument is variously made; different persons having their several ways of contriving it, each attempting to make it more simple and portable, more accurate and expeditious, than others. It usually consists of a brass circle, about a foot diameter, cut in form of fig. 5, pl. 31; having its limb divided into 360 degrees, and each degree subdivided either diagonally, or otherwise, into minutes. Underneath, at *ee*, are fixed two little pillars *bb* (fig. 6), which support an axis, bearing a telescope, for viewing remote objects.

On the centre of the circle moves the index C, which is a circular plate, having a compass in the middle, the meridian line of which answers to the fiducial line *aa*; at *bb* are fixed two pillars to support an axis, bearing a telescope like the former, whose line of collimation answers to the fiducial line *aa*. At each end of either telescope is, or may be, fixed a plain sight, for the viewing of nearer objects.

The ends of the index *aa* are cut circularly, to fit the divisions of the limb B; and when that limb is diagonally divided, the fiducial line at one end of the index shews the degrees and minutes upon the limb. It is also furnished with cross spirit levels, for setting the plane of the circle truly horizontal; and a vertical arch, divided into degrees, for taking angles of elevation and depression. The whole instrument is mounted with a ball and socket, upon a three-legged staff.

Many Theodolites however have no telescopes, but only four plain sights, two of them fastened on the limb, and two on the ends of the index. Two different ones, mounted on their stand, are represented in fig. 2 and 3, plate 33.

The use of the Theodolite is abundantly shewn in that of the semicircle, which is only half a Theodolite. And the index and compass of the Theodolite serve also for a circumferentor, and are used as such.

The ingenious Mr Ramsden has lately made a most excellent Theodolite, for the use of the military survey now carrying on in England.

THEODOSIUS, a celebrated mathematician, who flourished in the times of Cicero and Pompey; but the time and place of his death are unknown. This Theodosius, the Tripolite, as mentioned by Suidas, is probably the same with Theodosius the philosopher of Bythinia, who Strabo says excelled in the mathematical sciences, as also his sons; for the same person might have travelled from the one of those places to the other, and spent part of his life in each of them; like as Hipparchus was called by Strabo the Bythinian; but by Ptolomy and others the Rhodian.

Theodosius chiefly cultivated that part of geometry which relates to the doctrine of the sphere, concerning which he published three books. The first of these contains 22 propositions; the second 23; and the third 14; all demonstrated in the pure geometrical manner of the Ancients. Ptolomy made great use of these propositions, as well as all succeeding writers. These books were translated by the Arabians, out of the original Greek, into their own language. From the Arabic, the work was again translated into Latin, and printed at Venice. But the Arabic version being very defective, a more complete edition was published in Greek and Latin, at Paris 1558, by John Pena, Regius Professor of Astronomy. And Vitello acquired reputation by translating Theodosius into Latin. This author's works were also commented on and illustrated by Clavius, Heleganius, and Guarinus, and lastly by De-

De Chales, in his Cursus Mathematicus. But that edition of Theodosius's Spherics which is now most in use, was translated, and published, by our countryman the learned Dr. Barrow, in the year 1675, illustrated and demonstrated in a new and concise method. By this author's account, Theodosius appears not only to be a great master in this more difficult part of geometry, but the first considerable author of antiquity who has written on that subject.

Theodosius too wrote concerning the Celestial Houses; also of Days and Nights; copies of which, in Greek, are in the king's library at Paris. Of which there was a Latin edition, published by Peter Dasypody, in the year 1572.

THEON, of Alexandria, a celebrated Greek philosopher and mathematician, who flourished in the 4th century, about the year 380, in the time of Theodosius the Great; but the time and manner of his death are unknown. His genius and disposition for the study of philosophy were very early improved by a close application to study; so that he acquired such a proficiency in the sciences, as to render his name venerable in history; and to procure him the honour of being president of the famous Alexandrian school. One of his pupils was the admirable Hypatia, his daughter, who succeeded him in the presidency of the school; a trust, which, like himself, she discharged with the greatest honour and usefulness. [See her life in its place in the first volume of this Dictionary.]

The study of nature led Theon to many just conceptions concerning God, and to many useful reflections in the science of moral philosophy; hence, it is said, he wrote with great accuracy on divine providence. And he seems to have made it his standing rule, to judge the truth of certain principles, or sentiments, from their natural or necessary tendency. Thus, he says, that a full persuasion, that the Deity sees every thing we do, is the strongest incentive to virtue; for he insists, that the most profligate have power to refrain their hands, and hold their tongues, when they think they are observed, or overheard, by some person whom they fear or respect. With how much more reason then, says he, should the apprehension and belief, that God sees all things, restrain men from sin, and constantly excite them to their duty? He also represents this belief, concerning the Deity, as productive of the greatest pleasure imaginable, especially to the virtuous, who might depend with greater confidence on the favour and protection of Providence. For this reason, he recommends nothing so much as meditation on the presence of God: and he recommended it to the civil magistrate, as a restraint on such as were profane and wicked, to have the following inscription written, in large characters, at the corner of every street; GOD SEES THEE, O SINNER.

Theon wrote notes and commentaries on some of the ancient mathematicians. He composed also a book, entitled *Progymnasmata*, a rhetorical work, written with great judgment and elegance; in which he criticised on the writings of some illustrious orators and historians; pointing out, with great propriety and judgment, their beauties and imperfections; and laying down proper rules for propriety of style. He recommends conciseness of expression, and perspicuity, as the principal ornaments. This book was printed at Basle, in the year 1541; but the best edition is that of Leyden, in 1626, in 8vo.

THEOPHRASTUS, a celebrated Greek philosopher, was the son of Melanthus, and was born at Eretus in Bœotia. He was at first the disciple of Leucippus, then of Plato, and lastly of Aristotle; whom he succeeded in his school, about the 322d year before the Christian era, and taught philosophy at Athens with great applause.

He said of an orator without judgment, "that he was a horse without a bridle." He used also to say, "There is nothing so valuable as time, and those who lavish it are the most inexcusable of all prodigals."—He died at about 100 years of age.

Theophrastus wrote many works, the principal of which are the following—1. An excellent moral treatise entitled, *Characters*, which, he says in the preface, he composed at 99 years of age. Isaac Casaubon has written learned commentaries on this small treatise. It has been translated from the Greek into French, by Bruyere; and it has also been translated into English.—2. A curious treatise on Plants.—3. A treatise on fossils or stones; of which Dr. Hill has given a good edition, with an English translation, and learned notes, in 8vo.

THEOREM, a proposition which terminates in theory, and which considers the properties of things already made or done. Or, a Theorem is a speculative proposition, deduced from several definitions compared together. Thus, if a triangle be compared with a parallelogram standing on the same base, and of the same altitude, and partly from their immediate definitions, and partly from other of their properties already determined, it is inferred that the parallelogram is double the triangle; that proposition is a Theorem.

Theorem stands contradistinguished from problem, which denotes something to be done or constructed, as a Theorem proposes something to be proved or demonstrated.

There are two things to be chiefly regarded in every Theorem, viz, the proposition, and the demonstration. In the first is expressed what agrees to some certain thing, under certain conditions, and what does not. In the latter, the reasons are laid down by which the understanding comes to conceive that it does or does not agree to it.

Theorems are of various kinds: as,

Universal THEOREM, is that which extends to any quantity without restriction, universally. As this, that the rectangle or product of the sum and difference of any two quantities, is equal to the difference of their squares.

Particular THEOREM, is that which extends only to a particular quantity. As this, in an equilateral rectilinear triangle, each angle is equal to 60 degrees.

Negative THEOREM, is that which expresses the impossibility of any assertion. As, that the sum of two biquadrate numbers cannot make a square number.

Local THEOREM is that which relates to a surface. As, that triangles of the same base and altitude are equal.

Plane THEOREM, is that which relates to a surface that is either rectilinear or bounded by the circumference of a circle. As, that all angles in the same segment of a circle are equal.

Solid THEOREM, is that which considers a space terminat-

minated by a solid line; that is, by any of the three conic sections. As this, that if a right line cut two asymptotic parabolas, its two parts terminated by them shall be equal.

Reciprocal THEOREM, is one whose converse is true. As, that if a triangle have two sides equal, it has also two angles equal: the converse of which is likewise true, viz, that if the triangle have two angles equal, it has also two sides equal.

THEORY, a doctrine which terminates in the sole speculation or consideration of its object, without any view to the practice or application of it.

To be learned in an art, &c, the Theory is sufficient; to be a master of it, both the Theory and practice are requisite.—Machines often promise very well in Theory, but fail in the practice.

We say Theory of the moon, Theory of the rainbow, of the microscope, of the camera obscura, &c.

THEORIES *of the Planets*, &c, are systems or hypotheses, according to which the astronomers explain the reasons of the phenomena or appearances of them.

THERMOMETER, an instrument for measuring the temperature of the air, &c, as to heat and cold.

The Thermometer and thermoscope are usually accounted the same thing. But Wolfius makes a difference; and he also shews that what we call Thermometers, are really no more than thermoscopes.

The invention of the Thermometer is attributed to several persons by different authors, viz, to Sanctorio, Galileo, father Paul, and to Drebbel. Thus, the invention is ascribed to Cornelius Drebbel of Alcmar, about the beginning of the 17th century, by his countrymen Boerhaave (Chem. 1, pa. 152, 156), and Muschenbroeck (Introd. ad Phil. Nat. vol. 2, pa. 625).—Fulgenzio, in his Life of father Paul, gives him the honour of the first discovery.—Vincenzio Viviani (Vit. de l'Galil. pa. 67; also Oper. di Galil. pref. pa. 47) speaks of Galileo as the inventor of Thermometers.—But Sanctorino (Com. in Galen. Art. Med. pa. 736, 842, Com. in Avicen. Can. Fen. 1, pa. 22, 78, 219) expressly assumes to himself this invention: and Borelli (De Mot. Animal. 2, prop. 175) and Malpighi (Oper. Posth. pa. 30) ascribe it to him without reserve. Upon which Dr. Martine remarks, that these Florentine academicians are not to be suspected of partiality in favour of one of the Patavinian school.

But whoever was the first inventor of this instrument, it was at first very rude and imperfect; and as the various degrees of heat were indicated by the different contraction or expansion of air, it was afterwards found to be an uncertain and sometimes a deceiving measure of heat, because the bulk of the air was affected, not only by the difference of heat, but also by the variable weight of the atmosphere.

There are various kinds of Thermometers, the construction, defects, theory, &c, of which, are as follow.

The Air THERMOMETER.—This instrument depends on the rarefaction of the air. It consists of a glass tube BE (fig. 1, pl. 34) connected at one end with a large glass ball A, and at the other end immersed in an open vessel, or terminating in a ball DE, with a narrow orifice at D; which vessel, or ball, contains any coloured liquor that will not easily freeze. Aquafortis tinged of a fine blue colour with solution of vitriol or copper, or spirit of wine tinged with cochineal, will answer this purpose. But the ball A must be first moderately warmed, so that a part of the air contained in it may be expelled through the orifice D; and then the liquor pressed by the weight of the atmosphere, will enter the ball DE, and rise, for example, to the middle of the tube at C, at a mean temperature of the weather; and in this state the liquor by its weight, and the air included in the ball and tube ABC, by its elasticity, will counterbalance the weight of the atmosphere. As the surrounding air becomes warmer, the air in the ball and the upper part of the tube, expanding by heat, will drive the liquor into the lower ball, and consequently its surface will descend; on the contrary, as the ambient air becomes colder, that in the ball is condensed, and the liquor, pressed by the weight of the atmosphere, will ascend: so that the liquor in the tube will ascend or descend more or less, according to the state of the air contiguous to the instrument. To the tube is affixed a scale of the same length, divided upwards and downwards, from the middle C, into 100 equal parts, by means of which may be observed the ascent and descent of the liquor in the tube, and consequently the variations also in the temperature of the atmosphere.

A similar Thermometer may be constructed by putting a small quantity of mercury, not exceeding the bulk of a pea, into the tube BC (fig. 4, pl. 33), bent into wreaths, that taking up the less height, it may be the more manageable, and less liable to harm; divide this tube into any number of equal parts to serve for a scale. Here the approaches of the mercury towards the ball A will shew the increase of the degree of heat. The reason of which is the same as in the former.

The defect of both these instruments consists in this, that they are liable to be acted on by a double cause: for, not only a decrease of heat, but also an increase of weight of the atmosphere, will make the liquor rise in the one, and the mercury in the other; and, on the contrary, either an increase of heat, or decrease of the weight of the atmosphere, will cause them to descend.

For these, and other reasons, Thermometers of this kind have been long disused. However, M. Amontons, in 1702, with a view of perfecting the aerial Thermometer, contrived his *Universal Thermometer*. Finding that the changes produced by heat and cold in the bulk of the air were subject to invincible irregularities, he substituted for these the variations produced by heat in the elastic force of this fluid. This Thermometer consisted of a long tube of glass (fig. 3, pl. 34) open at one end, and recurved at the other end, which terminated in a ball. A certain quantity of air was compressed into this ball by the weight of a column of mercury, and also by the weight of the atmosphere. The effect of heat on this included air was to make it sustain a greater or less weight; and this effect was measured by the variation of the column of mercury in the tube, corrected by that of the barometer, with respect to the changes of the weight of the external air. This instrument, though much more perfect than the former, is nevertheless subject to very considerable defects and incon-

inconveniences. Its length of 4 feet renders it unfit for a variety of experiments, and its construction is difficult and complex: it is extremely inconvenient for carriage, as a very small inclination of the tube would suffer the included air to escape: and the friction of the mercury in the tube, and the compressibility of the air, contribute to render the indications of this instrument extremely uncertain. Besides, the dilatation of the air is not so regularly proportional to its heat, nor is its dilatation by a given heat nearly so uniform as he supposed. This depends much on its moisture; for dry air does not expand near so much by a given heat, as air stored with watery particles. For these, and other reasons, enumerated by De Luc (Recherches sur les Mod. de l'Atmo. tom. 1, pa. 278 &c), this instrument was imitated by very few, and never came into general use.

Of the Florentine THERMOMETER.—The academists del Cimento, about the middle of the 17th century, considering the inconveniencies of the air Thermometers above described, attempted another, that should measure heat and cold by the rarefaction and condensation of spirit of wine; though much less than those of air, and consequently the alterations in the degree of heat likely to be much less sensible.

The spirit of wine coloured, was included in a very fine and cylindrical glass tube (fig. 2, pl. 34), exhausted of its air, having a hollow ball at one end A, and hermetically sealed at the other end D. The ball and tube are filled with rectified spirit of wine to a convenient height, as to C, when the weather is of a mean temperature, which may be done by inverting the tube into a vessel of stagnant coloured spirit, under a receiver of the air-pump, or in any other way. When the thermometer is properly filled, the end D is heated red hot by a lamp, and then hermetically sealed, leaving the included air of about ⅓ of its natural density, to prevent the air which is in the spirit from dividing it in its expansion. To the tube is applied a scale, divided from the middle, into 100 equal parts, upwards and downwards.

Now spirit of wine rarefying and condensing very considerably; as the heat of the ambient atmosphere increases, the spirit will dilate, and so ascend in the tube; and as the heat decreases, the spirit will descend; and the degree or quantity of the motion will be shewn by the attached scale.

These Thermometers could not be subject to any inconvenience by an evaporation of the liquor, or a variable gravity of the incumbent atmosphere. Instruments of this kind were first introduced into England by Mr. Boyle, and they soon came into general use among philosophers in other countries. They are however subject to considerable inconveniences, from the weight of the liquor itself, and from the elasticity of the air above it in the tube, both which prevent the freedom of its ascent; besides, the rarefactions are not exactly proportional to the surrounding heat. Moreover spirit of wine is incapable of bearing very great heat or very great cold: it boils sooner than any other liquor; and therefore the degrees of heat of boiling fluids cannot be determined by this Thermometer. And though it retains its fluidity in pretty severe cold, yet it seems not to condense very regularly in them: and at Torneao, near the polar circle, the winter cold was so severe, as Maupertuis informs us, that the spirits were frozen in all their Thermometers. So that the degrees of heat and cold, which spirit of wine is capable of indicating, is much too limited to be of very great or general use.

Another great defect of these, and other Thermometers, is, that their degrees cannot be compared with each other. It is true they mark the variations of heat and cold; but each marks for itself, and after its own manner; because they do not proceed from any point of temperature that is common to all of them.

From these and various other imperfections in these Thermometers, it happens, that the comparisons of them become so precarious and defective: and yet the most curious and interesting use of them, is what ought to arise from such comparison. It is by this we should know the heat or cold of another season, of another year, another climate, &c; and what is the greatest degree of heat or cold that men and other animals can subsist in.

Reaumur contrived a new Thermometer, in which the inconveniences of the former are proposed to be remedied. He took a large ball and tube, the content or dimensions of which are known in every part; he graduated the tube, so that the space from one division to another might contain a 1000th part of the liquor, which liquor would contain 1000 parts when it stood at the freezing point: then putting the ball of his Thermometer and part of the tube into boiling water, he observed whether it rose 80 divisions: if it exceeded these, he changed his liquor, and by adding water lowered it, till upon trial it should just rise 80 divisions; or if the liquor, being too low, fell short of 80 divisions, he raised it by adding rectified spirit to it. The liquor thus prepared suited his purpose, and served for making a Thermometer of any size, whose scale would agree with his standard. Such liquor, or spirits, being about the strength of common brandy, may easily be had any where, or made of a proper degree of density by raising or lowering it.

The abbé Nollet made many excellent Thermometers upon Reaumur's principle. Dr. Martine however expresses his apprehensions that Thermometers of this kind cannot admit of such accuracy as might be wished. The balls or bulbs, being large, as 3 or 4 inches in diameter, are neither heated nor cooled soon enough to shew the variations of heat. Small bulbs and small tubes, he says, are much more convenient, and may be constructed with sufficient accuracy. Though it must be allowed that Reaumur, by his excellent scale, and by depriving the spirit of its air, and expelling the air by means of heat from the ball and tube of his Thermometer, has brought it to as much perfection as may be; yet it is liable to some of the inconveniences of spirit Thermometers, and is much inferior to mercurial ones. These two kinds do not agree together in indicating the same degrees of intense cold; for when the mercury has stood at 22° below 0, the spirit indicated only 18°, and when the mercury stood at 28° or 37° below 0, the spirit rested at 25° or 29°. See the description of Reaumur's Thermometer at large in Mem. de l'Acad. des Scienc. an. 1730, pa. 645, Hist. pa. 15. Ib. an. 1731, pa. 354, Hist. pa. 7.

Mercurial

Mercurial THERMOMETER.——It is a most important circumstance in the construction of Thermometers, to procure a fluid that measures equal variations of heat by corresponding equal variations in its own bulk: and the fluid which possesses this essential requisite in the most perfect degree, is mercury: the variations in its bulk approaching nearer to a proportion with the corresponding variations of its heat, than any other fluid. Besides, it is the most easy to purge of its air; and is also the most proper for measuring very considerable variations of heat and cold, as it will bear more cold before freezing, and more heat before boiling, than any other fluid. Mercury is also more sensible than any other fluid, air excepted, or conforms more speedily to the several variations of heat. Moreover, as mercury is an homogeneous fluid, it will in every Thermometer exhibit the same dilatation or condensation by the same variations of heat.

Dr. Halley, though apprized only of some of the remarkable properties of mercury above recited, seems to have been the first who suggested the application of this fluid to the construction of Thermometers. Philos. Trans. Abr. vol. 2, pa. 34.

Boerhaave (Chem. 1, pa. 720) says, these mercurial Thermometers were first contrived by Olaus Roemer; but the claims of Fahrenheit of Amsterdam, who gave an account of his invention to the Royal Society in 1724, (Philos. Trans. num. 381, or Abr. vol. 7, pa. 49) have been generally allowed. And though Prins and others, in England, Holland, France, and other countries, have made this instrument as well as Fahrenheit, most of the mercurial Thermometers are graduated according to his scale, and are called *Fahrenheit's Thermometers.*

The cone or cylinder, which these Thermometers are often made with, instead of the ball, is made of glass of a moderate thickness, lest, when the exhausted tube is hermetically sealed, its internal capacity should be diminished by the weight of the ambient atmosphere. When the mercury is thoroughly purged of its air and moisture by boiling, the Thermometer is filled with a sufficient quantity of it; and before the tube is hermetically sealed, the air is wholly expelled from it by heating the mercury, so that it may be rarefied and ascend to the top of the tube. To the side of the tube is annexed a scale (fig. 3, pl. 34), which Fahrenheit divided into 600 parts, beginning with that of the severe cold which he had observed in Iceland in 1709, or that produced by surrounding the bulb of the Thermometer with a mixture of snow or beaten ice and sal ammoniac or sea salt. This he apprehended to be the greatest degree of cold, and accordingly he marked this, as the beginning of his scale, with 0; the point at which mercury begins to boil, he conceived to shew the greatest degree of heat, and this he made the limit of his scale. The distance between these two points he divided into 600 equal parts or degrees; and by trials he found at the freezing point, when water just begins to freeze, or snow or ice just begins to thaw, that the mercury stood at 32 of these divisions, therefore called the degree of the freezing point; and when the tube was immersed in boiling water, the mercury rose to 212, which therefore is the boiling point, and is just 180 degrees above the former or freezing point. But the present method of making the scale of these Thermometers, which is the sort in most common use, is first to immerge the bulb of the Thermometer in ice or snow just beginning to thaw, and mark the place where the mercury stands with a 32; then immerge it in boiling water, and again mark the place where the mercury stands in the tube, which mark with the num. 212, exceeding the former by 180; dividing therefore the intermediate space into 180 equal parts, will give the scale of the Thermometer, and which may afterwards be continued upwards and downwards at pleasure.

Other Thermometers of a similar construction have been accommodated to common use, having but a portion of the above scale. They have been made of a small size and portable form, and adapted with appendages to particular purposes; and the tube with its annexed scale has often been enclosed in another thicker glass tube, also hermetically sealed, to preserve the Thermometer from injury. And all these are called *Fahrenheit's Thermometers.*

In 1733, M. De l'Isle of Petersburgh constructed a mercurial Thermometer (see fig. 3, pl. 34), on the principles of Reaumur's spirit Thermometer. In his Thermometer, the whole bulk of quicksilver, when immerged in boiling water, is conceived to be divided into 100,000 parts; and from this one fixed point the various degrees of heat, either above or below it, are marked in these parts on the tube or scale, by the various expansion or contraction of the quicksilver in all imaginable varieties of heat.—Dr. Martine apprehends it would have been better if De l'Isle had made the integer 100,000 parts, or fixed point, at freezing water, and from thence computed the dilatations or condensations of the quicksilver in those parts; as all the common observations of the weather, &c, would have been expressed by numbers increasing as the heat increased, instead of decreasing, or counting the contrary way. However, in practice it will not be very easy to determine exactly all the divisions from the alteration of the bulk of the contained fluid. And besides, as glass itself is dilated by heat, though in a less proportion than quicksilver, it is only the excess of the dilatation of the contained fluid above that of the glass that is observed; and therefore if different kinds of glass be differently affected by a given degree of heat, this will make a seeming difference in the dilatations of the quicksilver in the Thermometers constructed in the Newtonian method, either by Reaumur's rules or De l'Isle's. Accordingly it has been found, that the quicksilver in De l'Isle's Thermometers, has stood at different degrees of the scale when immerged in thawing snow: having stood in some at 154°, while in others it has been at 156 or even 158°.

Metallic THERMOMETER.—This is a name given to a machine composed of two metals, which, whilst it indicates the variations of heat, serves to correct the errors hence resulting in the going of pendulum clocks and watches. Instruments of this kind have been contrived by Graham, Le Roy, Ellicot, Harrison, and other eminent artificers. See the Philos. Trans. vol. 44, pa. 689, and vol. 45, pa. 129, and vol. 51, pa. 823, where the particular descriptions &c may be seen.

M. De Luc has likewise described two Thermometers

of metal, which he uses for correcting the effects of heat upon a barometer, and an hygrometer of his construction connected with them. See Philos. Trans. vol. 68, p. 437.

Oil THERMOMETERS.—To this class belongs Newton's Thermometer, constructed in 1701, with linseed oil, instead of spirit of wine. This fluid has the advantage of being sufficiently homogeneous, and capable of a considerable rarefaction, not less than 15 times greater than that of spirit of wine. It has not been observed to freeze even in very great colds; and it sustains a great heat, about 4 times that of water, before it boils. With these advantages it was made use of by Sir I. Newton, who discovered by it the comparative degree of heat for boiling water, melting wax, boiling spirit of wine, and melting tin; beyond which it does not appear that this Thermometer was applied. The method he used for adjusting the scale of this oil Thermometer, was as follows: supposing the bulb, when immerged in thawing snow, to contain 10,000 parts, he found the oil expanded by the heat of the human body so as to take up a 39th more space, or 10256 such parts; and by the heat of water boiling strongly 10725; and by the heat of melting tin 11516. So that, reckoning the freezing point as a common limit between heat and cold, he began his scale there, marking it 0, and the heat of the human body he made 12°; and consequently, the degrees of heat being proportional to the degrees of rarefaction, or 256 : 725 :: 12 : 34, this number 34 will express the heat of boiling water; and, by the same rule, 72 that of melting tin. Philos. Trans. number 270, or Abridg. vol. 4, par. 2, p. 3.

There is an insuperable inconvenience attending all Thermometers made with oil, or any other viscid fluid, viz, that such liquor adheres too much to the sides of the tube, and so inevitably disturbs the regularity and uniformity of the Thermometer.

Of the fixed points of THERMOMETERS.—Various methods have been proposed by different authors, for finding a fixed point or degree of heat, from which to reckon the other degrees, and adjust the scale; so that different observations and instruments might be compared together. Mr. Boyle was very sensible of the inconveniences arising from the want of a universal scale and mode of graduation; and he proposed either the freezing of the essential oil of aniseeds, or of distilled water, as a term to begin the numbers at, and from thence to graduate them according to the proportional dilatations or contractions of the included spirits.

Dr. Halley (Philos. Trans. Abr. vol. 2, p. 36) seems to have been fully apprized of the bad effects of the indefinite method of constructing Thermometers, and wished to have them adjusted to some determined points. What he seems to prefer, for this purpose, is the degree of temperature found in subterranean places, where the heat in summer or cold in winter appears to have no influence. But this degree of temperature, Dr. Martine shews, is a term for the universal construction of Thermometers, both inconvenient and precarious, as it cannot be easily ascertained, and as the difference of soils and depths may occasion a considerable variation. Another term of heat, which he thought might be of use in a general graduation of Thermometers, is that of boiling spirit of wine that has been highly rectified.

The first trace that occurs of the method of actually applying fixed points or terms to the Thermometer, and of graduating it, so that the unequal divisions of it might correspond to equal degrees of heat, is the project of Renaldini, professor at Padua, in 1694: it is thus described in the Acta Erud. Lips. "Take a slender tube, about 4 palms long, with a ball fastened to the same; pour into it spirit of wine, enough just to fill the ball, when surrounded with ice, and not a drop over: in this state seal the orifice of the tube hermetically, and provide 12 vessels, each capable of containing a pound of water, and somewhat more; and into the first pour 11 ounces of cold water, into the second 10 ounces, into the third 9, &c: this done, immerge the Thermometer in the first vessel, and pour into it one ounce of hot water, observing how high the spirit rises in the tube, and noting the point with unity; then remove the Thermometer into the second vessel, into which are to be poured 2 ounces of hot water, and note the place the spirit rises to with 2: by thus proceeding till the whole pound of water is spent, the instrument will be found divided into 12 parts, denoting so many terms or degrees of heat; so that at 2 the heat is double to that at 1, at 3 triple, &c."

But this method, though plausible, Wolfius shews, is deceitful, and built on false suppositions; for it takes for granted, that we have one degree of heat, by adding one ounce of hot water to 11 of cold; two degrees by adding 2 ounces to 10, &c: it supposes also, that a single degree of heat acts on the spirit of wine, in the ball, with a single force; a double with a double force, &c; lastly it supposes, that if the effect be produced in the Thermometer by the heat of the ambient air, which is here produced by the hot water, the air has the same degree of heat with the water.

Soon after this project of Renaldini, viz, in 1701, Newton constructed his oil Thermometer, and placed the base or lowest fixed point of his scale at the temperature of thawing snow, and 12 at that of the human body, &c, as above explained.—De Luc observes, that the 2d term of this scale should have been at a greater distance from the first, and that the heat of boiling water would have answered the purpose better than that of the human body.

In 1702, Amontons contrived his universal Thermometer, the scale of which was graduated in the following manner. He chose for the first term, the weight that counterbalanced the air included in his Thermometer, when it was heated by boiling water: and in this state he so adjusted the quantity of mercury contained in it, till the sum of its height in the tube, and of its height in the barometer at the moment of observation, was equal to 73 inches. Fixing this number at the point to which the mercury in the tube rose by plunging it in boiling water, it is evident that if the barometer at this time was at 28 inches, the height of the column of mercury in the Thermometer, above the level of that in the ball, was 45 inches; but if the height of the barometer was less by a certain quantity, the column of the Thermometer ought to be greater by the same quantity, and reciprocally. He formed his scale on the supposition, that the weight of the atmosphere was always equal to that of a column of mercury of 28 inches, and he divided it into inches

from

from the point 73 downward, marking the divisions with 72, 71, 70, &c, and subdividing the inches into lines. But as the weight of the atmosphere is variable, the barometer must be observed at the same time with the Thermometer, that the number indicated by this last instrument may be properly corrected, by adding or subtracting the quantity which the mercury is below or above 28 inches in the barometer. In this scale then, the freezing point is at $51\frac{1}{2}$ inches, corresponding to 32 degrees of Fahrenheit, and the heat of boiling water at 73 inches, answering to 212 of Fahrenheit's; and thus they may be easily compared together.

The fixed points of Fahrenheit's Thermometer, as has been already observed, are the congelation produced by sal ammoniac and the heat of boiling water. The interval between these points is divided into 212 equal parts; the former of these points being marked 0, and the other 212.

Reaumur in his Thermometer, the construction of which he published in 1730, begins his scale at an artificial congelation of water in warm weather, which, as he uses large bulbs for his glasses, gives the freezing point much higher than it should be, and at boiling water he marks 80 degrees, which point Dr. Martine thinks is more vague and uncertain than his freezing point. In order to determine the correspondence of his scale with that of Fahrenheit, it is to be considered that his boiling water heat, is really only the boiling heat of weakened spirit of wine, coinciding nearly, as Dr. Martine apprehends, with Fahrenheit's 180 degrees. And as his $10\frac{1}{4}$ degrees is the constant heat of the cave of the observatory at Paris, or Fahrenheit's 53°, he thence finds his freezing point, instead of answering just to 32°, to be somewhat above 34°.

De l'Isle's Thermometer, an account of which he presented to the Petersburgh Academy in 1733, has only one fixed point, which is the heat of boiling water, and, contrary to the common order, the several degrees are marked from this point downward, according to the condensations of the contained quicksilver, and consequently by numbers increasing as the heat decreases. The freezing point of De l'Isle's scale, Dr. Martine makes near to his 150°, corresponding to Fahrenheit's 32, by means of which they may be compared; but Ducrest says, that this point ought to be marked at least at 154°.

Ducrest, in his spirit Thermometer, constructed in 1740, made use of two fixed points; the first, or 0, indicated the temperature of the earth, and was marked on his scale in the cave of the Paris Observatory; and the other was the heat of boiling water, which that spirit in his Thermometer was made to endure, by leaving the upper part of the tube full of air. He divided the interval between these points into 100 equal parts; calling the divisions upward, degrees of heat, and those below 0, degrees of cold.—It is said that he has since regulated his Thermometer by the degree of cold indicated by melting ice, which he found to be $10\frac{2}{5}$.

The Florentine Thermometers were of two sorts. In one sort the freezing point, determined by the degree at which the spirit stood in the ordinary cold of ice or snow (probably in a thawing state) and coinciding with 32° of Fahrenheit, fell at 20°; and in the other sort at $13\frac{1}{2}$. And the natural heat of the viscera of cows and deer, &c, raised the spirit in the latter, or less sort, to about 40°, coinciding with their summer heat, and nearly with 102° in Fahrenheit's; and in their other or long Thermometer, the spirit, when exposed to the great midsummer heat in their country, rose to the point at which they marked 80°.

In the Thermometer of the Paris Observatory, made of spirit of wine by De la Hire, the spirit always stands at 48° in the cave of the observatory, corresponding to 53 degrees in Fahrenheit's; and his 28° corresponded with 51 inches 6 lines in Amontons' Thermometer, and consequently with the freezing point, or 32° of Fahrenheit's.

In Poleni's Thermometer, made after the manner of Amontons', but with less mercury, 47 inches corresponded, according to Dr. Martine, with 51 in that of Amontons, and 53 with $59\frac{1}{4}$.

In the standard Thermometer of the Royal Society of London, according to which Thermometers were for a long time constructed in England, Dr. Martine found that $34\frac{1}{2}$ degrees answered to 64° in Fahrenheit, and 0 to 89.

In the Thermometers graduated for adjusting the degrees of heat proper for exotic plants, &c, in stoves and greenhouses, the middle temperature of the air is marked at 0, and the degrees of heat and cold are numbered both above and below. Many of these are made on no regular and fixed principles. But in that formerly much used, called Fowler's regulator, the spirit fell, in melting snow, to about 34° under 0; and Dr. Martine found that his 16° above 0, nearly coincided with 64° of Fahrenheit.

Dr. Hales (Statical Essays, vol. 1, p. 58), in his Thermometer, made with spirit of wine, and used in experiments on vegetation, began his scale with the lowest degree of freezing, or 32° of Fahrenheit, and carried it up to 100°, which he marked where the spirit stood when the ball was heated in hot water, upon which some wax floating first began to coagulate, and this point Dr. Martine found to correspond with 142° of Fahrenheit. But by experience it is found that Hales's 100 falls considerably above our 142.

In the Edinburgh Thermometer, made with spirit of wine, and used in the meteorological observations published in the Medical Essays, the scale is divided into inches and tenths. In melting snow the spirit stood at $8\frac{2}{10}$, and the heat of the human skin raised it to $22\frac{2}{10}$. Dr. Martine found that the heat of the person who graduated it, was 97 of Fahrenheit.

As it is often of use to compare different Thermometers, in order to judge of the result of former observations, I have annexed from Dr. Martine's Essays, the table by which he compared 15 different thermometers. See Plate 34, fig. 3.

There is a Thermometer which has often been used in London, called the Thermometer of Lyons, because M. Cristin

M. Cristin brought it there into use, which is made of mercury: the freezing point is marked 0, and the interval from that point to the heat of boiling water is divided into 100 equal degrees.

From the abstract of the history of the construction of Thermometers it appears, that freezing and boiling water have furnished the distinguishing points that have been marked upon almost all Thermometers. The inferior fixed point is that of freezing, which some have determined by the freezing of water, and others by the melting of ice, plunging the ball of the Thermometer into the water and ice, while melting, which is the best way. The superior fixed point of almost all Thermometers, is the heat of boiling water. But this point cannot be considered as fixed and certain, unless the heat be produced by the same degree of boiling, and under the same weight of the atmosphere; for it is found that the higher the barometer, or the heavier the atmosphere, the greater is the heat when the water boils. It is now agreed therefore that the operation of plunging the ball of the Thermometer in the boiling water, or suspending it in the steam of the same in an inclosed vessel, be performed when the water boils violently, and when the barometer stands at 30 English inches, in a temperature of 55° of the atmosphere, marking the height of the Thermometer then for the degree of 212 of Fahrenheit; the point of melting ice being 32 of the same; thus having 180 degrees between those two fixed points, so determined. This was Mr. Bird's method, who it is apprehended first attended to the state of the barometer, in the making of Thermometers. But these instruments may be made equally true under any pressure of the atmosphere, by making a proper allowance for the difference in the height of the barometer from 30 inches. M. De Luc, in his Recherches sur les Mod. de l'Atmosphere, from a series of experiments, has given an equation for the allowance on account of this difference, in Paris measure, which has been verified by Sir George Schuckburgh, Philos. Trans. 1775 and 1778; also Dr. Horsley, Dr. Maskelyne, and Sir George Shuckburgh have adapted the equation and rules, to English measures, and have reduced the allowances into tables for the use of the artist. Dr. Horsley's rule, deduced from De Luc's, is this:

$$\frac{99}{8990000} \log. z - 92{\cdot}804 = h,$$

where h denotes the height of a Thermometer plunged in boiling water, above the point of melting ice, in degrees of Bird's Fahrenheit, and z the height of the barometer in 10ths of an inch. From this rule he has computed the following table, for finding the heights, to which a good Bird's Fahrenheit will rise, when plunged in boiling water, in all states of the barometer, from 27 to 31 English inches; which will serve, among other uses, to direct instrument makers in making a true allowance for the effect of the variation of the barometer, if they should be obliged to finish a Thermometer at a time when the barometer is above or below 30 inches; though it is best to fix the boiling point when the barometer is at that height.

Equation of the Boiling Point.

Barometer.	Equation.	Difference.
31·0	+ 1·57	
30·5	+ 0·79	0·78
30·0	0·00	0·79
29·5	− 0·80	0·80
29·0	− 1·62	9·82
28·5	− 2·45	0 83
28·0	− 3·31	0·85
27·5	− 4·16	0·86
27·0	− 5·04	0·88

The numbers in the first column of this table express heights of the quicksilver in the barometer in English inches and decimal parts: the 2d column shews the equation to be applied, according to the sign prefixed, to 212° of Bird's Fahrenheit, to find the true boiling point for every such state of the barometer. The boiling point for all intermediate states of the barometer may be had with sufficient accuracy by taking proportional parts, by means of the 3d column of differences of the equations. See Philos. Trans. vol. 64, art. 30; also Dr. Maskelyne's paper, vol. 64, art. 20.

Sir Geo. Shuckburgh (Philos. Trans. vol. 69, pa. 362) has also given several tables and rules relating to the boiling point, both from his own observations, and De Luc's, from whence is extracted the following table, for the use of artists in constructing the Thermometer.

Height of the Barometer.	Corr. of the Boil. Point.	Differences.	Correct. accord. to De Luc.	Differences.
26·0	− 7·09		− 6·83	
26·5	− 6 18	0·91	− 5·93	0·90
27·0	− 5·27	0·91	− 5·04	0·89
27·5	− 4·37	0·90	− 4·16	0·88
28·0	− 3·48	0·89	− 3·31	0·87
28·5	− 2·59	0·89	− 2·45	0·86
29·0	− 1·72	0·87	− 1·62	0·83
29·5	− 0·85	0·87	− 0·80	0·82
30·0	0·00	0·85	0·00	0·80
30·5	+ 0·85	0·85	+ 0·79	0·79
31·0	+ 1·60	0·84	+ 1·57	0·78

The Royal Society too, fully sensible of the importance of adjusting the fixed points of Thermometers, appointed a committee of seven gentlemen to consider of the best method for this purpose; and their report may be seen in the Philos. Trans. vol. 67, art. 37.

They observe, that although the boiling point be placed so much higher on some of the Thermometers now made, than on others, yet this does not produce any considerable error in the observations of the weather, at least in this climate; for an error of 1½ degree in the position of the boiling point, will make an error only of half a degree in the position of 92°, and of not more than

than a quarter of a degree in the point of 62°. It is only in nice experiments, or in trying the heat of hot liquors, that this error in the boiling point can be of much signification.

In adjusting the freezing, as well as the boiling point, the quickfilver in the tube ought to be kept of the same heat as that in the ball. When the freezing point is placed at a considerable distance from the ball, the pounded ice should be piled up very near to it; if it be not so piled, then the observed point, to be very accurate, should be corrected, according to the following table.

Heat of the Air.	Correction.
42°	·00087
52	·00174
62	·00261
72	·00348
82	·00435

The correction in this table is expressed in 1000th parts of the distance between the freezing point and the surface of the ice: ex. gr. if the freezing point stand 6 inches above the surface of the ice, and the heat of the room be 62, then the point of 32 should be placed 6 × ·00261, or ·01566 of an inch lower down than the observed point.

The committee farther observe, that in trying the heat of liquors, care should be taken that the quickfilver in the tube of the Thermometer be heated to the same degree as that in the ball: or if this cannot be done conveniently, the observed heat should be corrected on that account; for the manner of doing which, and a table calculated for that purpose, see Philos. Transf. vol. 67, art. 37.

It was for some time thought, especially from the experiments at Petersburgh, that quickfilver suffered a cold of several hundred degrees below 0 before it congealed and became fixed and malleable; but later experiments have shewn that this persuasion was merely owing to a deception in the experiments, and later ones have made it appear that its point of congelation is no lower than − 40°, or rather − 39°, of Fahrenheit's scale. But that it will bear however to be cooled a few degrees below that point, to which it leaps up again on beginning to congeal; and that its rapid descent in a Thermometer, through many hundred degrees, when it has once passed the above-mentioned limit, proceeds merely from its great contraction in the act of freezing. See Philos. Transf. vol. 73, art. *20, 20, 21.

Miscellaneous Observations.

It is absolutely necessary that those who would derive any advantage from these instruments, should agree in using the same liquor, and in determining, according to the same method, the two fundamental points. If they agree in these fixed points, it is of no great importance whether they divide the interval between them into a greater or a less number of equal parts. The scale of Fahrenheit, in which the fundamental interval between 212°, the point of boiling water, and 32° that of melting ice, is divided into 180 parts, should be retained in the northern countries, where Fahrenheit's Thermometer is used: and the scale in which the fundamental interval is divided into 80 parts, will serve for those countries where Reaumur's Thermometer is adopted. But no inconvenience is to be apprehended from varying the scale for particular uses, provided care be taken to signify into what number of parts the fundamental interval is divided, and the point where 0 is placed.

With regard to the choice of tubes, it is best to have them exactly cylindrical through their whole length. The capillary tubes are preferable to others, because they require smaller bulbs, and they are also more sensible, and less brittle. The most convenient size for common experiments has the internal diameter about the 40th or 50th of an inch, about 9 inches long, and made of thin glass, that the rise and fall of the mercury may be better seen.

For the whole process of filling, marking, and graduating, see De Luc's Recherches &c, tom. 1, p. 393, &c.

Experiments with THERMOMETERS.

The following is a table of some observations made with Fahrenheit's Thermometer, the barometer standing at 29 inches, or little higher.

At 600° Mercury boils.
546 Oil of vitriol boils.
242 Spirit of nitre boils.
240 Lixivium of tartar boils.
213 Cow's milk boils.
212 Water boils.
206 Human urine boils.
190 Brandy boils.
175 Alcohol boils.
156 Serum of blood and white of eggs harden.
146 Kills animals in a few minutes.
108 to 99, Hens hatch eggs.
107 103 { Heat of skin in ducks, geese, hens, pigeons, partridges, and swallows.
106 Heat of skin in a common ague and fever.
103 100 { Heat of skin in dogs, cats, sheep, oxen, swine, and most other quadrupeds.
99 to 92, Heat of the human skin in health.
97 Heat of a swarm of bees.
96 A perch died in 3 minutes in water so warm.
80 Heat of air in the shade, in very hot weather.
74 Butter begins to melt.
64 Heat of air in the shade, in warm weather.
55 Mean temperature of air in England.
43 Oil of olives begins to stiffen and grow opake.
32 { Water just freezing, or snow and ice just melting.
30 Milk freezes.
28 Urine and common vinegar freezes.
25 Blood out of the body freezes.
20 Burgundy, Claret, and Madeira freeze.
5 { Greatest cold in Pennsylvania in 1731-2, lat. 40°.
4 Greatest cold at Utrecht in 1728-9.
0 { A mixture of snow and salt, which can freeze oil of tartar per deliquium, but not brandy.
−39 Mercury freezes.

On

On the general subject of Thermometers also see Martine's Essays, Medical and Philosophical. Desaguliers's Exp. Phil. vol. 2, p. 289. Musschenbroeck's Int. ad Phil. Nat. vol. 2, p. 625, ed. 1762. De Luc's Recherches sur les Modif. &c, tom. 1, part 2, ch. 2. Nollet's Leçons de Physique, tom. 4, p. 375.

THERMOMETERS *for particular uses.*—In 1757, lord Cavendish presented to the Royal Society an account of a curious construction of Thermometers, of two different forms; one contrived to shew the greatest degree of heat, and the other the greatest cold, that may happen at any time in a person's absence. Philos. Trans. vol. 50, p. 300.

Since the publication of Mr. Canton's discovery of the compressibility of spirits of wine and other fluids, there are two corrections necessary to be made in the result given by lord Cavendish's Thermometer. For in estimating, for instance, the temperature of the sea at any depth, the Thermometer will appear to have been colder than it really was: and besides, the expansion of spirits of wine by any given number of degrees of Fahrenheit's Thermometer, is greater in the higher degrees than in the lower. For the method of making these two corrections by Mr. Cavendish, see Phipps's Voyage to the North Pole, p. 145.

Instruments of this kind, for determining the degree of heat or cold in the absence of the observer, have been invented and described by others. Van Swinden (Diss. sur la Comparaison du Therm. p. 253 &c) describes one, which he says was the first of the kind, made on a plan communicated by Bernoulli to Leibnitz. Mr. Kraft, he also tells us, made one nearly like it. Mr. Six has lately, viz, in 1782, proposed another construction of a Thermometer of the same kind, described in the Philos. Trans. vol. 72, p. 72 &c.

M. De Luc has described the best method of constructing a Thermometer, fit for determining the temperature of the air, in the measuring of heights by the barometer. He has also shewn how to divide the scale of a Thermometer, so as to adapt it for astronomical purposes in the observation of refractions. See Recherches &c, tom. 2, p. 35 and 265.

Mr. Cavallo, in 1781, proposed the construction of a *Thermometrical Barometer*, which, by means of boiling water, might indicate the various gravity of the atmosphere, or the height of the barometer. This Thermometer, he says, with its apparatus, might be packed up into a small portable box, and serve for determining the heights of mountains &c, with greater facility, than with the common portable barometer. The instrument, in its present state, consists of a cylindrical tin vessel, about 2 inches in diameter, and 5 inches high, in which vessel the water is contained, which may be made to boil by the flame of a large wax-candle. The Thermometer is fastened to the tin vessel in such a manner, as that its bulb may be about an inch above the bottom. The scale of this Thermometer, which is of brass, exhibits on one side of the glass tube a few degrees of Fahrenheit's scale, viz, from 200° to 216°. On the other side of the tube are marked the various barometrical heights, at which the boiling water shews those particular degrees of heat which are set down in Sir Geo. Shuckburgh's table. With this instrument the barometrical height is shewn within one 10th of an inch. The degrees of this Thermometer are rather longer than one 9th of an inch, and therefore may be divided into many parts, especially by a Nonius. But a considerable imperfection arises from the smallness of the tin vessel, which does not admit a sufficient quantity of water; but when the quantity of water shall be sufficiently large, as for instance 10 or 12 ounces, and is kept boiling in a proper vessel, its degree of heat under the same pressure of the atmosphere is very settled; whereas when a Thermometer is kept in a small quantity of boiling water, the mercury in its stem does not stand very steady, sometimes rising or falling so much as half a degree. Mr. Cavallo proposes a farther improvement of this instrument, in the Philos. Trans. vol. 71, p. 524.

The ingenious Mr. Wedgwood, so well known for his various improvements in the different sorts of pottery ware, has contrived to make a Thermometer for measuring the higher degrees of heat, by means of a distinguishing property of argillaceous bodies, viz, the diminution of their bulk by fire. This diminution commences in a low red heat, and proceeds regularly, as the heat increases, till the clay becomes vitrified. The total contraction of some good clays which he has examined in the strongest of his own fires, is considerably more than one-fourth part in every dimension. By measuring the contraction of such substances then, Mr. Wedgwood contrived to measure the most intense heats of ovens, furnaces, &c. For the curious particulars of which, see Philos. Trans. vol. 72, p. 305 &c.

THERMOSCOPE, an instrument shewing the changes happening in the air with respect to heat and cold.

The word Thermoscope is often used indifferently with that of thermometer. There is some difference however in the literal import of the two; the first signifying an instrument that shews or exhibits the changes of heat &c to the eye; and the latter an instrument that measures those changes; so that a thermometer should be a more accurate Thermoscope.

THIR, in Chronology, the name of the 5th month of the Ethiopians, which corresponds, according to Ludolf, to the month of January.

THIRD, in Music, a concord resulting from a mixture of two sounds containing an interval of 2 degrees: being called a third, because containing 3 terms, or sounds, between the extremes.

There is a greater and a less Third. The former takes its form from the sesquiquarta ratio, 4 to 5. The logarithm or measure of the octave $\frac{2}{1}$ being 1·00000, the measure of the greater Third $\frac{5}{4}$ will be 0·32193.—The *greater Third* is by practitioners often taken for the third part of an octave; which is an error, since three greater Thirds fall short of the octave by a diesis; for $\frac{5}{4} \times \frac{5}{4} \times \frac{5}{4} \times \frac{128}{125} = \frac{2}{1}$.

The *lesser Third* takes its form from the sesquiquinta ratio 5 to 6; the measure or logarithm of this lesser Third $\frac{6}{5}$, being 0·26303, that of the octave $\frac{2}{1}$ being 1·00000.

Both these Thirds are of great use in melody; making as it were the foundation and life of harmony.

THIRD-*Point*, or *Tierce-point*, in Architecture, the point of section in the vertex of an equilateral triangle.—Arches or vaults of the Third Point, are those consisting

fifting of two arches of a circle, meeting in an angle at top.

THREE-*legged-ftaff*, an inftrument confifting of three wooden legs, made with joints, fo as to fhut all together, and to take off in the middle for the better carriage. It has ufually a ball and focket on the top; and its ufe is to fupport and adjuft inftruments for aftronomy, furveying, &c.

THUNDER, a noife in the lower region of the air, excited by a fudden explofion of electrical clouds; which are therefore called Thunder-clouds.

The phenomenon of Thunder is varioufly accounted for. Seneca, Rohault, and fome other authors, both ancient and modern, account for Thunder, by fuppofing two clouds impending over one another, the upper and rarer of which, becoming condenfed by a frefh acceffion of air raifed by warmth from the lower parts of the atmofphere, or driven upon it by the wind, immediately falls forcibly down upon the lower and denfer cloud; by which fall, the air interpofed between the two being compreffed, that next the extremities of the two clouds is fqueezed out, and leaves room for the extremity of the upper cloud to clofe tight upon the under; thus a great quantity of the air is enclofed, which at length efcaping through fome winding irregular vent or paffage, occafions the noife called Thunder.

But this lame device could only reach at moft to the cafe of Thunder heard without lightning; and therefore recourfe has been had to other modes of folution. Thus, it has been faid that Thunder is not occafioned by the falling of clouds, but by the kindling of fulphurous exhalations, in the fame manner as the noife of the aurum fulminans. "There are fulphurous exhalations, fays Sir I. Newton, always afcending into the air when the earth is dry; there they ferment with the nitrous acids, and, fometimes taking fire, generate Thunder, lightning, &c."

The effects of Thunder are fo like thofe of fired gunpowder, that Dr. Wallis thinks we need not fcruple to afcribe them to the fame caufe; and the principal ingredients in gunpowder, we know, are nitre and fulphur; charcoal only ferving to keep the parts feparate, for their better kindling. Hence, if we conceive in the air a convenient mixture of nitrous and fulphurous particles; and thofe, by any caufe, to be fet on fire, fuch explofion may well follow, and with fuch noife and light as attend the firing of gunpowder; and being once kindled, it will run from place to place, different ways, as the exhalations happen to lead it; much as is found in a train of gunpowder.

But a third, and moft probable opinion is, that Thunder is the report or noife produced by an electrical explofion in the clouds. Ever fince the year 1752, in which the identity of the matter of lightning and of the electrical fluid has been afcertained, philofophers have generally agreed in confidering Thunder as a concuffion produced in the air by an explofion of electricity. For the illuftration and proof of this theory, fee ELECTRICITY, and LIGHTNING.

It may here be obferved, that Mr. Henry Eeles, in a letter written in 1751, and read before the Royal Society in 1752, confiders the electrical fire as the caufe of Thunder, and accounts for it on this hypothefis; and he tells us, that he did not know of any other perfon's having made the fame conjecture. Philof. Tranf. vol. 47, p. 524 &c.

That rattling in the noife of Thunder, which makes it feem as if it paffed through arches, or were varioufly broken, is probably owing to the found being excited among clouds hanging over one another, and the agitated air paffing irregularly between them.

The explofion, if high in the air, and remote from us, will do no mifchief; but when near, it may deftroy trees, animals, &c.

This proximity, or fmall diftance, may be eftimated nearly by the interval of time between feeing the flafh of lightning, and hearing the report of the Thunder, eftimating the diftance, after the rate of 1142 feet per fecond of time, or $3\frac{1}{7}$ feconds to the mile. Dr. Wallis obferves, that commonly the difference between the two is about 7 feconds, which, at the rate above mentioned, gives the diftance almoft 2 miles. But fometimes it comes in a fecond or two, which argues the explofion very near us, and even among us. And in fuch cafes, the doctor affures us, he has fometimes foretold the mifchiefs that happened.

The noife of Thunder, and the flame of lightning, are eafily made by art. If a mixture of oil or fpirit of vitriol be made with water, and fome filings of fteel added to it, there will immediately arife a thick fmoke, or vapour, out of the mouth of the veffel; and if a lighted candle be applied to this, it will take fire, and the flame will immediately defcend into the veffel, which will be burft to pieces with a noife like that of a cannon.

This is fo far analogous to Thunder and lightning, that a great explofion and fire are occafioned by it; but in this they differ, that this matter when once fired is deftroyed, and can give no more explofions; whereas, in the heavens, one clap of Thunder ufually follows another, and there is a continued fucceffion of them for a long time. Mr. Homberg explained this by the lightnefs of the air above us, in comparifon of that near, which therefore would not fuffer all the matter fo kindled to be diffipated at once, but keeps it for feveral returns.

THUNDERBOLT. When lightning acts with extraordinary violence, and breaks or fhatters any thing, it is called a *Thunderbolt*, which the vulgar, to fit it for fuch effects, fuppofe to be a hard body, and even a ftone.—But that we need not have recourfe to a hard folid body to account for the effects commonly attributed to the Thunderbolt, will be evident to any one, who confiders thofe of the pulvis fulminans, and of gunpowder; but more efpecially the aftonifhing powers of electricity, when only collected and employed by human art, and much more when directed and exercifed in the courfe of nature.

When we confider the known effects of electrical explofions, and thofe produced by lightning, we fhall be at no lofs to account for the extraordinary operations vulgarly afcribed to Thunderbolts. As ftones and bricks ftruck by lightning are often found in a vitrified ftate, we may reafonably fuppofe, with Beccaria, that fome ftones in the earth, having been ftruck in this manner, gave occafion to the vulgar opinion of the Thunderbolt.

THUNDER-*clouds*, in Phyfiology, are thofe clouds which

which are in a ftate fit for producing lightning and thunder.

From Beccaria's exact and circumftantial account of the external appearances of Thunder-clouds, the following particulars are extracted.

The firft appearance of a Thunder ftorm, which ufually happens when there is little or no wind, is one denfe cloud, or more, increafing very faft in fize, and rifing into the higher regions of the air. The lower furface is black and nearly level; but the upper finely arched, and well defined. Many of thefe clouds often feem piled upon one another, all arched in the fame manner; but they are continually uniting, fwelling, and extending their arches.

At the time of the rifing of this cloud, the atmofphere is commonly full of a great many feparate clouds, that are motionlefs, and of odd whimfical fhapes. All thefe, upon the appearance of the Thunder-cloud, draw towards it, and become more uniform in their fhapes as they approach; till, coming very near the Thunder-cloud, their limbs mutually ftretch toward one another, and they immediately coalefce into one uniform mafs. Thefe he calls adfcititious clouds, from their coming in, to enlarge the fize of the Thunder-cloud. But fometimes the Thunder-cloud will fwell, and increafe very faft, without the conjunction of any adfcititious clouds; the vapours in the atmofphere forming themfelves into clouds wherever it paffes. Some of the adfcititious clouds appear like white fringes, at the fkirts of the Thunder-cloud, or under the body of it, but they keep continually growing darker and darker, as they approach to unite with it.

When the Thunder-cloud is grown to a great fize, its lower furface is often ragged, particular parts being detached towards the earth, but ftill connected with the reft. Sometimes the lower furface fwells into various large protuberances bending uniformly downward; and fometimes one whole fide of the cloud will have an inclination to the earth, and the extremity of it nearly touch the ground. When the eye is under the Thunder-cloud, after it is grown larger, and well formed, it is feen to fink lower, and to darken prodigioufly; at the fame time that a number of fmall adfcititious clouds (the origin of which can never be perceived) are feen in a rapid motion, driving about in very uncertain directions under it. While thefe clouds are agitated with the moft rapid motions, the rain commonly falls in the greateft plenty, and if the agitation be exceedingly great, it commonly hails.

While the Thunder-cloud is fwelling, and extending its branches over a large tract of country, the lightning is feen to dart from one part of it to another, and often to illuminate its whole mafs. When the cloud has acquired a fufficient extent, the lightning ftrikes between the cloud and the earth, in two oppofite places, the path of the lightning lying through the whole body of the cloud and its branches. The longer this lightning continues, the lefs denfe does the cloud become, and the lefs dark its appearance; till at length it breaks in different places, and fhews a clear fky.

Thefe Thunder-clouds were fometimes in a pofitive as well as a negative ftate of electricity. The electricity continued longer of the fame kind, in proportion as the Thunder-cloud was fimple, and uniform in its direction: but when the lightning changed its place, there commonly happened a change in the electricity of the apparatus, over which the clouds paffed. It would change fuddenly after a very violent flafh of lightning, but the change would be gradual when the lightning was moderate, and the progrefs of the Thunder-cloud flow. Beccar. Lettere dell'Elettricifmo pa. 107; or Prieftley's Hift. Elec. vol. 1, p. 397. See alfo Lightning.

THUNDER-*Houfe*, in Electricity, is an inftrument invented by Dr. James Lind, for illuftrating the manner in which buildings receive damage from lightning, and to evince the utility of metallic conductors in preferving them from it.

A (fig. 1, pl. 35), is a board about ¾ of an inch thick, and fhaped like the gable end of a houfe. This board is fixed perpendicularly upon the bottom board B, upon which the perpendicular glafs pillar CD is alfo fixed in a hole about 8 inches diftant from the bafis of the board A. A fquare hole ILMK, about a quarter of an inch deep, and nearly one inch wide, is made in the board A, and is filled with a fquare piece of wood, nearly of the fame dimenfions. It is nearly of the fame dimenfions, becaufe it muft go fo eafily into the hole, that it may drop off, by the leaft fhaking of the inftrument. A wire LK is faftened diagonally to this fquare piece of wood. Another wire IH of the fame thicknefs, having a brafs ball H, fcrewed on its pointed extremity, is faftened upon the board A: fo alfo is the wire MN, which is fhaped in a ring at O. From the upper extremity of the glafs pillar CD, a crooked wire proceeds, having a fpring focket F, through which a double knobbed wire flips perpendicularly, the lower knob G of which falls juft above the knob H. The glafs pillar DC muft not be made very faft into the bottom board; but it muft be fixed fo that it may be pretty eafily moved round its own axis, by which means the brafs ball G may be brought nearer to or farther from the ball H, without touching the part EFG. Now when the fquare piece of wood LMIK (which may reprefent the fhutter of a window or the like) is fixed into the hole fo that the wire LK ftands in the dotted reprefentation IM, then the metallic communication from H to O is complete, and the inftrument reprefents a houfe furnifhed with a proper metallic conductor; but if the fquare piece of wood LMIK be fixed fo that the wire LK ftands in the direction LK, as reprefented in the figure, then the metallic conductor HO, from the top of the houfe to its bottom, is interrupted at IM, in which cafe the houfe is not properly fecured.

Fix the piece of wood LMIK, fo that its wire may be as reprefented in the figure, in which cafe the metallic conductor HO is difcontinued. Let the ball G be fixed at about half an inch perpendicular diftance from the ball H; then, by turning the glafs pillar DC, remove the former ball from the latter; by a wire or chain connect the wire EF with the wire Q of the jar P; and let another wire or chain, faftened to the hook O, touch the outfide coating of the jar. Connect the wire Q with the prime conductor, and charge the jar; then, by turning the glafs pillar DC, let the ball G come gradually near the ball H, and when they are arrived fufficiently near one another, you will obferve, that the jar explodes and the piece of wood LMIK is pufhed

pushed out of the hole to a considerable distance from the Thunder-house.

Now the ball G, in this experiment, represents an electrified cloud, which, when it is arrived sufficiently near the top of the house A, the electricity strikes it; and as this house is not secured with a proper conductor, the explosion breaks part of it, i. e. knocks off the piece of wood IM.

Repeat the experiment with only this variation, viz, that this piece of wood IM be situated so that the wire LK may stand in the situation IM; in which case the conductor HO is not discontinued; and you will observe that the explosion will have no effect upon the piece of wood LM; this remaining in the hole unmoved; which shews the usefulness of the metallic conductor.

Farther, unscrew the brass ball H from the wire HI, so that this may remain pointed, and with this difference only in the apparatus repeat both the above experiments, and you will find that the piece of wood IM is in neither case moved from its place, nor will any explosion be heard; which not only demonstrates the preference of conductors with pointed terminations to those with blunted ones, but also shews that a house, furnished with sharp terminations, although not furnished with a regular conductor, is almost sufficiently guarded against the effects of lightning.

Mr. Henley, having connected a jar containing 509 square inches of coated surface with his prime conductor, observed that if it was so charged as to raise the index of his electrometer to 60°, by bringing the ball on the wire of the Thunder-house, to the distance of half an inch from that connected with the prime conductor, the jar would be discharged, and the piece in the Thunder-house thrown out to a considerable distance. Using a pointed wire for a conductor to the Thunder-house, instead of the knob, the charge being the same as before, the jar was discharged silently, though suddenly; and the piece was not thrown out of the Thunder-house. In another experiment, having made a double circuit to the Thunder-house, the first by the knob, the second by a sharp-pointed wire, at an inch and a quarter distance from each other, but of exactly the same height (as in fig. 2) the charge being the same; although the knob was brought first under that connected with the prime conductor, which was raised half an inch above it, and followed by the point, yet no explosion could fall upon the knob: the point drew off the whole charge silently, and the piece in the Thunder-house remained unmoved.

Phil. Trans. vol. 64, p. 136. See Points in Electricity.

THURSDAY, the 5th day of the Christian's week, but the 6th of the Jews. The name is from Thor, one of the Saxon Gods.

THUS, in Sea-Language, a word used by the pilot in directing the helmsman or steersman to keep the ship in her present situation when sailing with a scant wind, so that she may not approach too near the direction of the wind, which would shiver her sails, nor fall to leeward, and run farther out of her course.

TIDES, two periodical motions of the waters of the sea; called also the *flux* and *reflux*, or the *ebb* and *flow*.

The Tides are found to follow periodically the course of the sun and moon, both as to time and quantity. And hence it has been suspected, in all ages, that the Tides were somehow produced by the influence of these luminaries. Thus, several of the ancients, and among others, Pliny, Ptolomy, and Macrobius, were acquainted with the influence of the sun and moon upon the Tides; and Pliny says expressly, that the cause of the ebb and flow is in the sun, which attracts the waters of the ocean; and adds, that the waters rise in proportion to the proximity of the moon to the earth. It is indeed now well known, from the discoveries of Sir Isaac Newton, that the Tides are caused by the gravitation of the earth towards the sun and moon. Indeed the sagacious Kepler, long ago, conjectured this to be the cause of the Tides: "If, says he, the earth ceased to attract its waters towards itself, all the water in the ocean would rise and flow into the moon; the sphere of the moon's attraction extends to our earth, and draws up the water." Thus thought Kepler, in his Introd. ad Theor. Mart. This surmise, for it was then no more, is now abundantly verified in the theory laid down by Newton, and by Halley, from his principles.

As to the Phenomena of the Tides: 1. The sea is observed to flow, for about 6 hours, from south towards north; the sea gradually swelling; so that, entering the mouths of rivers, it drives back the river-waters towards their heads, or springs. After a continual flux of 6 hours, the sea seems to rest for about a quarter of an hour; after which it begins to ebb, or retire back again, from north to south, for 6 hours more; in which time, the water sinking, the rivers resume their natural course. Then, after a seeming pause of a quarter of an hour, the sea again begins to flow, as before: and so on alternately.

2. Hence, the sea ebbs and flows twice a day, but falling every day gradually later and later, by about 48 minutes, the period of a flux and reflux being on an average about 12 hours 24 minutes, and the double of each 24 hours 48 minutes; which is the period of a lunar day, or the time between the moon's passing a meridian, and coming to it again. So that the sea flows as often as the moon passes the meridian, both the arch above the horizon, and that below it; and ebbs as often as she passes the horizon, both on the eastern and western side.

Other phenomena of the Tides are as below; and the reasons of them will be noticed in the Theory of the Tides that follows.

3. The elevation towards the moon a little exceeds the opposite one. And the quantity of the ascent of the water is diminished from the equator towards the poles.

4. From the sun, every natural day, the sea is twice elevated, and twice depressed, the same as for the moon. But the solar Times are much less than the lunar ones, on account of the immense distance of the sun; yet they are both subject to the same laws.

5. The Tides which depend upon the actions of the sun and moon, are not distinguished, but compounded, and so forming as to sense one united Tide, increasing and decreasing, and thus making neap and spring Tides: for, by the action of the sun, the lunar

lunar Tide is only changed; which change varies every day, by reafon of the inequality between the natural and lunar day.

6. In the fyzygies the elevations from the action of both luminaries concur, and the fea is more elevated. But the fea afcends lefs in the quadratures; for where the water is elevated by the action of the moon, it is depreffed by the action of the fun; and vice verfa. Therefore, while the moon paffes from the fyzygy to the quadrature, the daily elevations are continually diminifhed: on the contrary, they are increafed while the moon moves from the quadrature to the fyzygy. At a new moon alfo, *cæteris paribus*, the elevations are greater; and thofe that follow one another the fame day, are more different than at full moon.

7. The greateft elevations and depreffions are not obferved till the 2d or 3d day after the new or full moon. And if we confider the luminaries receding from the plane of the equator, we fhall perceive that the agitation is diminifhed, and becomes lefs, according as the declination of the luminaries becomes greater.

8. In the fyzygies, and near the equinoxes, the Tides are obferved to be the greateft, both luminaries being in or near the equator.

9. The actions of the fun and moon are greater, the nearer thofe bodies are to the earth; and the lefs, as they are farther off. Alfo the greateft Tides happen near the equinoxes, or rather when the fun is a little to the fouth of the equator, that is, a little before the vernal, and after the autumnal equinox. But yet this does not happen regularly every year, becaufe fome variation may arife from the fituation of the moon's orbit, and the diftance of the fyzygy from the equinox.

10. All thefe phenomena obtain, as defcribed, in the open fea, where the ocean is extended enough to be fubject to thefe motions. But the particular fituations of places, as to fhores, capes, ftraits, &c, difturb thefe general rules. Yet it is plain, from the moft common and univerfal obfervations, that the Tides follow the laws above laid down.

11. The mean force of the moon to move the fea, is to that of the fun, nearly as $4\frac{1}{2}$ to 1. And therefore, if the action of the fun alone produce a Tide of 2 feet, which it has been ftated to do, that of the moon will be 9 feet; from which it follows, that the fpring Tides will be 11 feet, and the neap Tides 7 feet high. But as to fuch elevations as far exceed thefe, they happen from the motion of the waters againft fome obftacles, and from the fea violently entering into ftraits or gulphs where the force is not broken till the water rifes higher.

Theory of the Tides.

1. If the earth were entirely fluid, and quiefcent, it is evident that its particles, by their mutual gravity towards each other, would form the whole mafs into the figure of an exact fphere. Then fuppofe fome power to act on all the particles of this fphere with an equal force, and in parallel directions; by fuch a power the whole mafs will be moved together, but its figure will fuffer no alteration by it, being ftill the fame perfect fphere, whofe centre will have the fame motion as each particle.

Upon this fuppofition, if the motion of the earth round the common centre of gravity of the earth and moon were deftroyed, and the earth left to the influence of its gravitation towards the moon, as the acting power above mentioned; then the earth would fall or move ftraight towards the moon, but ftill retaining its true fpherical figure.

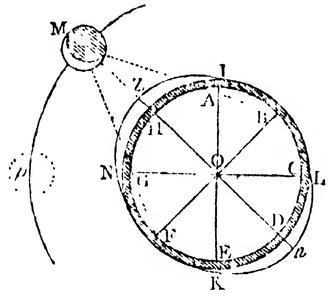
But the fact is, that the effects of the moon's action, as well as the action itfelf, on different parts of the earth, are not equal: thofe parts, by the general law of gravity, being moft attracted that are neareft the moon, and thofe being leaft attracted that are fartheft from her, while the parts that are at a middle diftance are attracted by a mean degree of force: befides, all the parts are not acted on in parallel lines, but in lines directed towards the centre of the moon: on both which accounts the fpherical figure of the fluid earth muft fuffer fome change from the action of the moon. So that, in falling, as above, the neareft parts, being moft attracted, would fall quickeft; the farther parts, being leaft attracted, would fall floweft; and the fluid mafs would be lengthened out, and take a kind of fpheroidical form.

Hence it appears, and what muft be carefully obferved, that it is not the action of the moon itfelf, but the inequalities in that action, that caufe any variation from the fpherical figure; and that, if this action were the fame in all the particles as in the central parts, and operating in the fame direction, no fuch change would enfue.

Let us now admit the parts of the earth to gravitate toward its centre; then, as this gravitation far exceeds the action of the moon, and much more exceeds the differences of her actions on different parts of the earth, the effect that refults from the inequalities of thefe actions of the moon, will be only a fmall diminution of the gravity of thofe parts of the earth which it endeavoured in the former fuppofition to feparate from its centre; that is, thofe parts of the earth which are neareft to the moon, and thofe that are fartheft from her, will have their gravity toward the earth fomewhat abated; to fay nothing of the lateral parts. So that fuppofing the earth fluid, the columns from the centre to the neareft, and to the fartheft parts, muft rife, till by their greater height they be able to balance the other columns, whofe gravity is lefs altered by the inequalities of the moon's action. And thus the figure of the earth muft ftill be an oblong fpheroid.

Let us now confider the earth, inftead of falling toward the moon by its gravity, as projected in any direction, fo as to move round the centre of gravity of the earth and moon: it is evident that in this cafe, the feveral parts of the fluid earth will ftill preferve their relative pofitions; and the figure of the earth will remain the fame as if it fell freely toward the moon; that is, the earth will ftill affume a fpheroidal form, having its longeft diameter directed toward the moon.

From



From the above reasoning it appears, that the parts of the earth directly under the moon, as at H, and also the opposite parts at D, will have the flood or highwater at the same time; while the parts, at B and F, at 90° distance, or where the moon appears in the horizon, will have the ebbs or lowest waters at that time.

Hence, as the earth turns round its axis from the moon to the moon again in 24 hours 48 minutes, this oval of water must shift with it; and thus there will be two Tides of flood and two of ebb in that time.

But it is further evident that, by the motion of the earth on her axis, the most elevated part of the water is carried beyond the moon in the direction of the rotation. So that the water continues to rise after it has passed directly under the moon, though the immediate action of the moon there begins to decrease, and comes not to its greatest elevation till it has got about half a quadrant farther. It continues also to descend after it has passed at 90° distance from the point below the moon, to a like distance of about half a quadrant. The greatest elevation therefore is not in the line drawn through the centres of the earth and moon, nor the lowest points where the moon appears in the horizon, but all these about half a quadrant removed eastward from these points, in the direction of the motion of rotation. Thus in open seas, where the water flows freely, the moon M is generally past the north and south meridian, as at *p*, when the high water is at Z and at *n*: the reason of which is plain, because the moon acts with the same force after she has passed the meridian, and thus adds to the libratory or waving motion, which the water acquired when she was in the meridian; and therefore the time of high water is not precisely at the time of her coming to the meridian, but some time after, &c.

Besides, the Tides answer not always to the same distance of the moon, from the meridian, at the same places; but are variously affected by the action of the sun, which brings them on sooner when the moon is in her first and third quarters, and keeps them back later when she is in her 2d and 4th; because, in the former case the Tide raised by the sun alone would be earlier than the Tide raised by the moon, and in the latter case later.

2. We have hitherto adverted only to the action of the moon in producing Tides; but it is manifest that, for the same reasons, the inequality of the sun's action on different parts of the earth, would produce a like effect, and a like variation from the exact spherical figure of a fluid earth. So that in reality there are two Tides every natural day from the action of the sun, as there are in the lunar day from that of the moon, subject to the same laws; and the lunar Tide, as we have observed, is somewhat changed by the action of the sun, and the change varies every day on account of the inequality between the natural and the lunar day. Indeed the effect of the sun in producing Tides, because of his immense distance, must be considerably less than that of the moon, though the gravity toward the sun be much greater: for it is not the action of the sun or moon itself, but the inequalities in that action, that have any effect: the sun's distance is so great, that the diameter of the earth is but as a point in comparison with it, and therefore the difference between the sun's actions on the nearest and farthest parts, becomes vastly less than it would be if the sun were as near as the moon. However the immense bulk of the sun makes the effect still sensible, even at so great a distance; and therefore, though the action of the moon has the greatest share in producing the Tides, the action of the sun adds sensibly to it when they conspire together, as in the full and change of the moon, when they are nearly in the same line with the centre of the earth, and therefore unite their forces: consequently, in the syzygies, or at new and full moon, the Tides are the greatest, being what are called the *Spring-Tides*. But the action of the sun diminishes the effect of the moon's action in the quarters, because the one raises the water in that case where the other depresses it; therefore the Tides are the least in the quadratures, and are called *Neap-Tides*.

Newton has calculated the effects of the sun and moon respectively upon the Tides, from their attractive powers. The former he finds to be to the force of gravity, as 1 to 12868200, and to the centrifugal force at the equator as 1 to 44527. The elevation of the waters by this force is considered by Newton as an effect similar to the elevation of the equatorial parts above the polar parts of the earth, arising from the centrifugal force at the equator; and as it is 44527 times less, he finds it to be $24\frac{1}{4}$ inches, or 2 feet and $\frac{1}{4}$ an inch.

To find the force of the moon upon the water, Newton compares the spring-tides at the mouth of the river Avon, below Bristol, with the neap-tides there, and finds the proportion as 9 to 5; whence, after several necessary corrections, he concludes that the force of the moon to that of the sun, in raising the waters of the ocean, is as 4·4815 to 1; so that the force of the moon is able of itself to produce an elevation of 9 feet $1\frac{3}{4}$ inch, and the sun and moon together may produce an elevation of about 11 feet 2 inches, when at their mean distances from the earth, or an elevation of about $12\frac{1}{2}$ feet, when the moon is nearest the earth. The height to which the water is found to rise, upon coasts of the open and deep ocean, is agreeable enough to this computation.

Dr. Horsley estimates the force of the moon to that of the sun, as 5·0469 to 1, in his edit. of Newton's Princip. See the Princip. lib. 3, sect. 3, pr. 36 and 37; also Maclaurin's Dissert. de Causa Physica Fluxus et Refluxus Maris apud Phil. Nat. Princ. Math. Comment.

ment, le Seur & Jacquier, tom. 3, p. 272. And other calculators make the proportion ſtill more different.

3. It muſt be obſerved, that the ſpring-tides do not happen preciſely at new and full moon, nor the neap-tides at the quarters, but a day or two after; becauſe, as in other caſes, ſo in this, the effect is not greateſt or leaſt when the immediate influence of the cauſe is greateſt or leaſt. As, for example, the greateſt heat is not on the day of the ſolſtice, when the immediate action of the ſun is greateſt, but ſome time after; ſo likewiſe, if the actions of the ſun and moon ſhould ſuddenly ceaſe, yet the Tides would continue to have their courſe for ſome time; and like alſo as the waves of the ſea continue after a ſtorm.

4. The different diſtances of the moon from the earth produce a ſenſible variation in the Tides. When the moon approaches toward the earth, her action on every part increaſes, and the differences of that action, on which the Tides depend, alſo increaſe; and as the moon approaches, her action on the neareſt parts increaſes more quickly than that on the remote parts, ſo that the Tides increaſe in a higher proportion as the moon's diſtances decreaſe. In fact, it is ſhewn by Newton, that the Tides increaſe in proportion as the cubes of the diſtances decreaſe; ſo that the moon at half her diſtance would produce a Tide 8 times greater.

The moon deſcribes an oval about the earth, and at her neareſt diſtance produces a Tide ſenſibly greater than at her greateſt diſtance from the earth: and hence it is that two great ſpring-tides never ſucceed each other immediately; for if the moon be at her leaſt diſtance from the earth at the change, ſhe muſt be at her greateſt diſtance at the full, having made half a revolution in the intervening time, and therefore the ſpring-tide then will be much leſs than that at the laſt change was; and for the ſame reaſon, if a great ſpring-tide happen at the time of full moon, the Tide at the enſuing change will be leſs.

5. The ſpring-tides are higheſt, and the neap-tides loweſt, about the time of the equinoxes, or the latter end of March and September; and, on the contrary, the ſpring-tides are the loweſt, and the neap-tides the higheſt, at the ſolſtices, or about the latter end of June and December: ſo that the difference between the ſpring and neap Tides, is much more conſiderable about the equinoctial than the ſolſtitial ſeaſons of the year. To illuſtrate and evince the truth of this obſervation, let us conſider the effect of the luminaries upon the Tides, when in and out of the plane of the equator. Now it is manifeſt, that if either the ſun or moon were in the pole, they could not have any effect on the Tides; for their action would raiſe all the water at the equator, or at any parallel, quite around, to a uniform height; and therefore any place of the earth, in deſcribing its parallel to the equator, would not meet, in its courſe, with any part of the water more elevated than another; ſo that there could be no Tide in any place, that is, no alteration in the height of the waters.

On the other hand, the effect of the ſun or moon is greateſt when in the equinoctial; for then the axis of the ſpheroidal figure, ariſing from their action, moves in the greateſt circle, and the water is put into the greateſt agitation; and hence it is that the ſpring-tides produced when the ſun and moon are both in the equinoctial, are the greateſt of any, and the neaptides the leaſt of any about that time. And when the luminary is any where between the equinoctial and the pole, the Tides are the ſmaller.

6. The higheſt ſpring tides are after the autumnal and before the vernal equinox: the reaſon of which is, becauſe the ſun is nearer the earth in winter than in ſummer.

7. Since the greateſt of the two Tides happening in every diurnal revolution of the moon, is that in which the moon is neareſt the zenith, or nadyr: for this reaſon, while the ſun is in the northern ſigns, the greater of the two diurnal Tides in our climates, is that ariſing from the moon above the horizon; when the ſun is in the ſouthern ſigne, the greateſt is that ariſing from the moon below the horizon. Thus it is found by obſervation that the evening Tides in the ſummer exceed the morning Tides, and in winter the morning Tides exceed the evening Tides. The difference is found at Briſtol to amount to 15 inches, and at Plymouth to 12. It would be ſtill greater, but that a fluid always retains an impreſſed motion for ſome time; ſo that the preceding Tides affect always thoſe that follow them. Upon the whole, while the moon has a north declination, the greateſt Tides in the northern hemiſphere are when ſhe is above the horizon, and the reverſe while her declination is ſouth.

8. Such would the Tides regularly be, if the earth were all over covered with the ſea very deep, ſo that the water might freely follow the influence of the ſun and moon; but, by reaſon of the ſhoalneſs of ſome places, and the narrowneſs of the ſtraits in others, through which the Tides are propagated, there ariſes a great diverſity in the effect according to the various circumſtances of the places. Thus, a very ſlow and imperceptible motion of the whole body of water, where it is very deep, as 2 miles for inſtance, will ſuffice to raiſe its ſurface 10 or 12 feet in a Tide's time: whereas, if the ſame quantity of water were to be conveyed through a channel of 40 fathoms deep, it would require a very rapid ſtream to effect it in ſo large inlets as are the Engliſh channel, and the German ocean; whence the Tide is found to ſet ſtrongeſt in thoſe places where the ſea grows narroweſt, the ſame quantity of water being in that caſe to paſs through a ſmaller paſſage. This is particularly obſervable in the ſtraits between Portland and Cape la Hogue in Normandy, where the Tide runs like a ſluice: and would be yet more ſo between Dover and Calais, if the Tide coming round the iſland did not check it.

This force, when once impreſſed, continues to carry the water above the ordinary height in the ocean, eſpecially where the water meets a direct obſtacle, as it does in St. Maloes; and where it enters into a long channel which, running far into the land, grows very ſtrait at its extremity, as it does into the Severn ſea at Chepſtow and Briſtol.

This ſhoalneſs of the ſea, and the intercurrent continents, are the reaſons that in the open ocean the Tides riſe but to very ſmall heights in proportion to what they do in wide-mouthed rivers, opening in the direction

tion of the ſtream of the Tide; and that high water is not ſoon after the moon's appulſe to the meridian, but ſome hours after it, as it is obſerved upon all the weſtern coaſt of Europe and Africa, from Ireland to the Cape of Good Hope; in all which a ſouth-weſt moon makes high water; and the ſame it is ſaid is the caſe on the weſtern ſide of America. So that Tides happen to different places at all diſtances of the moon from the meridian, and conſequently at all hours of the day.

To allow the Tides their full motion, the ocean in which they are produced, ought to be extended from eaſt to weſt 90 degrees at leaſt; becauſe that is the diſtance between the places where the water is moſt raiſed and depreſſed by the moon. Hence it appears that it is only in the great oceans that ſuch Tides can be produced, and why in the larger Pacific ocean they exceed thoſe in the Atlantic ocean. Hence alſo it is obvious, why the Tides are not ſo great in the torrid zone, between Africa and America, where the ocean is narrower, as in the temperate zones on either ſide; and hence we may alſo underſtand why the Tides are ſo ſmall in iſlands that are very far diſtant from the ſhores. It is farther manifeſt that, in the Atlantic ocean, the water cannot riſe on one ſhore but by deſcending on the other; ſo that at the intermediate iſlands it muſt continue at a mean height between its elevations on thoſe two ſhores. But when Tides paſs over ſhoals, and through ſtraits into bays of the ſea, their motion becomes more various, and their height depends on many circumſtances.

To be more particular. The Tide that is produced on the weſtern coaſts of Europe, in the Atlantic, correſponds to the ſituation of the moon already deſcribed. Thus it is high water on the weſtern coaſts of Ireland, Portugal and Spain, about the 3d hour after the moon has paſſed the meridian: from thence it flows into the adjacent channels, as it finds the eaſieſt paſſage. One current from it, for inſtance, runs up by the ſouth of England, and another comes in by the north of Scotland; they take a conſiderable time to move all this way, making always high water ſooner in the places to which they firſt come; and it begins to fall at theſe places while the currents are ſtill going on to others that are farther diſtant in their courſe. As they return, they are not able to raiſe the Tide, becauſe the water runs faſter off than it returns, till, by a new Tide, propagated from the open ocean, the return of the current is ſtopped, and the water begins to riſe again. The Tide propagated by the moon in the German ocean, when ſhe is 3 hours paſt the meridian, takes 12 hours to come from thence to London bridge; ſo that when it is high water there, a new Tide is already come to its height in the ocean; and in ſome intermediate place it muſt be low water at the ſame time. Conſequently when the moon has north declination, and we ſhould expect the Tide at London to be the greateſt when the moon is above the horizon, we find it is leaſt; and the contrary when ſhe has ſouth declination.

At ſeveral places it is high water 3 hours before the moon comes to the meridian; but that Tide, which the moon puſhes as it were before her, is only the Tide oppoſite to that which was raiſed by her when ſhe was 9 hours paſt the oppoſite meridian.

It would be endleſs to recount all the particular ſolutions, which are eaſy conſequences from this doctrine: as, why the lakes and ſeas, ſuch as the Caſpian ſea and the Mediterranean ſea, the Black ſea and the Baltic, have little or no ſenſible Tides: for lakes are uſually ſo ſmall, that when the moon is vertical ſhe attracts every part of them alike, ſo that no part of the water can be raiſed higher than another: and having no communication with the ocean, it can neither increaſe nor diminiſh their water, to make it riſe and fall; and ſeas that communicate by ſuch narrow inlets, and are of ſo immenſe an extent, cannot ſpeedily receive and empty water enough to raiſe or ſink their ſurface any thing ſenſibly.

In general; when the time of high water at any place is mentioned, it is to be underſtood on the days of new and full moons.—Among pilots, it is cuſtomary to reckon the time of flood, or high water, by the point of the compaſs the moon bears on, at that time, allowing ¾ of an hour for each point. Thus, on the full and change days, in places where it is flood at noon, the Tide is ſaid to flow north and ſouth, or at 12 o'clock: in other places, on the ſame days, where the moon bears 1, 2, 3, 4, or more points to the eaſt or weſt of the meridian, when it is high water, the Tide is ſaid to flow on ſuch point; thus, if the moon bears SE, at flood, it is ſaid to flow SE and NW, or 3 hours before the meridian, that is, at 9 o'clock; if it bears SW, it flows SW and NE, or at 3 hours after the meridian; and in like manner for the other points of the moon's bearing.

The times of high water in any place fall about the ſame hours after a period of about 15 days, or between one ſpring Tide and another; but during that period, the times of high water fall each day later by about 48 minutes.

On the ſubject of this article, ſee Newton Princ. Math. lib. 3, prop. 24, and De Syſtem. Mundi ſect. 38, &c. Apud Opera edit. Horſley, tom. 3, pa. 52. &c. p. 203 &c. Maclaurin's Account of Newton's Diſcoveries, book 4, ch. 7. Ferguſon's Aſtron. ch. 17. Robertſon's Navig. book 6, ſect. 7, 8, 9. Lalande's Aſtron. vol. 4.

Tide *Dial*, an inſtrument contrived by Mr. Ferguſon, for exhibiting and determining the ſtate of the Tides. For the conſtruction and uſe of which ſee his Aſtron. p. 297.

Tide *Tables*, are tables commonly exhibiting the times of high water at ſundry places, as they fall on the days of the full and change of the moon, and ſometimes the height of them alſo. Theſe are common in moſt books on Navigation, particularly Robertſon's, and the 2d ed. of Tables requiſite to be uſed with the Nautical Almanac. See one at High-*water*.

TIERCE, or Teirce, a liquid meaſure, as of wine, oil, &c, containing 42 gallons, or the 3d part of a pipe; whence its name.

TIME, a ſucceſſion of phenomena in the univerſe; or a mode of duration, marked by certain periods and meaſures; chiefly indeed by the motion and

and revolution of the luminaries, and particularly of the fun.

The idea of Time in general, Locke obferves, we acquire by confidering any part of infinite duration, as fet out by periodical meafures: the idea of any particular Time, or length of duration, as a day, an hour, &c, we acquire firft by obferving certain appearances at regular and feemingly equidiftant periods. Now, by being able to repeat thefe lengths or meafures of Time as often as we will, we can imagine duration, where nothing really endures or exifts; and thus we imagine tomorrow, or next year, &c.

Some of the later fchool-philofophers define Time to be the duration of a thing whofe exiftence is neither without beginning nor end: by this, Time is diftinguifhed from eternity.

Ariftotle and the Peripatetics define it, *numerus motus fecundum prius & pofterius*, or a multitude of tranfient parts of motion, fucceeding each other, in a continual flux, in the relation of priority and pofteriority. Hence it fhould follow that Time is motion itfelf, or at leaft the duration of motion, confidered as having feveral parts, fome of which are continually fucceeding to others. But on this principle, Time or temporal duration would not agree to bodies at reft, which yet nobody will deny to exift in Time, or to endure for a Time.

To avoid this inconvenience, the Epicureans and Corpufcularians made Time to be a fort of flux different from motion, confifting of infinite parts, continually and immediately fucceeding each other, and this from eternity to eternity. But others directly explode this notion, as eftablifhing an eternal being, independent of God. For how fhould there be a flux before any thing exifted to flow? and what fhould that flux be, a fubftance, or an accident? According to the philofophic poet,

> " Time of itfelf is nothing, but from thought
> Receives its rife; by labouring fancy wrought
> From things confider'd, whilft we think on fome
> As prefent, fome as paft, or yet to come.
> No thought can think on Time, that's ftill confeft,
> But thinks on things in motion or at reft."

And fo on. Vide Lucretius, book i.

Time may be diftinguifhed, like place, into *abfolute* and *relative*.

Abfolute TIME, is Time confidered in itfelf, and without any relation to bodies, or their motions.

Relative or *Apparent* TIME, is the fenfible meafure of any duration by means of motion.

Some authors diftinguifh Time into *aftronomical* and *civil*.

Aftronomical TIME, is that which is taken purely from the motion of the heavenly bodies, without any other regard.

Civil TIME, is the former Time accommodated to civil ufes, and formed or diftinguifhed into years, months, days, &c.

Time makes the fubject of chronology.

TIME, in mufic, is an affection of found, by which it is faid to be long or fhort, with regard to its continuance in the fame tone or degree of tune.

Mufical Time is diftinguifhed into *common* or *duple* Time, and *triple* Time.

Double, *duple*, or *common Time*, is when the notes are in a duple duration of each other,* viz, a femibreve equal to 2 minims, a minim to 2 crotchets, a crotchet to 2 quavers, &c.

Common or double Time is of two kinds. The firft when every bar or meafure is equal to a femibreve, or its value in any combination of notes of a lefs quantity. The fecond is where every bar is equal to a minim, or its value in lefs notes. The movements of this kind of meafure are various, but there are three common diftinctions; the firft *flow*, denoted at the beginning of the line by the mark C; the 2d *brifk*, marked thus ₵; and the 3d *very brifk*, thus marked .

Triple Time is when the durations of the notes are triple of each other, that is, when the femibreve is equal to 3 minims, the minim to 3 crotchets, &c. and it is marked T.

TIME-*keepers*, in a general fenfe, denote inftruments adapted for meafuring time. See CHRONOMETER.

In a more peculiar and definite fenfe, Time-keeper is a term firft applied by Mr. John Harrifon to his watches, conftructed and ufed for determining the longitude at fea, and for which he received, at different times, the parliamentary reward of 20 thoufand pounds. And feveral other artifts have fince received alfo confiderable fums for their improvements of Time-keepers; as Arnold, Mudge, &c. See LONGITUDE.

This appellation is now become common among artifts, to diftinguifh fuch watches as are made with extraordinary care and accuracy for nautical or aftronomical obfervations.

The principles of Mr. Harrifon's Time-keeper, as they were communicated by himfelf, to the commiffioners appointed to receive and publifh the fame in the year 1765, are as below:

" In this Time-keeper there is the greateft care taken to avoid friction, as much as can be, by the wheel moving on fmall pivots, and in ruby-holes, and high numbers in the wheels and pinions.

" The part which meafures time goes but the eighth part of a minute without winding up; fo that part is very fimple, as this winding-up is performed at the wheel next to the balance-wheel; by which means there is always an equal force acting at that wheel, and all the reft of the work has no more to do in the meafuring of time than the perfon that winds up once a day.

" There is a fpring in the infide of the fufee, which I will call a fecondary main fpring. This fpring is always kept ftretched to a certain tenfion by the main fpring; and during the time of winding-up the Time-keeper, at which time the main-fpring is not fuffered to act, this fecondary-fpring fupplies its place.

" In common watches in general, the wheels have about one-third the dominion over the balance, that the balance-fpring has; that is, if the power which the balance-fpring has over the balance be called three, that

that from the wheel is one: but in this my Time-keeper, the wheels have only about one-eightieth part of the power over the balance that the balance ſpring has; and it muſt be allowed, the leſs the wheels have to do with the balance, the better. The wheels in a common watch having this great dominion over the balance, they can, when the watch is wound up, and the balance at reſt, ſet the watch a-going; but when my Time-keeper's balance is at reſt, and the ſpring is wound up, the force of the wheels can no more ſet it a-going, than the wheels of a common regulator can, when the weight is wound-up, ſet the pendulum a-vibrating; nor will the force from the wheels move the balance when at reſt, to a greater angle in proportion to the vibration that it is to fetch, than the force of the wheels of a common regulator can move the pendulum from the perpendicular, when it is at reſt.

"My Time-keeper's balance is more than three times the weight of a large ſized common watch balance, and three times its diameter; and a common watch balance goes through about ſix inches of ſpace in a ſecond, but mine goes through about twenty-four inches in that time: ſo that had my Time-keeper only theſe advantages over a common watch, a good performance might be expected from it. But my Time-keeper is not affected by the different degrees of heat and cold, nor agitation of the ſhip; and the force from the wheels is applied to the balance in ſuch a manner, together with the ſhape of the balance-ſpring, and (if I may be allowed the term) an artificial cycloid, which acts at this ſpring; ſo that from theſe contrivances, let the balance vibrate more or leſs, all its vibrations are performed in the ſame time; and therefore if it go at all, it muſt go true. So that it is plain from this, that ſuch a Time-keeper goes entirely from principle, and not from chance."

We muſt refer thoſe who may deſire to ſee a minute account of the conſtruction of Mr. Harriſon's Time-keeper, to the publication by order of the commiſſioners of longitude.

We ſhall here ſubjoin a ſhort view of the improvements in Mr. Harriſon's watch, from the account preſented to the board of longitude by Mr. Ludlam, one of the gentlemen to whom, by order of the commiſſioners, Mr. Harriſon diſcovered and explained the principle upon which his Time-keeper is conſtructed. The defects in common watches which Mr. Harriſon propoſes to remedy, are chiefly theſe: 1. That the main ſpring acts not conſtantly with the ſame force upon the wheels, and through them upon the balance: 2. That the balance, either urged with an unequal force, or meeting with a different reſiſtance from the air, or the oil, or the friction, vibrates through a greater or leſs arch: 3. That theſe unequal vibrations are not performed in equal times: and, 4. That the force of the balance-ſpring is altered by a change of heat.

To remedy the firſt defect, Mr. Harriſon has contrived that his watch ſhall be moved by a very tender ſpring, which never unrolls itſelf more than one-eighth part of a turn, and acts upon the balance through one wheel only. But ſuch a ſpring cannot keep the watch in motion a long time. He has, therefore, joined another, whoſe office is to wind up the firſt ſpring eight times in every minute, and which is itſelf wound up but once a day. To remedy the ſecond defect, he uſes a much ſtronger balance ſpring than in a common watch. For if the force of this ſpring upon the balance remains the ſame, whilſt the force of the other varies, the errors ariſing from that variation will be the leſs, as the fixed force is the greater. But a ſtronger ſpring will require either a heavier or a larger balance. A heavier balance would have a greater friction. Mr. Harriſon, therefore, increaſes the diameter of it. In a common watch it is under an inch, but in Mr. Harriſon's two inches and two tenths. However, the methods already deſcribed only leſſening the errors, and not removing them, Mr. Harriſon uſes two ways to make the times of the vibrations equal, though the arches may be unequal: one is to place a pin, ſo that the balance-ſpring preſſing againſt it, has its force increaſed, but increaſed leſs when the variations are larger: the other to give the pallets ſuch a ſhape, that the wheels preſs them with leſs advantage, when the vibrations are larger. To remedy the laſt defect, Mr. Harriſon uſes a bar compounded of two thin plates of braſs and ſteel, about two inches in length, riveted in ſeveral places together, faſtened at one end and having two pins at the other, between which the balance ſpring paſſes. If this bar be ſtraight in temperate weather (braſs changing its length by heat more than ſteel) the braſs ſide becomes convex when it is heated, and the ſteel ſide when it is cold: and thus the pins lay hold of a different part of the ſpring in different degrees of heat, and lengthen or ſhorten it as the regulator does in a common watch.

The principles, on which Mr. Arnold's Time keeper is conſtructed, are theſe: The balance is unconnected with the wheel work, except at the time it receives the impulſe to make it continue its motion, which is only whilſt it vibrates 10° out of 380° which is the whole vibration; and during this ſmall interval it has little or no friction, but what is on the pivots, which work in ruby holes on diamonds. It has but one pallet, which is a plane ſurface formed out of a ruby, and has no oil on it. Watches of this conſtruction, ſays Mr. Lyons, go whilſt they are wound up; they keep the ſame rate of going in every poſition, and are not affected by the different forces of the ſpring; and the compenſation for heat and cold is abſolutely adjuſtable. Phipps's Voyage to the North Pole, p. 230. See LONGITUDE.

TISRI, or TIZRI, in chronology, the firſt Hebrew month of the civil year, and the 7th of the eccleſiaſtical or ſacred year. It anſwered to part of our September and October.

TOD *of wool*, is mentioned in the ſtatute 12 Carol. II. c. 32, as a weight containing 2 ſtone, or 28 pounds.

TOISE, a French meaſure, containing 6 of their feet, ſimilar to our fathom.

TONDIN, or TANDINO, in Architecture. See TORE.

TONE, or TUNE, in Muſic, a property of ſound, by which it comes under the relation of grave and acute; or the degree of elevation any ſound has, from the degree of ſwiftneſs of the vibrations of the parts of the ſonorous body.

For the cause, measure, degree, difference, &c, of Tones, see TUNE.

The word Tone is taken in four different senses among the ancients. 1, For any sound. 2, For a certain interval; as when it is said the difference between the diapente and diatessaron is a Tone. 3, For a certain locus or compass of the voice; in which sense they used the Dorian, Phrygian, Lydian Tones. 4. For tension; as when they speak of an acute, a grave, or a middle Tone. Wallis's Append. Ptolom. Harm. p. 172.

TONE is more particularly used, in music, for a certain degree or interval of tune, by which a sound may be either raised or lowered from one extreme of a concord to the other, so as still to produce true melody.

In tempered scales of music, the Tones are made equal, but in a true and accurate practice of singing they are not so. Pepusch, in Philos. Trans. No. 481, p. 274.

Beside the concords, or harmonical intervals, musicians admit three less kinds of intervals, which are the measures and component parts of the greater, and are called *degrees*.

Of these degrees, two are called Tones, and the third a semitone. Their ratios in numbers are 8 to 9, called a *greater Tone*; 9 to 10, called a *lesser Tone*; and 15 to 16, a *semitone*.

The Tones arise out of the simple concords, and are equal to their differences. Thus the greater Tone, 8 : 9, is the difference of a 5th and a 4th; the less Tone 9 : 10, the difference of a less 3d and a 4th, or of a 5th and a greater 6th; and the semitone 15 : 16, the difference of a greater 3d and a 4th.

Of these Tones and semitones every concord is compounded, and consequently every one is resolvable into a certain number of them. Thus the less 3d consists of one greater Tone and one semitone: the greater 3d, of one greater Tone and one less Tone: the 4th, of one greater Tone, one less Tone, and one semitone: and the 5th, of two greater Tones, one less Tone, and one semitone.

TONSTALL (CUTHBERT), a learned English divine and mathematician, was born in the year 1476. He entered a student at the university of Oxford about the year 1491; but afterwards, being driven from thence by the plague, he went to Cambridge, and shortly after to the university of Padua in Italy, which was then in a flourishing state of literature, where his genius and learning acquired him great respect from every one, particularly for his knowledge in mathematics, philosophy, and jurisprudence.

Upon his return home, he met with great favours from the government, obtaining several church preferments, and the office of secretary to the cabinet of the king, Henry the 8th. This prince, having also employed him on several foreign embassies, was so well satisfied with his conduct, that he first gave him the bishopric of London in 1522, and afterwards that of Durham in 1530.

Tonstall approved at first of the dissolution of the marriage of his benefactor with Catherine of Spain, and even wrote a book in favour of that dissolution; but he afterwards condemned that work, and experienced a great reverse of fortune. He was ejected from the see of Durham for his religion in the time of Edward the 6th, to which however he was restored again by queen Mary in the beginning of her reign, but was again expelled in 1559 when queen Elizabeth was settled in her throne, and he died in a prison a few months after, in the 84th year of his age.

Tonstall was doubtless one of the most learned men of his time. "He was, says Wood, a very good Grecian and Ebritian, an eloquent rhetorician, a skilful mathematician, a noted civilian and canonist, and a profound divine. But that which maketh for his greatest commendation, is, that Erasmus was his friend, and he a fast friend to Erasmus, in an epistle to whom from Sir Thomas More, I find this character of Tonstall, that, "As there was no man more adorned with knowledge and good literature, no man more severe and of greater integrity for his life and manners; so there was no man a more sweet and pleasant companion, with whom a man would rather choose to converse."

His writings that were published, were chiefly the following:

1. *In Laudem Matrimonii*, Lond. 1518, 4to.—But that for which he is chiefly entitled to a place in this work, was his book upon arithmetic, viz,

2. *De Arte Supputandi*, Lond. 1522, 4to, dedicated to Sir Thomas More. This was afterwards several times printed abroad.

3. A Sermon on Palm Sunday before king Henry the 8th, &c. Lond. 1539 and 1633, 4to.

4. *De Veritate Corporis & Sanguinis Domini in Eucharistia*. Lutet. 1554, 4to.

5. *Compendium in decem Libros Ethicorum Aristotelis*. Par. 1554, in 8vo.

6. *Contra impios Blasphematores Dei prædestinationis opera*. Antw. 1555, 4to.

7. Godly and devout Prayers in English and Latin. 1558, in 8vo.

TOPOGRAPHY, is a description or draught of some particular place, or small tract of land; as that of a city or town, manor or tenement, field, garden, house, castle, or the like; such as surveyors set out in their plots, or make draughts of, for the information and satisfaction of the proprietors.

Topography differs from Chorography, as a particular from a more general.

TORNADO, a sudden and violent gust of wind arising suddenly from the shore, and afterwards veering round all points of the compass like a hurricane; very frequent on the coast of Guinea.

TORRENT, in Hydrography, a temporary stream of water, falling suddenly from mountains, &c, where there have been great rains, or an extraordinary thaw of snow; sometimes making great ravages in the plains.

TORRICELLI (EVANGELISTE), an illustrious mathematician and philosopher of Italy, was born at Faenza in 1608, and trained up in Greek and Latin literature by an uncle, who was a monk. Natural inclination led him to cultivate mathematical knowledge, which he pursued some time without a master; but at about 20 years of age, he went to Rome, where he continued

continued the pursuit of it under father Benedict Castelli. Castelli had been a scholar of the great Galileo, and had been appointed by the pope professor of mathematics at Rome. Torricelli made such progress under this master, that having read Galileo's *Dialogues*, he composed a *Treatise concerning motion* upon his principles. Castelli, surprised at the performance, carried it and read it to Galileo, who heard it with great pleasure, and conceived a high esteem and friendship for the author. Upon this, Castelli proposed to Galileo, that Torricelli should come and live with him; recommending him as the most proper person he could have, since he was the most capable of comprehending those sublime speculations, which his own great age, infirmities, and want of sight, prevented him from giving to the world. Galileo accepted the proposal, and Torricelli the employment, as things of all others the most advantageous to both. Galileo was at Florence, at which place Torricelli arrived in 1641, and began to take down what Galileo dictated, to regulate his papers, and to act in every respect according to his directions. But he did not long enjoy the advantages of this situation, as Galileo died at the end of only three months.

Torricelli was then about returning to Rome; but the Grand Duke engaged him to continue at Florence, making him his own mathematician for the present, and promising him the professor's chair as soon as it should be vacant.

Here he applied himself intensely to the study of mathematics, physics, and astronomy, making many improvements and some discoveries. Among others, he greatly improved the art of making microscopes and telescopes; and it is generally acknowledged that he first found out the method of ascertaining the weight of the atmosphere by a proportionate column of quicksilver, the barometer being called from him the *Torricellian tube*, and *Torricellian experiment*. In short, great things were expected from him, and great things would probably have been farther performed by him, if he had lived; but he died, after a few days illness, in 1647, when he was but just entered the 40th year of his age.

Torricelli published at Florence in 1644, a volume of ingenious pieces, intitled, *Opera Geometrica*, in 4to. There was also published at the same place, in 1715, *Lezzioni Accademiche*, consisting of 96 pages in 4to. These are discourses that had been pronounced by him upon different occasions. The first of them was to the academy of La Crusca, by way of thanks for admitting him into their body. The rest are upon subjects of mathematics and physics. Prefixed to the whole is a long life of Torricelli by Thomas Buonaventuri, a Florentine gentleman.

TORRICELLIAN, a term very frequent among physical writers, used in the phrases, *Torricellian tube*, or *Torricellian experiment*, on account of the inventor Torricelli, a disciple of the great Galileo.

TORRICELLIAN *Tube*, is the barometer tube, being a glass tube, open at one end, and hermetically sealed at the other, about 3 feet long, and $\frac{1}{4}$ of an inch in diameter.

TORRICELLIAN *Experiment*, or the filling the barometer tube, is performed by filling the Torricellian tube with mercury, then stopping the open orifice with the finger, inverting the tube, and plunging that orifice into a vessel of stagnant mercury. This done, the finger is removed, and the tube sustained perpendicular to the surface of the mercury in the vessel.

The consequence is, that part of the mercury falls out of the tube into the vessel; and there remains only enough in the tube to fill about 30 inches of its capacity, above the surface of the stagnant mercury in the vessel; these being sustained in the tube by the pressure of the atmosphere on the surface of the stagnant mercury; and according as the atmosphere is more or less heavy, or as the winds, blowing upward or downward, heave up or depress the air, and so increase or diminish its weight and spring, more or less mercury is sustained, from 28 to 31 inches.

The Torricellian Experiment constitutes what we now call the *Barometer*.

TORRICELLIAN *Vacuum*, is the vacuum produced by filling a tube with mercury, and when inverted allowing it to descend to such a height as is counterbalanced by the pressure of the atmosphere, as in the Torricellian Experiment and Barometer, the vacuum being that part of the tube above the surface of the mercury.

TORRID *Zone*, is that round the middle of the earth, extending to $23\frac{1}{2}$ degrees on both sides of the equator.

TORUS, or TORE, in Architecture, is a large round moulding in the bases of the columns.

TOUCAN, or *American Goose*, is one of the modern constellations of the southern hemisphere, consisting of 9 small stars.

TRACTION, or *Drawing*, is the act of a moving power, by which the moveable is brought nearer to the mover, called also attraction.

TRACTRIX, in Geometry, a curve line called also Catenaria; which see.

TRAJECTORY, a term often used generally for the path of any body moving either in a void, or in a medium that resists its motion; or even for any curve passing through a given number of points. Thus Newton, Princip. lib. 1, prob. 22, proposes to describe a Trajectory that shall pass through five given points.

TRAJECTORY *of a Comet*, is its path or orbit, or the line it describes in its motion. This path, Hevelius, in his Cometographia, will have to be very nearly a right line; but Dr. Halley concludes it to be, as it really is, a very excentric ellipsis; though its place may often be well computed on the supposition of its being a parabola.—Newton, in prop. 41 of his 3d book, shews how to determine the Trajectory of a comet from three observations; and in his last prop. how to correct a Trajectory graphically described.

TRAMMELS, in Mechanics, an instrument used by artificers for drawing ovals upon boards, &c. One part of it consists of a cross with two grooves at right angles; the other is a beam carrying two pins which slide in those grooves, and also the describing pencil. All the engines for turning ovals are constructed on the same principles with the Trammels: the only difference is, that in the Trammels the board is at rest, and the pencil

cil moves upon it: in the turning engine, the tool, which supplies the place of the pencil, is at rest, and the board moves against it. See a demonstration of the chief properties of these instruments by Mr. Ludlam, in the Philos. Trans. vol. 70, pa. 378 &c.

TRANSACTIONS, *Philosophical*, are a collection of the principal papers and matters read before certain philosophical societies, as the Royal Society of London, and the Royal Society of Edinburgh. These Transactions contain the several discoveries and histories of nature and art, either made by the members of those societies, or communicated by them from their correspondents, with the various experiments, observations, &c, made by them, or transmitted to them, &c.

The Philos. Trans. of the Royal Society of London were set on foot in 1665, by Mr. Oldenburg, the then secretary of that Society, and were continued by him till the year 1677. They were then discontinued upon his death, till January 1678, when Dr. Grew resumed the publication of them, and continued it for the months of December 1678, and January and February 1679, after which they were intermitted till January 1683. During this last interval their want was in some measure supplied by Dr. Hook's Philosophical Collections. They were also interrupted for 3 years, from December 1687 to January 1691, beside other smaller interruptions amounting to near a year and a half more, before October 1695, since which time the Transactions have been carried on regularly to the present day, with various degrees of credit and merit.

Till the year 1752 these Transactions were published in numbers quarterly, and the printing of them was always the single act of the respective secretaries till that time; but then the society thought fit that a committee should be appointed to consider the papers read before them, and to select out of them such as they should judge most proper for publication in the future Transactions. For this purpose the members of the council for the time being, constitute a standing committee: they meet on the first Thursday of every month, and no less than seven of the members of the committee (of which number the president, or in his absence a vice president, is always to be one) are allowed to be a *quorum*, capable of acting in relation to such papers; and the question with regard to the publication of any paper, is always decided by the majority of votes taken by ballot.

They are published annually in two parts, at the expence of the society; and each fellow, or member, is entitled to receive one copy *gratis* of every part published after his admission into the society. For many years past, the collection, in two parts, has made one volume in each year; and in the year 1793 the number of the volumes was 83, being 10 less than the number of the year in the century. They were formerly much respected for the great number of excellent papers and discoveries contained in them; but within the last dozen years there has been a great falling off, and the volumes are now considered as of very inferior merit, as well as quantity.

There is also a very useful Abridgment, of those volumes of the Transactions that were published before the year 1752, when the society began to publish the Transactions on their own account. Those to the end of the year 1700 were abridged, in 3 volumes, by Mr. John Lowthorp: those from the year 1700 to 1720 were abridged, in 2 volumes, by Mr. Henry Jones: and those from 1719 to 1733 were abridged, in 2 volumes, by Mr. John Eames and Mr. John Martyn; Mr. Martyn also continued the abridgment of those from 1732 to 1744 in 2 volumes, and of those from 1744 to 1750 in 2 volumes; making in all 11 volumes, of very curious and useful matters in all the arts and sciences.

The Royal Society of Edinburgh, instituted in 1783, have also published 3 volumes of their Philosophical Transactions; which are deservedly held in the highest respect for the importance of their contents.

TRANSCENDENTAL *Quantities*, among Geometricians, are indeterminate ones; or such as cannot be expressed or fixed to any constant equation: such is a transcendental curve, or the like.

M. Leibnitz has a dissertation in the Acta Erud. Lips. in which he endeavours to shew the origin of such quantities; viz, why some problems are neither plain, solid, nor sursolid, nor of any certain degree, but do *transcend* all algebraic equations.

He also shews how it may be demonstrated without calculus, that an algebraic quadratrix for the circle or hyperbola is impossible: for if such a quadratrix could be found, it would follow, that by means of it any angle, ratio, or logarithm, might be divided in a given proportion of one right line to another, and this by one universal construction: and consequently the problem of the section of an angle, or the invention of any number of mean proportionals, would be of a certain finite degree. Whereas the different degrees of algebraic equations, and therefore the problem understood in general of any number of parts of an angle, or mean proportionals, is of an indefinite degree, and *transcends* all algebraical equations.

Others define Transcendental equations, to be such fluxional equations as do not admit of fluents in common finite algebraical equations, but as expressed by means of some curve, or by logarithms, or by infinite series; thus the expression $\dot{y} = \frac{\dot{x}}{\sqrt{aa - xx}}$ is a Transcendental equation, because the fluents cannot both be expressed in finite terms. And the equation which expresses the relation between an arc of a circle and its sine is a Transcendental equation; for Newton has demonstrated that this relation cannot be expressed by any finite algebraic equation, and therefore it can only be by an infinite or a Transcendental equation.

It is also usual to rank exponential equations among Transcendental ones; because such equations, although expressed in finite terms, have variable exponents, which cannot be expunged but by putting the equation into fluxions, or logarithms, &c. Thus, the exponential equation

equation $y = a^x$, gives $x \times \log. a = \log. y$, or $\dot{x} \times \log. a = \frac{\dot{y}}{y}$.

Transcendental *Curve*, in the Higher Geometry, is such a one as cannot be defined by an algebraic equation; or of which, when it is expressed by an equation, one of the terms is a variable quantity, or a curve line. And when such curve line is a geometrical one, or one of the first degree or kind, then the Transcendental curve is said to be of the second degree or kind, &c.

These curves are the same with what Des Cartes, and others after him, call mechanical curves, and which they would have excluded out of geometry; contrary however to the opinion of Newton and Leibnitz; for as much as, in the construction of geometrical problems, one curve is not to be preferred to another as it is defined by a more simple equation, but as it is more easily described than that other: besides, some of these Transcendental, or mechanical curves, are found of greater use than almost all the algebraical ones.

M. Leibnitz, in the Acta Erudit. Lipf. has given a kind of Transcendental equations, by which these Transcendental curves are actually defined, and which are of an indefinite degree, or are not always the same in every point of the curve. Now whereas algebraists use to assume some general letters or numbers for the quantities sought, in these Transcendental problems Leibnitz assumes general or indefinite equations for the lines sought; thus, for example, putting x and y for the abscis and ordinate, the equation he uses for a line required, is $a + bx + cy + exy + fxx + gyy$ &c $= 0$: by the help of which indefinite equation, he seeks for the tangent; and comparing that which results with the given property of tangents, he finds the value of the assumed letters a, b, c, &c, and thus defines the equation of the line sought.

If the comparison abovementioned do not succeed, he pronounces the line sought not to be an algebraical, but a Transcendental one.

This supposed, he proceeds to find the species of Transcendency: for some Transcendentals depend on the general division or section of a ratio, or upon logarithms, others upon circular arcs, &c.

Here then, beside the symbols x and y, he assumes a third, as v, to denote the Transcendental quantity; and of these three he forms a general equation of the line sought, from which he finds the tangent according to the differential method, which succeeds even in Transcendental quantities. This found, he compares it with the given properties of the tangents, and so discovers not only the values of a, b, c, &c, but also the particular nature of the Transcendental quantity.

Transcendental problems are very well managed by the method of fluxions. Thus, for the relation of a circular arc and right-line, let a denote the arc, and x the versed sine, to the radius 1, then is $a =$ fluent of $\frac{\dot{x}}{\sqrt{2x - xx}}$; and if the ordinate of a cycloid be y, then is

$$y = \sqrt{2x - xx} + \text{fluent of } \frac{\dot{x}}{\sqrt{2x - xx}}.$$

Thus is the analytical calculus extended to those lines which have hitherto been excluded, for no other cause but that they were thought incapable of it.

TRANSFORMATION, in Geometry, is the changing or reducing of a figure, or of a body, into another of the same area, or the same solidity, but of a different form. As, to Transform or reduce a triangle to a square, or a pyramid to a parallelopipedon.

Transformation *of Equations*, in Algebra, is the changing equations into others of a different form, but of equal value. This operation is often necessary, to prepare equations for a more easy solution, some of the principal cases of which are as follow.—1. The signs of the roots of an equation are changed, viz, the positive roots into negative, and the negative roots into positive ones, by only changing the signs of the 2d, 4th, and all the other even terms of the equation. Thus, the roots of the equation

$x^4 - x^3 - 19x^2 + 49x - 30 = 0$, are $+1, +2, +3, -5$;

whereas the roots of the same equation having only the signs of the 2d and 4th terms changed, viz, of

$x^4 + x^3 - 19x^2 - 49x - 30 = 0$, are $-1, -2, -3, +5$.

2. To Transform an equation into another that shall have its roots greater or less than the roots of the proposed equation by some given difference, proceed as follows. Let the proposed equation be the cubic $x^3 - ax^2 + bx - c = 0$; and let it be required to Transform it into another, whose roots shall be less than the roots of this equation by some given difference d; if the root y of the new equation must be the less, take it $y = x - d$, and hence $x = y + d$; then instead of x and its powers substitute $y + d$ and its powers, and there will arise this new equation

$$\text{(A)} \quad \left.\begin{array}{rrrr} y^3 & + 3dy^2 & + 3d^2y & + d^3 \\ & - ay^2 & - 2ady & - ad^2 \\ & & + by & + bd \\ & & & - c \end{array}\right\} = 0,$$

whose roots are less than the roots of the former equation by the difference d. If the roots of the new equation had been required to be greater than those of the old one, we must then have substituted $y = x + d$, or $x = y - d$, &c.

3. To take away the 2d or any other particular term out of an equation; or to Transform an equation, so as the new equation may want its 2d, or 3d, or 4th, &c term of the given equation $x^3 - ax^2 + bx - c = 0$, which is transformed into the equation (A) in the last article. Now to make any term of this equation (A) vanish, is only to make the coefficient of that term $= 0$, which will form an equation that will give the value of the assumed quantity d, so as to produce the desired effect, viz, to make that term vanish. So, to take away the 2d term, make $3d - a = 0$, which makes the assumed quantity $d = \frac{1}{3}a$. To take away the 3d term, we must put the sum of the coefficients of that term $= 0$, that is $3d^2 - 2ad + b = 0$, or $3d^2 - 2ad = -b$; then by resolving this quadratic equation, there is found the assumed quantity $d = \frac{1}{3}a \pm \frac{1}{3}\sqrt{a^2 - 3b}$, by the substitution of which for d, the 3d term will be taken away out of the equation.

In like manner, to take away the 4th term, we must make the sum of its coefficients $d^3 - ad^2 + bd - c = 0$; and

and so on for any other term whatever. And in the same manner we must also proceed when the proposed equation is not a cubic, but of any height whatever, as

$$x^n - ax^{n-1} + bx^{n-2} - cx^{n-3} \text{ \&c} = 0:$$

this is first, by substituting $y + d$ for x, to be Transformed to this new equation

$$\left.\begin{array}{l} y^n + ndy^{n-1} + \tfrac{1}{2}n.\overline{n-1}.d^2y^{n-2} \text{ \&c} \\ \quad - ay^{n-1} - a.\overline{n-1}.dy^{n-2} \text{ \&c} \\ \qquad\qquad + by^{n-2} \text{ \&c} \end{array}\right\} = 0;$$

then, to take away the 2d term, we must make $nd - a = 0$, or $d = \frac{a}{n}$; to take away the 3d term, we must make $\frac{1}{2}n.\overline{n-1}.d^2 - a.\overline{n-1}d + b = 0$, or $d^2 - \frac{2a}{n}d = -\frac{2b}{n(n-1)}$; and so on.

From whence it appears that, to take away the 2d term of an equation, we must resolve a simple equation; for the 3d term, a quadratic equation; for the 4th term, a cubic equation, and so on.

4. To multiply or divide the roots of an equation by any quantity; or to Transform a given equation to another, that shall have its roots equal to any multiple or submultiple of those of the proposed equation. This is done by substituting, for x and its powers, $\frac{y}{m}$ or py, and their powers, viz, $\frac{y}{m}$ for x, to multiply the roots by m; and py for x, to divide the roots by p.

Thus, to multiply the roots by m, substituting $\frac{y}{m}$ for x in the proposed equation

$$x^n - ax^{n-1} + bx^{n-2} \text{ \&c} = 0, \text{ and it becomes}$$

$$\frac{y^n}{m^n} - \frac{ay^{n-1}}{m^{n-1}} + \frac{by^{n-2}}{m^{n-2}} \text{ \&c} = 0;$$

or multiply all by m^n, then is

$$y^n - amy^{n-1} + bm^2y^{n-2} - cm^3y^{n-3} \text{ \&c} = 0,$$

an equation that hath its roots equal to m times the roots of the proposed equation.

In like manner, substituting py for x, in the proposed equation, &c, it becomes

$$y^n - \frac{ay^{n-1}}{p} + \frac{by^{n-2}}{p^2} - \frac{cy^{n-3}}{p^3} \text{ \&c} = 0,$$

an equation that hath its roots equal to those of the proposed equation divided by p.

From whence it appears, that to multiply the roots of an equation by any quantity m, we must multiply its terms, beginning at the 2d term, respectively by the terms of the geometrical series, m, m^2, m^3, m^4, &c. And to divide the roots of an equation by any quantity p, that we must divide its terms, beginning at the 2d, by the corresponding terms of this series p, p^2, p^3, p^4, &c.

5. And sometimes, by these Transformations, equations are cleared of fractions, or even of surds. Thus the equation $x^3 - ax^2\sqrt{p} + bx - c\sqrt{p} = 0$, by putting $y = x\sqrt{p}$, or multiplying the terms, from the 2d, by the geometricals $\sqrt{p}$, p, $p\sqrt{p}$, is Transformed to

$$y^3 - apy^2 + bpy - cp^2 = 0.$$

6. An equation, as $x^3 - ax^2 + bx - c = 0$, may be Transformed into another, whose roots shall be the reciprocals of the roots of the given equation, by substituting $\frac{1}{y}$ for x; by which it becomes $\frac{1}{y^3} - \frac{a}{y^2} + \frac{b}{y} - c = 0$, or, multiplying all by y^3, the same becomes $cy^3 - by^2 + ay - 1 = 0$.

On this subject, see Newton's Alg. on the Transmutation of Equations; Maclaurin's Algeb. pt. 2, chap. 3 and 4. Saunderson's Algebra, vol. 2, pa. 687, &c.

TRANSIT, in Astronomy, denotes the passage of any planet, just before or over another planet or star; or the passing of a star or planet over the meridian, or before an astronomical instrument.

Venus and Mercury, in their Transits over the sun, appear like dark specks.

Doctor Halley computed the times of a number of these visible Transits, for the last and present century, and published in the Philos. Trans. numb. 193. See also Abridg. vol. 1, pa. 427 &c. A Synopsis of these Transits is as follows, those of Mercury happening in the months of April and October, and those of Venus in May and November, both old-style; and if 11 days be added to the dates below, the sums will give the times for the new-style. First for Mercury, and then for Venus.

A Series of the Moments when Mercury is seen in Conjunction with the Sun, and within his Disc, with the Distances of the same Planet from the Sun's Centre.

In April, Old-Style.

Years.	Times of Mercury's Conjunction.			Distances from the the Sun's Centre.

"Those Transits which have the mark *, are but partly visible at London; but those which are marked **, are totally visible.

"Now it is to be observed, that at the ascending node of Mercury in the month of October, the diameter of the sun takes up 32′ 34″, and therefore the greatest duration of a central Transit is $5^h\ 29^m$. But in the month of April the diameter of the sun is 31′ 54″, whence by reason of the slower motion of the planet, there arises the greatest duration $8^h\ 1^m$. Now if Mercury approaches obliquely, these durations become shorter on account of the distance from the centre of the sun. And that the calculation may be more perfect, I have added the following Tables, in which are exhibited the half durations of these eclipses, to every minute of the distance seen from the centre of the sun. These added to or subtracted from the moment of conjunction found by the foregoing Table, give the beginning and end of the whole phenomenon."

April.

Of the Visible Conjunction of Venus with the Sun.

"Though Venus is the most beautiful of all the stars, yet (says Dr. Halley) like the rest of her sex, she does not care to appear in sight without her borrowed ornaments, and her assumed splendor. For the confined laws of motion envy this spectacle to the mortals of a whole age, like the secular games of the Ancients; though it be far the most noble among all those that astronomy can pretend to shew. Now it shall be declared hereafter, that by this one observation alone, the distance of the sun from the earth may be determined with the greatest certainty which hitherto has been included within wide limits, because of the parallax which is otherwise insensible. But as to the periods, they cannot be described so accurately as those of Mercury, since Venus has been observed within the sun's disk but once since the beginning of the world, and that by our Horrox." Dr. Halley then exhibits the principles of calculating these Transits, from whence he infers that,

"After 18 years Venus returns to the sun, taking away $2^d\ 10^h\ 52\frac{1}{2}^m$, from the moment of the foregoing Transit; and the planet proceeds in a path which is 24′ 41″ more to the south than the former.

"After 235 years adding $2^d\ 10^h\ 9^m$, Venus may again enter the sun, but in a more northern path by 11′ 33″. But if the foregoing year is bissextile, $3^d\ 10^h\ 9^m$ must be added.

"After 243 years Venus may also pass the sun, only taking away $0^h\ 43^m$ from the time of the former; but

but proceeds more foutherly by 13′ 8″. Now if the foregoing year be biffextile, add $23^h\ 17^m$.

" And in all thefe appulfes of Venus to the fun, in the month of November, the angle of her path with the ecliptic is 9° 5′, and her horary motion within the fun is 4′ 7″. And fince the femidiameter of the fun is 16′ 21″, the greateft duration of the Tranfit of the centre of Venus comes out $7^h\ 56^m$.

" Then let the fun and Venus be in conjunction at the defcending node in the month of May; and by the fame numbers the fame intervals may be computed. After 8 years let there be taken away $2^d\ 6^h\ 55'$. And Venus will make her Tranfit in a more northern path by 19′ 58″.

" After 235 years add $2^d\ 8^h\ 18^m$, or if the foregoing year be biffextile $3^d\ 8^h\ 18^m$, and you will have Venus more to the South by 9′ 21″.

" Laftly, after 243 years add $0^d\ 1^h\ 23^m$, or if the foregoing year be biffextile $1^d\ 1^h\ 23^m$, and Venus will be found in conjunction with the fun, but in a more northerly path by 10′ 37″.

" In every Tranfit within the fun at this node, the angle of Venus's path with the ecliptic is 8° 28′, and her horary motion is 4′ 0″; and the femidiameter of the fun fubtending 15′ 51″, the greateft duration of the central Tranfit comes out alfo $7^h\ 56^m$, exactly the fame as at the other node.

" As to the epochs, from that only ingrefs which Horrox obferved, the fun being then juft ready to fet, it is concluded, that Venus was in conjunction with the fun at London in the year 1639, Nov. $24^d\ 6^h\ 37^m$, and that fhe declined towards the fouth 8′ 30″. But in the month of May no mortal has feen her as yet within the fun. But from my numbers, which I judge to be not very different from the heavens, it appears that Venus for the next time will enter the fun in 1761, May $25^d\ 17^h\ 55^m$, that being the middle of the eclipfe, and then will be diftant from his centre 4′ 15″, towards the fouth. Hence and from the foregoing revolutions all the phenomena of this kind will be eafily exhibited for a whole millennium, as I have computed them in the following Table.

In November.

Years.	Times of Conjunction.			Diftance from the Sun's Centre.

1996	28	2	13	13	36	S
2004	25	19	18	6	22	N

" As for the durations of thefe eclipfes of Venus, they may be computed after the fame manner as thofe of Mercury in refpect of the centre. But fince Venus's diameter is pretty large, and fince the parallaxes alfo may bring a very notable difference as to time, a particular calculation muft neceffarily be made for every place.

"Now the diameter of Venus is fo great, that while fhe adheres to the fun's limb almoft 20 minutes of time will be elapfed, that is, when fhe applies directly to the fun. But when fhe is incident obliquely, fhe continues longer in the limb. Now that diameter, according to Horrox's obfervation, takes up 1′ 18″, when fhe is in conjunction with the fun at the afcending node, and 1′ 12″ at the other node.

" Now the chief ufe of thefe conjunctions is accurately to determine the fun's diftance from the earth, or his parallax, which aftronomers have in vain attempted to find by various other methods; for the minutenefs of the angles required eafily eludes the niceft inftruments. But in obferving the ingrefs of Venus into the fun, and her egrefs from the fame, the fpace of time between the moments of the internal contacts, obferved to a fecond of time, that is, to $\frac{1}{15}$ of a fecond or 4‴ of an arch, may be obtained by the affiftance of a moderate telefcope and a pendulum clock, that is confiftent with itfelf exactly for 6 or 8 hours. Now from two fuch obfervations rightly made in proper places, the diftance of the fun within a 500th part may be certainly concluded, &c." See Parallax.

Transit *Inftrument*, in Aftronomy, is a telefcope fixed at right angles to a horizontal axis; this axis being fo fupported that the line of collimation may move in the plane of the meridian.

The axis, to the middle of which the telefcope is fixed, fhould gradually taper toward its ends, and terminate in cylinders well turned and fmoothed; and a proper weight or balance is put on the tube, fo that it may ftand at any elevation when the axis refts on the fupporters. Two upright pofts of wood or ftone, firmly fixed at a proper diftance, are to fuftain the fupporters to this inftrument; thefe fupporters are two thick brafs plates,

plates, having well smoothed angular notches in their upper ends to receive the cylindrical arms of the axis; each of the notched plates is contrived to be moveable by a screw, which slides them upon the surfaces of two other plates immoveably fixed to the two upright posts; one plate moving in a vertical direction, and the other horizontally, they adjust the telescope to the planes of the horizon and meridian; to the plane of the horizon, by a spirit level hung in a position parallel to the axis, and to the plane of the meridian in the following manner. Observe the times by the clock when a circumpolar star, seen through this instrument, Transits both above and below the pole; then if the times of describing the eastern and western parts of its circuit be equal, the telescope is then in the plane of the meridian; otherwise the notched plates must be gently moved till the time of the star's revolution is bisected by both the upper and lower Transits, taking care at the same time that the axis keeps its horizontal position.

When the telescope is thus adjusted, a mark must be set up, or made, at a considerable distance (the greater the better) in the horizontal direction of the intersection of the cross wires, and in a place where it can be illuminated in the night-time by a lanthorn near it, which mark, being on a fixed object, will serve at all times afterwards to examine the position of the telescope, by first adjusting the tranverse axis by the level.

To adjust a clock by the sun's Transit over the meridian, note the times by the clock, when the preceding and following edges of the sun's limb touch the cross wires: the difference between the middle time and 12 hours, shews how much the mean, or clock time, is faster and slower than the apparent or solar time, for that day; to which the equation of time being applied, it will shew the time of mean noon for that day, by which the clock may be adjusted.

TRANSMISSION, in Optics, &c, denotes the property of a transparent or translucent body, by which it admits the rays of light to pass through its substance; in which sense, the word stands opposed to reflection.

For the cause of Transmission, or the reason why some bodies Transmit the rays, and others reflect them, see TRANSPARENCY and OPACITY.

The rays of light, Newton observes, are subject to fits of easy Transmission and reflection. See LIGHT, and REFLECTION.

TRANSMUTATION, or TRANSFORMATION, in Geometry, denotes the reduction or change of one figure or body into another of the same area or solidity; as a triangle into a square, a pyramid into a cube, &c.

TRANSMUTATION, in the Higher Geometry, has been used for the converting of a figure into another of the same kind and order, whose respective parts rise to the same dimensions in an equation, and admit the same tangents, &c.

If a rectilineal figure be to be Transmuted into another, it is sufficient that the intersections of the lines which compose it be transferred, and lines drawn through the same in the new figure. But if the figure to be Transmuted be curvilinear, the points, tangents, and other right lines, by means of which the curve line is to be defined, must be transferred.

TRANSOM, among Builders, the piece that is framed across a double light window.

TRANSOM, among Mathematicians, denotes the vane of a cross-staff; being a wooden member fixed across it, with a square upon which it slides, &c.

TRANSPARENCY, or TRANSLUCENCY, in Physics, a quality in certain bodies, by which they give passage to the rays of light.

The Transparency of natural bodies, as glass, water, air, &c, is ascribed by some, to the great number and size of the pores or interstices between the particles of those bodies. But this account is very defective; for the most solid and opaque body in nature, that we know of, contains a great deal more pores than it does matter; surely a great deal more than is necessary for the passage of so very fine and subtle a body as light.

Aristotle, Des Cartes, &c, make Transparency to consist in straightness or rectilineal direction of the pores; by means of which, say they, the rays can make their way through, without striking against the solid parts, and so being reflected back again. But this account, Newton shews, is imperfect; the quantity of pores in all bodies being sufficient to transmit all the rays that fall upon them, however those pores be situated with respect to each other.

The reason then why all bodies are not Transparent, is not to be ascribed to their want of rectilineal pores; but either to the unequal density of the parts, or to the pores being filled with some foreign matters, or to their being quite empty, by means of which the rays, in passing through, undergoing a great variety of reflections and refractions, are perpetually diverted different ways, till at length falling on some of the solid parts of the body, they are extinguished and absorbed.

Thus cork, paper, wood, &c, are opake; while glass, diamonds, &c, are Transparent; and the reason is, that in the neighbourhood of parts equal in density with respect to each other, as these latter bodies, the attraction being equal on every side, no reflection or refraction ensues: but the rays which entered the first surface of the body proceed quite through it without interruption, those few only excepted that chance to meet with the solid parts: but in the neighbourhood of parts that differ much in density, such as the parts of wood and paper are, both in respect of themselves and of the air, or the empty space in their pores; as the attraction is very unequal, the reflections and refractions must be very great; and therefore the rays will not be able to make their way through such bodies, but will be variously deflected, and at length quite stopped. See OPACITY.

TRANSPOSITION, in Algebra, is the bringing any term of an equation over to the other side of it. Thus, if $a + x = c$, and you make $x = c - a$, then a is said to be Transposed.

This operation is to be performed in order to bring all the known terms to one side of the equation, and all those that are unknown to the other side of it; and every term thus Transposed must always have its sign changed,

changed, from + to −, or from − to +; which in fact is no more than fubtracting or adding fuch term on both fides of the equation. See Reduction of Equations.

TRANSVERSE-*Axis*, or *Diameter*, in the Conic Sections, is the firft or principal diameter, or axis. See Axis, Diameter, and Latus Transversum.

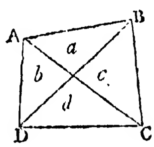
In an ellipfe the Tranfverfe is the longeft of all the diameters; but the fhorteft of all in the hyperbola; and in the parabola the diameters are all equal, or at leaft in a ratio of equality.

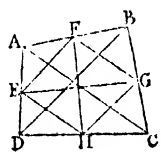
TRAPEZIUM, in Geometry, a plane figure contained under four right lines, of which both the oppofite pairs are not parallel.—When this figure has two of its fides parallel to each other, it is fometimes called a *trapezoid*.—The chief properties of the Trapezium are as follow:

1. Any three fides of a Trapezium taken together, are greater than the third fide.

2. The two diagonals of any Trapezium divide it into four proportional triangles, *a*, *b*, *c*, *d*. That is, the triangle $a : b :: c : d$.

3. The fum of all the four inward angles, A, B, C, D, taken together, is equal to 4 right angles, or 360°.



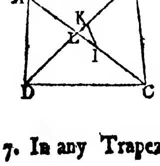


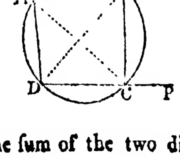
4. In a Trapezium ABCD, if all the fides be bifected, in the points E, F, G, H, the figure EFGH formed by joining the points of bifection will be a parallelogram, having its oppofite fides parallel to the correfponding diagonals of the Trapezium, and the area of the faid infcribed parallelogram is juft equal to half the area of the Trapezium.

5. The fum of the fquares of the diagonals of the Trapezium, is equal to twice the fum of the fquares of the diagonals of the parallelogram, or of the two lines drawn to bifect the oppofite fides of the Trapezium. That is, $AC^2 + BD^2 = 2EG^2 + 2FH^2$.

6. In any Trapezium, the fum of the fquares of all the four fides, is equal to the fum of the fquares of the two diagonals together with 4 times the fquare of the line KI joining their middle points. That is, (firft fig. below)

$$AB^2 + BC^2 + CD^2 + DA^2 = AC^2 + BD^2 + 4IK^2.$$





7. In any Trapezium, the fum of the two diagonals, is lefs than the fum of any four lines that can be drawn, to the four angles, from any point within the figure, befide the interfection of the diagonals.

8. The area of any Trapezium, is equal to half the rectangle or product under either diagonal and the fum of the two perpendiculars drawn upon it from the two oppofite angles.

9. The area of any Trapezium may alfo be found thus: Multiply the two diagonals together, then that product, multiplied by the fine of their angle of interfection, to the radius 1, will be the area. That is,

$$AC \times BD \times \text{fin. } \angle L = \text{area.}$$

10. The fame area will be otherwife found thus: Square each fide of a Trapezium, add the fquares of each pair of oppofite fides together, fubtract the lefs fum from the greater, multiply the remainder by the tangent of the angle of interfection of the diagonals (to radius 1), and ¼ of the product will be the area. That is, $(\overline{AB^2 + DC^2} - \overline{AD^2 + BC^2}) \times \frac{1}{4}\text{tang. } \angle L =$ area.

11. The area of a Trapezoid, or one that has two fides parallel, is equal to the rectangle or product under the fum of the two parallel fides and the perpendicular diftance between them.

12. If a Trapezium be infcribed in a circle; the fum of any two oppofite angles is equal to two right angles; and if the fum of two oppofite angles be equal to two right angles, the fum of the other two will alfo be equal to two right angles, and a circle may be defcribed about it; and farther, if one fide, as DC, be produced out, the external angle will be equal to the interior oppofite angle. That is, (laft fig. above)

$$\angle A + \angle C = \angle B + \angle D = 2 \text{ right angles,}$$
$$\text{and } \angle A = \angle BCP.$$

13. If a Trapezium be infcribed in a circle; the rectangle of the two diagonals, is equal to the fum of the two rectangles contained under the oppofite fides. That is,

$$AC \times BD = AB \times DC + AD \times BC.$$

14. If a Trapezium be infcribed in a circle; its area may be found thus: Multiply any two adjacent fides together, and the other two fides together; then add thefe two products together, and multiply the fum by the fine of the angle included by either of the pairs of fides that are multiplied together, and half this laft product will be the area. That is, the area is equal either

$$\text{to } (AB \times AD + CB \times CD) \times \tfrac{1}{2}\text{fin. } \angle A \text{ or } \angle C,$$
$$\text{or } (AB \times BC + AD \times DC) \times \tfrac{1}{2}\text{fin. } \angle B \text{ or } \angle D.$$

15. Or, when the Trapezium can be infcribed in a circle, the area may be otherwife found thus: Add all the four fides together, and take half the fum; then from this half fubtract each fide feverally; multiply the four remainders continually together, and the fquare root of the laft product will be the area.

16. Laftly, the area of the Trapezium infcribed in a circle may be otherwife found thus:

Put

Put $m = AB \times BC + AD \times DC$,
$n = BA \times AD + BC \times CD$,
$p = AB \times DC + AD \times BC$,
r = radius of the circumfcribing circle,

then $\frac{\sqrt{mnp}}{4r}$ = the area of the Trapezium.

TRAPEZOID, fometimes denotes a trapezium that has two of its fides parallel to each other; and fometimes an irregular folid figure, having four fides not parallel to each other.

TRAVERSE, in Gunnery, is the turning a piece of ordnance about, as upon a centre, to make it point in any particular direction.

TRAVERSE, in Fortification, denotes a trench with a little parapet, fometimes two, one on each fide, to ferve as a cover from the enemy that might come in flank.

TRAVERSE, in a wet foss, is a fort of gallery, made by throwing faucissons, joifts, fafcines, ftones, earth, &c, into the foss, oppofite the place where the miner is to be put, in order to fill up the ditch, and make a paffage over it.

TRAVERSE alfo denotes a wall of earth, or ftone, raifed acrofs a work, to ftop the fhot from rolling along it.

TRAVERSE alfo fometimes fignifies any retrenchment, or line fortified with fafcines, barrels or bags of earth, or gabions.

TRAVERSE, in Navigation, is the variation or alteration of a fhip's courfe, occafioned by the fhifting of the winds, or currents, &c; or a Traverfe is a compound courfe, confifting of feveral different courfes and diftances.

TRAVERSE *Sailing*, is the method of working, or calculating, Traverfes or compound courfes, fo as to bring them into one, &c.

Traverfe Sailing is ufed when a fhip, having failed from one port towards another, whofe courfe and diftance from the former is known, is by reafon of contrary winds, or other accidents, forced to fhift and fail upon feveral courfes, which are to be brought into one courfe, to learn, after fo many turnings and windings, the true courfe and diftance made good, or the true point the fhip is arrived at; and fo to know what muft be the new courfe and diftance to the intended port.

To Conftruct a Traverfe. Affume a convenient point or centre, to begin at, to reprefent the place failed from. From that point as a centre, with the chord of 60°, defcribe a circle, which quarter with two perpendicular lines interfecting in the centre, one to reprefent the meridian, or north-and-fouth line, and the other the eaft-and-weft line. From the interfections of thefe lines with the circle, fet off upon the circumference, the arcs or degrees, taken from the chords, for the feveral courfes that have been failed upon, marking the points they reach to in the circumference with the figures for the order or number of the courfes, 1, 2, 3, 4, &c; and from the centre draw lines to thefe feveral points in the circumference, or conceive them to be drawn. Upon the firft of thefe lines lay off the firft diftance failed; from the extremity of this diftance draw a line parallel to the fecond radius, or line drawn in the circle, upon which lay off the 2d diftance; through the end of this 2d diftance draw a line parallel to the 3d radius, for the direction of the 3d courfe, and upon it lay off the 3d diftance; and fo on, through all the courfes and diftances. This done, draw a line from the centre to the end of the laft diftance, which will be the whole diftance made good, and it will cut the circle in a point fhewing the courfe made good. Laftly, draw a line from the end of the laft diftance to the point reprefenting the port bound to, and it will fhew the diftance and courfe yet to be failed, to gain that port.

To work a Traverfe, or to compute it by the Traverfe Table of Difference of Latitude and Departure.

Make a little tablet with 6 columns; the 1ft for the courfes, the 2d for the diftances, the 3d for the northing, the 4th for the fouthing, the 5th for the eafting, and the 6th for the wefting; firft entering the feveral courfes and diftances, in fo many lines, in the 1ft and 2d columns. Then, from the Traverfe table, take out the quantity of the northings or fouthings, and eaftings or weftings, anfwering to the feveral given courfes and diftances, entering them on their correfponding lines, and in the proper columns of eafting, wefting, northing, and fouthing. This done, add up into one fum the numbers in each of thefe laft four columns, which will give four fums fhewing the whole quantity of eafting, wefting, northing, and fouthing made good; then take the difference between the whole eafting and wefting, and alfo between the northing and fouthing, fo fhall thefe fhew the fpaces made good in thefe two directions, viz, eaft or weft, and north or fouth; which being compared with the given difference of latitude and departure, will fhew thofe yet to be made good in failing to the defired port, and thence the courfe and diftance to it.

Example. A fhip from the latitude 28° 32′ north, bound to a port diftant 100 miles, and bearing NE by N, has run the following courfes and diftances, viz, 1ft, NW by N dift. 20 miles; 2d, SW 40 miles; 3d, NE by E 60 miles; 4th, SE 55 miles; 5th, W by S 41 miles; 6th, ENE 66 miles. Required her prefent latitude, with the direct courfe and diftance made good, and thofe for the port bound to.

The numbers being taken out of the Traverfe table, and entered oppofite the feveral courfes and diftances, the tablet will be as here follows:

Courfes.	Dift.	North.	South.	Eaft.	Weft.
NW by N	20	16·6	·	·	11·1
SW	40	·	28·3	·	28·3
NE by E	60	33·3	·	49·9	·
SE	55	·	38·9	38·9	·

 where

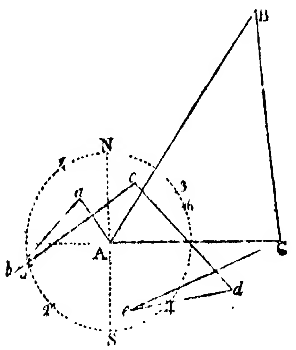
where the sums of the northings and southings, being both alike, 75·2, shews that the ship is come to the same parallel of latitude she set out from. And the difference between the sums of the eastings and westings, shews that the ship is 70·2 miles more to the eastward, that being the greater. Consequently the course made good is due east, and the distance is 70·2 miles.

But, by the Traverse table, the northing and easting to the proposed course NE by N, and distance 100, are thus, viz,

	northing	83·1	and easting	55·6
diff. from made good		0	and easting	70·2
give - -	northing	83·1	and westing	14·6

yet to be made good to arrive at the intended port; and therefore, by finding these in the Traverse table, answering to them are the intended course and distance, viz, distance 85, and course N 10° W.

The geometrical construction, according to the method before described, gives the figure as below: where A is the port set out from, B is the port bound to,



C is the place come to, by sailing the several courses and distances Aa, ab, bc, cd, de, and eC; then CB is the distance to be sailed to arrive at the port B, and its course, or direction with the meridian, is nearly 10°, or the angle ACB, made with the east-and-west line, nearly 80°.—*Note*, the radii from the centre to the several points in the circumference, are omitted, to prevent a confusion in the figure.

Traverse-*Board*, in a ship, a small round board, hanging up in the steerage, and pierced full of holes in lines shewing the points of the compass: upon which, by moving a small peg from hole to hole, the steersman keeps an account how many glasses, that is half hours, the ship steers upon any point.

Traverse-*Table*, in Navigation, is the same with a table of difference of latitude and departure; being the difference of latitude and departure ready calculated to every point, half point, quarter point, degree, &c, of the quadrant; and for every distance, up to 50 or 100 or 120, &c. Though it may serve for any greater distance whatever, by adding two or more together; or by taking their halves, thirds, fourths, &c, and then doubling, tripling, quadrupling, &c, the difference of latitude and departure found to those parts of the distance.

This table is one of the most necessary and useful things a navigator has occasion for; for by it he can readily reduce all his courses and distances, run in the space of 24 hours, into one course and distance; whence he finds the latitude he is in, and the departure from the meridian.

One of the best tables of this kind is in Robertson's Navigation, at the end of book 7, vol. I. The distances are there carried to 120, for the sake of more easy subdivisions; and it is divided into two parts; the first containing the courses for every quarter point of the compass, and the 2d adapted to every 15′, or quarter of a degree, in the quadrant. See Traverse *Sailing*.

A specimen of such a Traverse Table is the following, otherwise called a Table of Difference of Latitude and Departure. The distances are placed at top and bottom of the columns, from 1 to 10; but may be extended to any quantity by multiplying the parts, and taking out at several times. The courses, or angles of a right-angled triangle, are in a column, on both sides, each in two parts, the one containing the even points and quarter points, and the other whole degrees, as far as to 45°, or half the quadrant, on the left-hand side, and the other half quadrant, from 45° to 90°, returned upwards from bottom to top on the right-hand side. The corresponding Difference of Latitude and Departure are in two columns below or above the distances, viz, below them when the course or angle is within 45°, or found on the left-hand side; but above them when between 45 and 90°, or found on the right-hand side.

The same table serves also to work all cases of right-angled triangles, for any other purposes. For example, Suppose a given course be 15°, and distance 35 miles, to find the corresponding difference of latitude and the departure: Or, in a right-angled triangle, given the hypotenuse 35, and one angle 15°, to find the two legs.

Here, the distance 3 in the table must be accounted 30, moving the decimal point proportionally or one place in the other numbers; and those numbers taken out at twice, viz, once from the columns under 3 for the 30, and the other from the columns under the distance 5. Thus, on the line of 15°, and under the

	Dist.		*Lat.*		*Dep.*
	30	are	28·978	and	7·765
	5	are	4·830	and	1·294
theref. for	35	are	33·808	and	9·059

So that the other two legs of the triangle are 33·808 and 9·059.—If the course had been 75°, or the complement of the former, which is only the other angle of the same triangle, and which is found on the same line of the table, but on the right-hand side of it: then the numbers in the columns will be the same as before, and will give the same sums for the two legs of the triangle, only with the contrary names, as to Latitude and Departure, which change places.

A Table

TREBLE, in Music, the highest or acutest of the four parts in symphony, or that which is heard the clearest and shrillest in a concert. In the like sense we say, a Treble violin, Treble hautboy, &c.

In vocal music, the Treble is usually committed to boys and girls; their proper part being the Treble.

The Treble is divided into first or highest Treble, and second or bass Treble. The half Treble is the same with the counter-tenor.

TRENCHES, in Fortification, are ditches which the besiegers cut to approach more securely to the place attacked; whence they are called *lines of approach.* Their breadth is 8 or 10 feet, and depth 6 or 7.

They say, *mount the Trenches*, that is, go upon duty in them. To *relieve the Trenches*, is to relieve such as have been upon duty there. The enemy is said to have *cleared the Trenches*, when he has driven away or killed the soldiers who guarded them.

Tail of the TRENCH, is the place where it was begun. And the *Head* is the place where it ends.

Opening of the TRENCHES, is when the besiegers first begin to work upon them, or to make them; which is usually done in the night.

TREPIDATION, in the Ancient Astronomy, denotes what they call a libration of the 8th sphere; or a motion which the Ptolomaic system attributed to the firmament, to account for certain almost insensible changes and motions observed in the axis of the world; by means of which the latitudes of the fixed stars come to be gradually changed, and the ecliptic seems to approach reciprocally, first towards one pole, then towards the other.

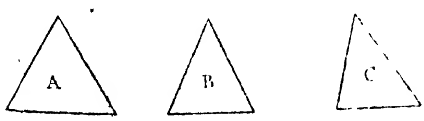
This motion is also called the *motion of the first libration.*

TRET, in Commerce, is an allowance made for the waste, or the dust, that may be mixed with any commodity; which is always 4 pounds on every 104 pounds weight. See TARE.

TRIANGLE, in Geometry, a figure bounded or contained by three lines or sides, and which consequently has three angles, from whence the figure takes its name.

Triangles are either plane or spherical or curvilinear. Plane when the three sides of the Triangle are right lines; but spherical when some or all of them are arcs of great circles on the sphere.

Plane Triangles take several denominations, both from the relation of their angles, and of their sides, as below. And 1st with regard to the sides.



An *Equilateral Triangle*, is that which has all its three sides equal to one another; as A.

An *Isosceles* or *Equicrural Triangle*, is that which has two sides equal; as B.

A *Scalene Triangle* has all its sides unequal; as C.

Again, with respect to the Angles.

A *Rectangular* or *Right-angled Triangle*, is that which has one right angle; as D.

An *Oblique Triangle* is that which has no right angle, but all oblique ones; as E or F.

An *Acutangular* or *Oxygone Triangle*, is that which has three acute angles; as E.

An *Obtusangular* or *Amblygone Triangle*, is that which has an obtuse angle; as F.

A *Curvilinear* or *Curvilineal Triangle*, is one that has all its three sides curve lines.

A *Mixtilinear Triangle* is one that has its sides some of them curves, and some right lines.

A *Spherical Triangle* is one that has its sides, or at least some of them, arcs of great circles of the sphere.

Similar Triangles are such as have the angles in the one equal to the angles in the other, each to each.

The *Base* of a Triangle, is any side on which a perpendicular is drawn from the opposite angle, called the *vertex*; and the two sides about the perpendicular, or the vertex, are called the *legs*.

The Chief Properties of Plane Triangles, are as follow, viz, In any plane Triangle,

1. The greatest side is opposite to the greatest angle, and the least side to the least angle, &c. Also, if two sides be equal, their opposite angles are equal; and if the Triangle be equilateral, or have all its sides equal, it will also be equiangular, or have all its angles equal to one another.

2. Any side of a Triangle is less than the sum, but greater than the difference, of the other two sides.

3. The sum of all the three angles, taken together, is equal to two right angles.

4. If one side of a Triangle be produced out, the external angle, made by it and the adjacent side, is equal to the sum of the two opposite internal angles.

5. A line drawn parallel to one side of a Triangle, cuts the other two sides proportionally, the corresponding segments being proportional, each to each, and to the whole sides; and the Triangle cut off is similar to the whole Triangle.

If a perpendicular be let fall from any angle of a Triangle, as a vertical angle, upon the opposite side as a base; then

6. The rectangle of the sum and difference of the sides, is equal to twice the rectangle of the base and the distance of the perpendicular from the middle of the base.—Or, which is the same thing in other words,

7. The difference of the squares of the sides, is equal to the difference of the squares of the segments of the base. Or, as the base is to the sum of the sides, so is the difference of the sides, to the difference of the segments of the base.

8. The rectangle of the legs or sides, is equal to the rectangle of the perpendicular and the diameter of the circumscribing circle.

If a line be drawn bisecting any angle, to the base or opposite side; then,

9. The segments of the base, made by the line bisecting the opposite angle, are proportional to the sides adjacent to them.

10. The square of the line bisecting the angle, is equal to the difference between the rectangle of the sides and the rectangle of the segments of the base.

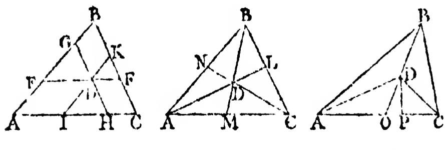
If a line be drawn from any angle to the middle of the opposite side, or bisecting the base; then

11. The sum of the squares of the sides, is equal to twice the sum of the squares of half the base and the line bisecting the base.

12. The angle made by the perpendicular from any angle and the line drawn from the same angle to the middle of the base, is equal to half the difference of the angles at the base.

13. If through any point D, within a Triangle ABC, three lines EF, GH, IK, be drawn parallel to the three sides of the Triangle; the continual products or solids made by the alternate segments of these lines will be equal; viz,

$$DE \times DK \times DH = DG \times DF \times DL$$



14. If three lines AL, BM, CN, be drawn from the three angles through any point D within a Triangle, to the opposite sides; the solid products of the alternate segments of the sides are equal; viz,

$AN \times BL \times CM = AM \times CL \times BN$, (2d fig. above).

15. Three lines drawn from the three angles of a Triangle to bisect the opposite sides, or to the middle of the opposite sides, do all intersect one another in the same point D, and that point is the centre of gravity of the Triangle, and the distance AD of that point from any angle as D, is equal to double the distance DL from the opposite side; or one segment of any of these lines is double the other segment: moreover the sum of the squares of the three bisecting lines, is $\frac{3}{4}$ of the sum of the squares of the three sides of the Triangle.

16. Three perpendiculars bisecting the three sides of a Triangle, all intersect in one point, and that point is the centre of the circumscribing circle.

17. Three lines bisecting the three angles of a Triangle, all intersect in one point, and that point is the centre of the inscribed circle.

18. Three perpendiculars drawn from the three angles of a Triangle, upon the opposite sides, all intersect in one point.

19. If the three angles of a Triangle be bisected by the lines AD, BD, CD (3d fig. above), and any one as BD be continued to the opposite side at O, and DP be drawn perp. to that side; then is

$\angle ADO = \angle CDP$, or $\angle ADP = \angle CDO$.

20. Any Triangle may have a circle circumscribed about it, or touching all its angles, and a circle inscribed within it, or touching all its sides.

21. The square of the side of an equilateral Triangle, is equal to 3 times the square of the radius of its circumscribing circle.

22. If the three angles of one Triangle be equal to the three angles of another Triangle, each to each; then those two Triangles are similar, and their like sides are proportional to one another, and the areas of the two Triangles are to each other as the squares of their like sides.

23. If two Triangles have any three parts of the one (except the three angles), equal to three corresponding parts of the other, each to each; those two Triangles are not only similar, but also identical, or having all their six corresponding parts equal, and their areas equal.

24. Triangles standing upon the same base, and between the same parallels, are equal; and Triangles upon equal bases, and having equal altitudes, are equal.

25. Triangles on equal bases, are to one another as their altitudes: and Triangles of equal altitudes, are to one another as their bases; also equal Triangles have their bases and altitudes reciprocally proportional.

26. Any Triangle is equal to half its circumscribing parallelogram, or half the parallelogram on the same or an equal base, and of the same or equal altitude.

27. Therefore the area of any Triangle is found, by multiplying the base by the altitude, and taking half the product.

28. The area is also found thus: Multiply any two sides together, and multiply the product by the sine of their included angle, to radius 1, and divided by 2.

29. The area is also otherwise found thus, when the three sides are given: Add the three sides together, and take half their sum; then from this half sum subtract each side severally, and multiply the three remainders and the half sum continually together; then the square root of the last product will be the area of the Triangle.

30. In a right-angled Triangle, if a perpendicular be let fall from the right angle upon the hypothenuse, it will divide it into two other Triangles similar to one another, and to the whole Triangle.

31. In a right-angled Triangle, the square of the hypothenuse is equal to the sum of the squares of the two sides; and, in general, any figure described upon the hypothenuse, is equal to the sum of two similar figures described upon the two sides.

32. In an isosceles Triangle, if a line be drawn from the vertex to any point in the base; the square of that line together with the rectangle of the segments of the base, is equal to the square of the side.

33. If one angle of a Triangle be equal to 120°; the square of the base will be equal to the squares of both the sides, together with the rectangle of those sides; and if those sides be equal to each other, then the square of the base will be equal to three times the square of one side, or equal to 12 times the square of the perpendicular from the angle upon the base.

34. In the same Triangle, viz, having one angle equal to 120°; the difference of the cubes of the sides, about that angle, is equal to a solid contained by the difference of the sides and the square of the base; and the sum of the cubes of the sides, is equal to a solid contained by the sum of the sides and the difference between

between the square of the base and twice the rectangle of the sides.

There are many other properties of Triangles to be found among the geometrical writers; so Gregory St. Vincent has written a folio volume upon Triangles; there are also several in his Quadrature of the circle. See also other properties under the article TRIGONOMETRY.

For the properties of spherical Triangles, see SPHERICAL *Triangles*.

Solution of TRIANGLES. See TRIGONOMETRY.

TRIANGLE, in Astronomy, one of the 48 ancient constellations, situated in the northern hemisphere. There is also the *Southern Triangle* in the southern hemisphere, which is a modern constellation. The stars in the Northern Triangle are, in Ptolomy's catalogue 4, in Tycho's 4, in Hevelius's 12, and in the British catalogue 16.

The stars in the Southern Triangle are, in Sharp's catalogue, 5.

Arithmetical TRIANGLE, a kind of numeral Triangle, or Triangle of numbers, being a table of certain numbers disposed in form of a Triangle. It was so called by Pascal; but he was not the inventor of this table, as some writers have imagined, its properties having been treated of by other authors, some centuries before him, as is shewn in my Mathematical Tracts, vol. 1, pa. 69 &c.

The form of the Triangle is as follows:

1					
1	1				
1	2	1			
1	3	3	1		
1	4	6	4	1	
1	5	10	10	5	1
1	6	15	20	&c	
1	7	21	&c		
1	8	&c			
1	9				
1					

And it is constructed by adding always the last two numbers of the next two preceding columns together, to give the next succeeding column of numbers.

The first vertical column consists of units; the 2d a series of the natural numbers 1, 2, 3, 4, 5, &c; the 3d a series of Triangular numbers 1, 3, 6, 10, &c; the 4th a series of pyramidal numbers, &c. The oblique diagonal rows, descending from left to right, are also the same as the vertical columns. And the numbers taken on the horizontal lines are the co-efficients of the different powers of a binomial. Many other properties and uses of these numbers have been delivered by various authors, as may be seen in the Introduction to my Mathematical Tables, pages 7, 8, 75, 76, 77, 89, 2d edition.

After these, Pascal wrote a treatise on the Arithmetical Triangle, which is contained in the 5th volume of his works, published at Paris and the Hague in 1779, in 5 volumes, 8vo.

In this publication is also a description, taken from the 1st volume of the French Encyclopedie, art. *Arithmetique Machine*, of that admirable machine invented by Pascal at the age of 19, furnishing an easy and expeditious method of making all sorts of arithmetical calculations without any other assistance than the eye and the hand.

TRIANGULAR, relating to a triangle; as

TRIANGULAR *Canon*, tables relating to trigonometry; as of sines, tangents, secants, &c.

TRIANGULAR *Compasses*, are such as have three legs or feet, by which any triangle, or three points, may be taken off at once. These are very useful in the construction of maps, globes, &c.

TRIANGULAR *Numbers*, are a kind of polygonal numbers; being the sums of arithmetical progressions, which have 1 for the common difference of their terms.

Thus, from these arithmeticals	1	2	3	4	5	6,
are formed the Triang. Numb.	1	3	6	10	15	21,

or the 3d column of the arithmetical triangle above-mentioned.

The sum of any number n of the terms of the Triangular numbers, 1, 3, 6, 10, &c, is =

$$\frac{n^3}{6} + \frac{n^2}{2} + \frac{n}{3}, \text{ or } \frac{n}{1} \times \frac{n+1}{2} \times \frac{n+2}{3}$$

which is also equal to the number of shot in a triangular pile of balls, the number of rows, or the number in each side of the base, being n.

The sum of the reciprocals of the Triangular series, infinitely continued, is equal to 2; viz,

$$1 + \tfrac{1}{3} + \tfrac{1}{6} + \tfrac{1}{10} + \tfrac{1}{15} \text{ \&c} = 2.$$

For the rationale and management of these numbers, see Malcolm's Arith. book 5, ch. 2; and Simpson's Algeb. sec. 15.

TRIANGULAR *Quadrant*, is a sector furnished with a loose piece, by which it forms an equilateral triangle. Upon it is graduated and marked the calendar, with the sun's place, and other useful lines; and by the help of a string and a plummet, with the divisions graduated on the loose piece, it may be made to serve for a quadrant.

TRIBOMETER, in Mechanics, a term applied by Musschenbroek to an instrument invented by him for measuring the friction of metals. It consists of an axis formed of hard steel, passing through a cylindrical piece of wood: the ends of the axis, which are highly polished, are made to rest on the polished semicircular cheeks of various metals, and the degree of friction is estimated by means of a weight suspended by a fine silken string or ribband over the wooden cylinder. For a farther description and the figure of this instrument, with the results of various experiments performed with it, see Musschenb. Introd. ad Phil. Nat. vol. 1, p. 151.

TRIDENT, is a particular kind of parabola, used by Descartes in constructing equations of 6 dimensions. See the article *Cartesian* PARABOLA.

TRIGLYPH, in Architecture, is a member of the Doric Frize, placed directly over each column, and at equal distances in the intercolumnation, having two entire glyphs or channels engraven in it, meeting in an angle, and separated by three legs from the two demi-channels of the sides.

TRIGON,

TRIGON, a figure of three angles, or a triangle.

TRIGON, in Astrology. See TRIPLICITY.

TRIGON, in Astronomy, denotes an aspect of two planets when they are 120 degrees distant from each other; called also a Trine, being the 3d part of 360 degrees.—The Trigons of Mars and Saturn are by astrologers held malific or malignant aspects.

TRIGON, in Dialling, is an instrument of a triangular form.

TRIGON, in Music, denoted a musical instrument, used among the ancients. It was a kind of triangular lyre, or harp, invented by Ibycus; and was used at feasts, being played on by women, who struck it either with a quill, or beat it with small rods of different lengths and weights, to occasion a diversity in the sounds.

TRIGONAL *Numbers*. See TRIANGULAR *Numbers*.

TRIGONOMETER *Armillary*. See ARMILLARY *Trigonometer*.

TRIGONOMETRY, the art of measuring the sides and angles of triangles, either plane or spherical, from whence it is accordingly called either Plane Trigonometry, or Spherical Trigonometry.

Every triangle has 6 parts, 3 sides, and 3 angles; and it is necessary that three of these parts be given, to find the other three. In spherical Trigonometry, the three parts that are given, may be of any kind, either all sides, or all angles, or part the one and part the other. But in plane Trigonometry, it is necessary that one of the three parts at least be a side, since from three angles can only be found the proportions of the sides, but not the real quantities of them.

Trigonometry is an art of the greatest use in the mathematical sciences, especially in astronomy, navigation, surveying, dialling, geography, &c, &c. By it, we come to know the magnitude of the earth, the planets and stars, their distances, motions, eclipses, and almost all other useful arts and sciences. Accordingly we find this art has been cultivated from the earliest ages of mathematical knowledge.

Trigonometry, or the resolution of triangles, is founded on the mutual proportions which subsist between the sides and angles of triangles; which proportions are known by finding the relations between the radius of a circle and certain other lines drawn in and about the circle, called *chords*, *sines*, *tangents*, and *secants*. The ancients Menelaus, Hipparchus, Ptolomy, &c, performed their Trigonometry, by means of the chords. As to the sines, and the common theorems relating to them, they were introduced into Trigonometry by the Moors or Arabians, from whom this art passed into Europe, with several other branches of science. The Europeans have introduced, since the 15th century, the tangents and secants, with the theorems relating to them. See the history and improvements at large, in the Introduction to my Mathematical Tables.

The proportion of the sines, tangents, &c, to their radius, is sometimes expressed in common or natural numbers, which constitute what we call the *tables of natural sines, tangents, and secants*. Sometimes it is expressed in logarithms, being the logarithms of the said natural sines, tangents, &c; and these constitute the table of *artificial sines*, &c. Lastly, sometimes the proportion is not expressed in numbers; but the several sines, tangents, &c, are actually laid down upon lines of scales; whence the *line of sines*, of *tangents*, &c. See SCALE.

In Trigonometry, as angles are measured by arcs of a circle described about the angular point, so the whole circumference of the circle is divided into a great number of parts, as 360 degrees, and each degree into 60 minutes, and each minute into 60 seconds, &c; and then any angle is said to consist of so many degrees, minutes and seconds, as are contained in the arc that measures the angle, or that is intercepted between the legs or sides of the angle.

Now the sine, tangent, and secant, &c, of every degree and minute, &c, of a quadrant, are calculated to the radius 1, and ranged in tables for use; as also the logarithms of the same; forming the triangular canon. And these numbers, so arranged in tables, form every species of right-angled triangles, so that no such triangle can be proposed, but one similar to it may be there found, by comparison with which, the proposed one may be computed by analogy or proportion.

As to the scales of chords, sines, tangents, &c, usually placed on instruments, the method of constructing them is exhibited in the scheme annexed to the article SCALE; which, having the names added to each, needs no farther explanation.

There are usually three methods of resolving triangles, or the cases of Trigonometry; viz, geometrical construction, arithmetical computation, and instrumental operation. In the 1st method, the triangle in question is constructed by drawing and laying down the several parts of their magnitudes given, viz, the sides from a scale of equal parts, and the angles from a scale of chords, or other instrument; then the unknown parts are measured by the same scales, and so they become known.

In the 2d method, having stated the terms of the proportion according to rule, which terms consist partly of the numbers of the given sides, and partly of the sines, &c, of angles taken from the tables, the proportion is then resolved like all other proportions, in which a 4th term is to be found from three given terms, by multiplying the 2d and 3d together, and dividing the product by the first. Or, in working with the logarithms, adding the log. of the 2d and 3d terms together, and from the sum subtracting the log. of the 1st term, then the number answering to the remainder is the 4th term sought.

To work a case instrumentally, as suppose by the log. lines on one side of the two-foot scales: Extend the compasses from the 1st term to the 2d, or 3d, which happens to be of the same kind with it; then that extent will reach from the other term to the 4th. In this operation, for the sides of triangles, is used the line of numbers (marked Num.); and for the angles, the line of sines or tangents (marked sin. and tan.) according as the proportion respects sines or tangents.

In every case of triangles, as has been hinted before, there

there muſt be three parts, one at leaſt of which muſt be a ſide. And then the different circumſtances, as to the three parts that may be given, admit of three caſes or varieties only; viz,

1ſt, When two of the three parts given, are a ſide and its oppoſite angle.—2d, When there are given two ſides and their contained angle.—3d, And thirdly, when the three ſides are given.

To each of theſe caſes there is a particular rule, or proportion, adapted, for reſolving it by.

1ſt. *The Rule for the 1ſt Caſe*, or that in which, of the three parts that are given, an angle and its oppoſite ſide are two of them, is this, viz, That the ſides are proportional to the ſines of their oppoſite angles,

That is,

As one ſide given :
To the ſine of its oppoſite angle : :
So is another ſide given :
To the ſine of its oppoſite angle.

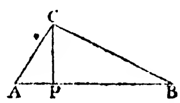
Or,

As the ſine of an angle given :
To its oppoſite ſide : :
So is the ſine of another angle given :
To its oppoſite ſide.

So that, to find an angle, we muſt begin the proportion with a given ſide that is oppoſite to a given angle; and to find a ſide, we muſt begin with an angle oppoſite to a given ſide.

Ex. Suppoſe, in the triangle ABC, there be given

AB = 365 feet,
AC = 154·33 f.
∠C = 98° 3′
to find the other ſide, and the angles.



1. *Geometrically, by Conſtruction.*

Draw AC = 154·33 from a ſcale of equal parts: Make the angle C = 98° 3′, producing CB indefinitely: With centre A, and radius 365 feet, croſs CB in B: Then join AB, and the figure is conſtructed. Then, by meaſuring the unknown angles and ſide, the former by the line of cords or otherwiſe, and the ſide by the line of equal parts, they will be found, as near as they can be meaſured, as below, viz,

BC = 310; the ∠A = 57°¼; and ∠B = 24°¾.

2. *Arithmetically, by Tables of Logs.*

As AB	= 365	log.	2·5622929
To AC	= 154·33		2·1884504
So fin. ∠C	= 98° 3′ or 81° 57′		9·9956993
To fin. ∠B	= 24° 45′		9·6218568
the ſum	122 48		
taken from	180 00		
leaves ∠A	57 12		

Then, again,

As ſin. ∠C	= 98° 3′	log.	9·9956993
To AB	= 365		2·5622929
So ſin. ∠A	= 57° 12′		9·9245721
To BC	= 309·86		2·4911657

3. *Inſtrumentally, by Gunter's Lines.*

In the firſt proportion, Extend the compaſſes from 365 to 154⅓ on the line of numbers; and that extent will reach, upon the line of ſines, from 82° to 24¾, which gives the angle B. And, in the ſecond proportion, Extend from 98° or 57¼ on the ſines; and that extent will reach, upon the numbers, from 365 to 310, or the ſide BC nearly.

2d *Caſe*; when there are Given two Sides and their contained angle, to find the reſt, the rule is this:

As the ſum of the two given ſides :
Is to the difference of the ſides : :
So is the tang. of half the ſum of the two oppoſite angles, or cotangent of half the given angle :
To tang. of half the diff. of thoſe angles.

Then the half diff. added to the half ſum, gives the greater of the two unknown angles; and ſubtracted, leaves the leſs of the two angles.

Hence, the angles being now all known, the remaining 3d ſide will be found by the former caſe.

Ex. Suppoſe, in the triangle ABC, there be given
the ſide AC = 154·33
the ſide BC = 309·86
the included ∠C = 98° 3′
to find the other ſide and the angles.

1. *Geometrically.*—Draw two indefinite lines making the angle C = 98° 3′: upon theſe lines ſet off CA = 154⅓, and CB = 310: Join the points A and B, and the figure is made. Then, by meaſurement, as before, we find the

∠A = 57¼; ∠B 24¾; and ſide AB = 365.

2. *By Logarithms.*

As CB + CA	= 464·19	log.	2·6666958
To CB − CA	= 155·53		2·1918142
So tan. ½A + ½B	= 40° 58½′		9·9387813
To tan. ½A − ½B	= 16 13½		9·4638997

ſum gives ∠A 57 12
diff. gives ∠B 24 45

Then,

As ſin. ∠B	= 24° 45′	log.	9·6218612
To ſide AC	= 154·33		2·1884504
So ſin. ∠C	= 98° 3′, or 81° 57		9·9956993
To ſide AB	= 365		2·5622885

3. *Inſtrumentally*:—Extend the compaſſes from 464 to 155½ upon the line of numbers; then that extent will reach, upon the line of tangents, from 41° to 16°¼. Then, in the 2d proportion, extend the compaſſes from 24°¾ to 82° on the ſines; and that extent

 will

will reach, upon the numbers, from $154\frac{1}{3}$ to 365, which is the third side.

3d *Case*, is when the three sides are given, to find the three angles; and the method of resolving this case is, to let a perpendicular fall from the greatest angle, upon the opposite side or base, dividing it into two segments, and the whole triangle into two smaller right-angled triangles: then it will be,

As the base, or sum of the two segments :
Is to the sum of the other two sides : :
So is the difference of those sides :
To the difference of the segments of the base.

Then half this difference of the two segments added to the half sum, or half the base, gives the greater segments, and subtracted, gives the less. Hence, in each of the two right-angled triangles, there are given the hypotenuse, and the base, besides the right angle, to find the other angles by the 1st case.

Ex. In the trangle ABC, suppose there are given the three sides, to find the three angles, viz,

$$\left.\begin{array}{l} AB = 365 \\ AC = 154{\cdot}33 \\ BC = 309{\cdot}86 \end{array}\right\} \text{to find the angles.}$$

1. *Geometrically*.—Draw the base AB = 365 : with the radius $154\frac{1}{3}$ and centre A describe an arc; and with the radius 310 and centre B describe another arc, cutting the former in C; then join AC and BC, and the triangle is constructed. And by measuring the angles, they are found, viz.

$\angle A = 57^\circ\frac{1}{4}$; $\angle B = 24^\circ\frac{3}{4}$; $\angle C = 98^\circ$ nearly.

2. *Arithmetically*.—Having let fall the perpendicular CP, dividing the base into the two segments AP, PB, and the given triangle ABC into the two right-angled triangles ACP, BCP. Then,

As AB	= 365	- - log.	2·5622929
To CB + CA	= 464·19	- - -	2·6666958
So CB − CA	= 155·53	- - -	2·1918142
To BP − PA	= 197·80	- - -	2·2962171
its half	= 98·90		
½AB	= 182·50		
sum BP	= 281·40		
dif. AP	= 83·60		

Then, in the triangle APC, right-angled at P,

As AC	= 154·33	- - log.	2·1884504
To sin. ∠P	= 90°	- - - -	10·0000000
So AP	= 83·6	- - -	1·9222063
To sin. ∠ACP	= 32° 48′	- - -	9·7337559
its comp. ∠A	= 57° 12		

And in the triangle BPC, right-angled at P,

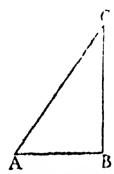
As BC	= 309·86	- - log.	2·4911653
To sin. ∠P	= 90°	- -	10·0000000
So BP	= 281·4	- -	2·4493241
To sin. ∠BCP	= 65° 15′	- -	9·9581586
its comp. ∠B	= 24 45		
Also to ∠ACP	= 32 48		
add ∠BCP	= 65 15		
makes ∠ACB	= 98 3		

3. *Instrumentally*.—In the 1st proportion, Extend the compasses from 365 to 464 on the line of numbers, and that extent will reach, on the same line, from $155\frac{1}{2}$ to 197·8 nearly.—In the 2d proportion, Extend the compasses from $154\frac{1}{3}$ to 83·6 on the line of numbers, and that extent will reach, on the sines, from 90° to $32^\circ\frac{3}{4}$ nearly.—In the 3d proportion, Extend the compasses from 310 to $281\frac{1}{2}$ on the line of numbers; then that extent will reach, on the sines, from 90° to $65^\circ\frac{1}{4}$.

The foregoing three cases include all the varieties of plane triangles that can happen, both of right and oblique-angled triangles. But beside these, there are some other theorems that are useful upon many occasions, or suited to some particular forms of triangles, which are often more expeditious in use than the foregoing general ones; one of which, for right angled triangles, as the case for which it serves so often occurs, may be here inserted, and is as follows.

Case 4. When, in a right-angled triangle, there are given the angles and one leg, to find the other leg, or the hypothenuse. Then it will,

As radius :
To given leg AB : :
So tang. adjacent ∠A :
To the opp. leg BC, and : :
So sec. of same ∠A :
To hypot. AC.



Ex. In the triangle ABC, right-angled at B,

$$\left.\begin{array}{l} \text{Given the leg } AB = 162 \\ \text{and the } \angle A = 53^\circ\ 7'\ 48'' \\ \text{conseq. } \angle C = 36\ 52\ 12 \end{array}\right\} \begin{array}{l}\text{to find BC} \\ \text{and AC.}\end{array}$$

1. *Geometrically*.—Draw the leg AB = 162 : Erect the indefinite perpendicular BC : Make the angle A = $53^\circ\frac{1}{8}$, and the side AC will cut BC in C, and form the triangle ABC. Then, by measuring, there will be found AC = 270, and BC = 216.

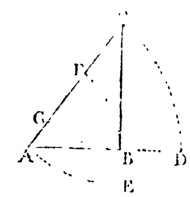
2. *Arithmetically*.

As radius	= 10	- -	log. 10·0000000
To AB	= 162	- - -	2·2095150
So tan. ∠A	= 53° 7′ 48″		10·1249372
To BC	= 216	- -	2·3344522
So sec. ∠A	= 53° 7′ 48″	- -	10·2218477
To AC	= 270	- - -	2·4313627

3. *Instrumentally*.

3. *Instrumentally.*—Extend the compasses from 45° at the end of the tangents (the radius) to the tangent of 53°$\frac{1}{4}$; then that extent will reach, on the line of numbers, from 162 to 216, for BC. Again, extend the compasses from 36° 52′ to 90 on the sines; then that extent will reach, on the line of numbers, from 162 to 270 for AC.

Note, another method, by making every side radius, is often added by the authors on Trigonometry, which is thus: The given right-angled triangle being ABC, make first the hypotenuse AC radius, that is, with the extent of AC as a radius, and each of the centres A and C, describe arcs CD and AE; then it is evident that each leg will represent the sine of its opposite angle, viz. the leg BC the sine of the arc CD or of the angle A, and the leg AB the sine of the arc AE or of the angle C. Again, making either leg radius, the other leg will represent the tangent of its opposite angle, and the hypotenuse the secant of the same angle; thus, with radius AB and centre A describing the arc BF, BC represents the tangent of that arc, or of the angle A, and the hypotenuse AC the secant of the same; or with the radius BC and centre C describing the arc BG, the other leg AB is the tangent of that arc BG, or of the angle C, and the hypotenuse CA the secant of the same.



And then the general rule for all these cases is this, viz. that the sides bear to each other the same proportions as the parts or things which they represent. And this is called making every side radius.

Spherical TRIGONOMETRY, is the resolution and calculation of the sides and angles of spherical triangles, which are made by three intersecting arcs of great circles on a sphere. Here, any three of the six parts being given, even the three angles, the rest can be found; and the sides are measured or estimated by degrees, minutes, and seconds, as well as the angles.

Spherical Trigonometry is divided into right-angled and oblique-angled, or the resolution of right and oblique-angled spherical triangles. When the spherical triangle has a right angle, it is called a right-angled triangle, as well as in plane triangles; and when a triangle has one of its sides equal to a quadrant of a circle, it is called a quadrantal triangle.

For the resolution of spherical Triangles, there are various theorems and proportions, which are similar to those in plane Trigonometry, by substituting the sines of sides instead of the sides themselves, when the proportion respects sines; or tangents of the sides for the sides, when the proportion respects tangents, &c; some of the principal of which theorems are as follow:

Theor. 1. In any spherical triangle, the sines of the sides are proportional to the sines of their opposite angles.

Theor. 2. In any right-angled triangle,

As radius :
To sine of one side : :
So tang. of the adjacent angle :
To tang. of the opposite side.

Theor. 3. If a perpendicular be let fall from any angle upon the base or opposite side of a spherical triangle it will be,

As the sine of the sum of the two sides :
To the sine of their difference : :
So cotan. $\frac{1}{2}$ sum angles at the vertex :
To tang. of half their difference.

Theor. 4.

As tang. half sum of the sides :
To tang. half their difference : :
So tang. $\frac{1}{2}$ sum ∠s at the base :
To tang. half their difference.

Theor. 5.

As cotan. $\frac{1}{2}$ sum of ∠s at the base :
To tang half their difference : :
So tang. $\frac{1}{2}$ sum of ∠s at the vertex :
To tang. half their difference.

Theor. 6.

As tang. $\frac{1}{2}$ sum segments of base :
To tang. half sum of the sides : :
So tang. half difference of the sides :
To tang. $\frac{1}{2}$ diff. segments of base.

Theor. 7.

As sin. sum of ∠s at the base :
To sine of their difference : :
So tang. $\frac{1}{2}$ sum segments of base :
To tang. of half their difference.

Theor. 8.

As sin. sum of segments of base :
To sine of their difference : :
So sin. sum of angles at the vertex :
To sine of their difference.

Theor. 9.

As sine of the base :
To sine of the vertical angle : :
So sin. of diff. segments of the base :
To sin. diff. ∠s at vertex, when the perp. falls within : :
Or so sin. sum segments of base :
To sin. sum vertical ∠s, where the perp. falls without.

Theor. 10.

As cosin. half sum of the two sides :
To cosine of half their difference : :
So cotang. of half the included angle :
To tang. half sum of opposite angles.

Theor. 11.

As sin. of half sum of two sides :
To sine of half their difference : :
So cotang. half the included angle :
To tang. $\frac{1}{2}$ diff. of the oppos. angles.

Theor.

Theor. 12.

As cofin. half fum of two angles :
To cofine of half their difference : :
So tang. of half the included fide :
To tang. $\frac{1}{2}$ fum of the oppofite fides.

Theor. 13.

As fin. half fum of two angles :
To fine of half their difference : :
So tang. half the included fide :
To tang. $\frac{1}{2}$ diff. of the oppofite fides.

Theor. 14. In a right-angled triangle,

As fin. fum of hypot. and one fide :
To fin. of their difference : :
So radius fquared :
To fquare of tang. $\frac{1}{2}$ contained angle.

Theor. 15. In any fpherical triangle;
The product of the fines of two fides and of the cofine of the included angle, added to the product of the cofines of thofe fides, is equal to the cofine of the third fide; the radius being 1.

Theor. 16. In any fpherical triangle;
The product of the fines of two angles and of the cofine of the included fide, minus the product of the cofines of thofe angles, is equal to the cofine of the third angle; the radius being 1.

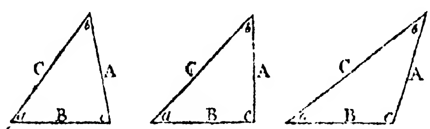
By fome or other of thefe theorems may all the cafes of fpherical triangles be refolved, both right-angled and oblique: viz, the cafes of right-angled triangles by the 1ft and 2d theorems, and the oblique triangles by fome of the other theorems.

In treatifes on Trigonometry are to be found many other theorems, as well as fynopfes or tables of all the cafes, with the theorem that is peculiar or proper to each. See the Introduction to my Mathematical Tables, p. 155 &c; or Robertfon's Navigation, vol. 1, p. 162. See alfo Napier's Catholic or Univerfal Rule, in this Dictionary.

To the foregoing Theorems may be added the following fynopfis of rules for refolving all the cafes of plane and fpherical triangles, under the title of

Trigonometrical Rules.

I. In a right-lined triangle, whofe fides are A, B, C, and their oppofite angles *a*, *b*, *c*; having given any three of thefe, of which one is a fide; to find the reft.



Put s for the fine, s′ the cofine, t the tangent, and t′ the cotangent of an arch or angle, to the radius *r*; alfo L for a logarithm, and L′ its arithmetical complement. Then

Cafe 1. When three fides A, B, C, are given.

Put $P = \frac{1}{2}.\overline{A+B+C}$ or femiperimeter.

Then $$s.\ \tfrac{1}{2}c = r\sqrt{\frac{\overline{P-A}\times\overline{P-B}}{A\times B}}.$$

And $$s'\ \tfrac{1}{2}c = r\sqrt{\frac{P\times\overline{P-C}}{A\times B}}.$$

$L.s.\frac{1}{2}c = \frac{1}{2}(L.\overline{P-A} + L.\overline{P-B} + L'A + L'B)$.

$L's.\frac{1}{2}c = \frac{1}{2}(L.P + L.\overline{P-C} + L'A + L'B)$.

Note, When A = B, then

$$s\ \tfrac{1}{2}c = \frac{C}{A}\times\frac{r}{2}.\quad \text{And}\quad s'\tfrac{1}{2}c = r\sqrt{\frac{A^2-\frac{1}{4}C^2}{A^2}}.$$

Cafe 2. Given two fides A, B, and their included angle *c*.

Put $s = 90^\circ - \frac{1}{2}c$, and $t.d = \frac{A-B}{A+B}\times t.s$, then $a = s + d$; and $b = s - d$. And

$$C = \sqrt{\frac{4AB\times s^2\frac{1}{2}c}{rr} + \overline{A-B}^2}.$$

Or in logarithms, putting $L.Q = 2L.\overline{A-B}$, and $L.R = L.2A + L.2B + 2L.s.\frac{1}{2}c - 20$, we fhall have $L.C = \frac{1}{2}L.\overline{Q+R}$.

If the angle *c* be right, or = 90°; then

$$t.a = \frac{A}{B}r;\quad t.b = \frac{B}{A}r;$$

$$C = \frac{r}{s.a}A,\ \text{or} = \frac{r}{s.b}B,\ \text{or} = \sqrt{A^2+B^2}.$$

If A = B; we fhall have $a = b = 90^\circ - \frac{1}{2}c$, and $\Big\}$ $C = \frac{s.\frac{1}{2}c}{r}\times 2A$.

Cafe 3. When a fide and its oppofite angle are among the terms given.

Then $\frac{A}{s.a} = \frac{B}{s.b} = \frac{C}{s.c}$; from which equations any term wanted may be found.

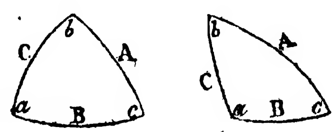
When an angle, as *a*, is 90°, and A and C are given, then

$$B = \sqrt{A^2 - C^2} = \sqrt{\overline{A+C}\times\overline{A-C}}.$$

And $L.B = \frac{1}{2}(L.\overline{A+C} + L.\overline{A-C})$.

Note, When two fides A, B, and an angle *a* oppofite to one of them, are given; if A be lefs than B, then *b*, *c*, C have each two values; otherwife, only one value.

II. In a fpherical triangle, whofe three fides are A, B, C, and their oppofite angles *a*, *b*, *c*; any three of thefe fix terms being given, to find the reft.



Case 1. Given the three sides A, B, C.

Calling 2P the perim. or $P = \frac{1}{2}.\overline{A+B+C}$.

$$\text{Then s.}\tfrac{1}{2}c = r\sqrt{\frac{\text{s.}\overline{P-A} \times \text{s.}\overline{P-B}}{\text{s.A} \times \text{s.B}}}$$

$$\text{And s}'\tfrac{1}{2}c = r\sqrt{\frac{\text{s.P} \times \text{s.}\overline{P-C}}{\text{s.A} \times \text{s.B}}}.$$

$\text{L.s}\frac{1}{2}c = \frac{1}{2}(\text{L.s.}\overline{P-A} + \text{L.s.}\overline{P-s} + \text{L}'\text{s.A} + \text{L}'\text{s.B})$

$\text{L.s}'c = \frac{1}{2}(\text{L.s.P} + \text{L.s.}\overline{P-C} + \text{L}'\text{s A} + \text{L}'\text{s.B})$.

And the same for the other angles.

Case 2. Given the three angles.

Put $2p = a + b + c$. Then

$$\text{s.}\tfrac{1}{2}C = r\sqrt{\frac{\text{s}'p \times \text{s}'\overline{p-c}}{\text{s.}a \times \text{s.}b}}. \text{ And}$$

$$\text{s}'\tfrac{1}{2}C = r\sqrt{\frac{\text{s}'\overline{p-a} \times \text{s}'\overline{p-b}}{\text{s.}a \times \text{s.}b}}.$$

$\text{L.s.}\frac{1}{2}C = \frac{1}{2}(\text{L.s}'p + \text{L.s}'\overline{p-c} + \text{L}'\text{s.}a + \text{L}'\text{s.B})$

$\text{L.s}'\frac{1}{2}C = \frac{1}{2}(\text{L.s}'\overline{p-a} + \text{L.s}'\overline{p-b} + \text{L}'\text{s.}a + \text{Ls}'.b)$

And the same for the other sides.

Note. The sign $>$ signifies greater than, and $<$ less; also $\backsim$ the difference.

Case 3. Given A, B, and included angle c.

To find an angle a opposite the side A,

let $r : \text{s}'c :: \text{t. A} : \text{t. M}$, like or unlike A, as c is $>$ or $< 90°$; also $N = B \backsim M$:

then $\text{s. N} : \text{s. M} :: \text{t.}\,c : \text{t.}\,a$, like or unlike c as M is $>$ or $<$ B.

Or let $\text{s}'\frac{1}{2}.\overline{A+B} : \text{s}'\frac{1}{2}.\overline{A \backsim B} :: \text{t}'\frac{1}{2}c : \text{t. M}$, which is $>$ or $< 90°$ as $A + B$ is $>$ or $< 180°$;

and $\text{s.}\frac{1}{2}.\overline{A+B} : \text{s.}\overline{A \backsim B} :: \text{t}'\frac{1}{2}c : \text{t. N}, > 90°$.

then $a = M + N$; and $b = M - N$.

Again let $r : \text{s}'c :: \text{t.A} : \text{t.M}$, like or unlike A as c is $>$ or $< 90°$; and $N = B \backsim M$.

Then $\text{s}'\text{M} : \text{s}'\text{N} :: \text{s}'\text{A}, \text{s}'\text{C}$, like or unlike N as c is $>$ or $< 90°$. Or,

$$\text{s.}\tfrac{1}{2}C = \sqrt{\frac{\text{s.A} \times \text{s.B} \times \text{s}^2\frac{1}{2}c}{rr} + \text{s}^2\tfrac{1}{2}.\text{A} \backsim \text{B}}.$$

In logarithms, put $\text{L.Q} = 2\text{L.s.}\frac{1}{2}\overline{A \backsim B}$; and $\text{L.R} = \text{L. s. A} + \text{L. s. B} + 2\text{L. s.}\frac{1}{2}c - 20$; then $\text{L.s.}\frac{1}{2}C = \frac{1}{2}\text{L.}\overline{Q+R}$.

Case 4. Given a, b, and included side C.

First, let $r : \text{s}'\text{C} :: \text{t.}\,a : \text{t}'m$, like or unlike a as C is $>$ or $< 90°$; also $n = b \backsim m$.

Then $\text{s}'n : \text{s}'m :: \text{t. C} : \text{t. A}$, like or unlike n as a is $>$ or $< 90°$.

Or, let $\text{s}'\frac{1}{2}\overline{a+b} : \text{s}'\frac{1}{2}.\overline{a \backsim b} :: \text{t.}\frac{1}{2}\text{C} : \text{t. M}$, $>$ or $< 90°$ as $a + b$ is $>$ or $< 180°$;

and $\text{s.}\frac{1}{2}\overline{a+b} : \text{s}\frac{1}{2}\overline{a \backsim b} :: \text{t.}\frac{1}{2}\text{C} : \text{tN}, > 90°$;

then $A = M \pm N$; and $B = M \mp N$.

Again, let $r : \text{s}'\text{C} :: \text{t.}\,a : \text{t}'m$, like or unlike a as C is $>$ or $< 90°$;

and $n = b \backsim m$:

then $\text{s.}m : \text{s}\,n :: \text{s}'a : \text{s}'c$, like or unlike a as m is $>$ or $<$ b.

Case 5. Given A, B, and an opposite angle a.

1st. $\text{s. A} : \text{s.}\,a :: \text{s. B} : \text{s.}\,b$, $>$ or $< 90°$.

2nd. Let $r : \text{s}'\text{B} :: \text{t.}\,a : \text{t}'m$, like or unlike s as a is $>$ or $< 90°$;

and $\text{t. A} : \text{t. B} :: \text{s}'m : \text{s}'n$, like or unlike A as a is $>$ or $> 90°$:

then $c = m \pm n$, two values also.

3dly. Let $r : \text{s}'a :: \text{t. B} : \text{t. M}$, like or unlike B as a is $>$ or $< 90°$;

and $\text{s}'\text{B} : \text{s}'\text{A} :: \text{s}'\text{M} : \text{s}'\text{N}$, like or unlike A as a is $>$ or $< 90°$:

then $C = M \pm N$, two values also.

But if A be equal to B, or to its supplement, or between B and its supplement; then is b like to B; also c is $= m \mp n$, and $C = M \pm N$, as B is like or unlike a.

Case 6. Given a, b, and an opposite side A.

1st. $\text{s}\,a : \text{s. A} :: \text{s.}\,b : \text{s. B}$, $>$ or $< 90°$.

2nd. Let $r : \text{s}'b :: \text{t. A} : \text{to tM}$, like or unlike b as A is $>$ or $< 90°$;

and $\text{t.}\,a : \text{t.}\,b :: \text{s. M} : \text{s. N}$, $>$ or $< 90°$:

then $C = M \mp N$, as a is like or unlike b.

3dly. Let $r : \text{s}'\text{A} :: \text{t.}\,b : \text{t}'m$, like or unlike b as A $>$ or $< 90°$;

and $\text{s}'b : \text{s}'a :: \text{s.}\,m : \text{s.}\,n$, $>$ or $< 90°$:

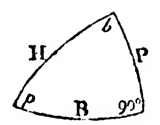
then $c = m \pm n$, as a is like or unlike b.

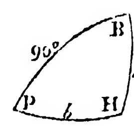
But if A be equal to B, or to its supplement, or between B and its supplement; then B is unlike b, and only the less values of N, n, are possible.

Note, When two sides A, B, and their opposite angles a, b, are known; the third side C, and its opposite angle c, are readily found thus:

$\text{s.}\frac{1}{2}\overline{a \backsim b} : \text{s.}\frac{1}{2}.\overline{a+b} :: \text{t.}\frac{1}{2}\overline{A \backsim B} : \text{t.}\frac{1}{2}\text{C}$.

$\text{s.}\frac{1}{2}\overline{A \backsim B} : \text{s.}\frac{1}{2}\overline{A+B} :: \text{t.}\frac{1}{2}.\overline{a \backsim b} : \text{t.}\frac{1}{2}c$.





III. In a right-angled spheric triangle, where H is the hypotenuse, or side opposite the right angle, B, P the other two sides, and b, p their opposite angles; any two of these five terms being given, to find the rest; the cases, with their solutions, are as in the following Table.

The fame Table will alfo ferve for the quadrantal triangle, or that which has one fide = 90°, H being the angle oppofite that fide, B, P the other two angles, and *b*, *p* their oppofite fides: obferving, inftead of H, to take its fupplement: and mutually change the terms *like* and *unlike* for each other where H is concerned.

Cafe	Given	Req^d^	SOLUTIONS.
1	H B	*b* *p* P	s. H. : *r* : : s B : s*b*, and is like B *r* : t′H : : t. B : s′*p* } s′B : *r* : : s′H : s′P } , $>$ or $<$ 90° as H is like or unlike B
2	H *b*	B P *p*	*r* : s′H : : s.*b* : s.B, like *b* *r* : s′*b* : : t.H : t.P } *r* : s′H : : t.*b* : t′*p* } , $>$ or $<$ 90° as H is like or unlike *b*
3	B *b*	H P *p*	s *b* : *r* : : s.B : s.H } *r* : t.B : : t′*b* : s.P } s′B : *r* : : s′*b* : s.*p* } , each $>$ or $<$ 90°; both values true
4	B *p*	H *b* *p*	*r* : t′B : : s′*p* : t′H, $>$ or $<$ 90 as B is like or unlike *p* *r* : s′B : : s.*p* : s′*b*, like B *r* : s.B : : t.*p* : t.P, like *p*
5	B P	H *b* *p*	*r* : s′B : : s′P : s′H, $>$ or $<$ 90° as B is like or unlike P *r* : s.P : : t′B : t′*b*, like B *r* : s.B : : t′P : t′*p*, like P
6	*b* *p*	H B P	*r* : t′*b* : : t′*p* : s′H, $>$ or $<$ 90° as *b* is like or unlike *p* s.*p* : *r* : : s′*b* : s′B like *b* s.*b* : *r* : : s′*p* . s′P like *p*

The following Propofitions and Remarks, concerning Spherical Triangles, (felected and communicated by the reverend Nevil Mafkelyne, D. D. Aftronomer Royal, F. R. S.) will alfo render the calculation of them perfpicuous, and free from ambiguity.

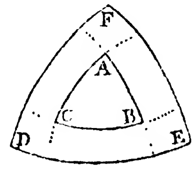
" 1. A fpherical triangle is equilateral, ifofcelar, or fcalene, according as it has its three angles all equal, or two of them equal, or all three unequal; and *vice verfa*.

2. The greateft fide is always oppofite the greateft angle, and the fmalleft fide oppofite the fmalleft angle.

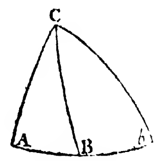
3. Any two fides taken together, are greater than the third.

4. If the three angles are all acute, or all right, or all obtufe; the three fides will be, accordingly, all lefs than 90°, or equal to 90°, or greater than 90°; and *vice verfa*.

5. If from the three angles A, B, C, of a triangle ABC, as poles, there be defcribed, upon the furface of the fphere, three arches of a great circle DF, DF, FE, forming by their interfections a new fpherical triangle DEF; each fide of the new triangle will be the fupplement of the angle at its pole; and each angle of the fame triangle, will be the fupplement of the fide oppofite to it in the triangle ABC.



6. In any triangle ABC, or A*b*C, right angled in A, 1ft, The angles at the hypotenufe are always of the fame kind as their oppofite fides; 2dly, The hypotenufe is lefs or greater than a quadrant, according as the fides including the right angle are of the fame or different kinds; that is to fay, according as thefe fame fides are either both acute or both obtufe, or as one is acute and the other obtufe. And, *vice verfa*, 1ft, The fides including the right angle, are always of the fame kind as their oppofite angles: 2dly, The fides including the right angle will be of the fame or different kinds, according as the hypotenufe is lefs or more than 90°; but one at leaft of them will be of 90°, if the hypotenufe is fo."



TRILATERAL, three-fided, a term applied to all figures of three fides, or triangles.

TRILLION, in Arithmetic, the number of a million of billions, or a million of million of millions.

TRIMMERS, in Architecture, pieces of timber framed at right-angles to the joifts, againft the ways for chimneys to fupport the hearths, and the well-holes for ftairs.

TRINE *Dimenfion*, or *threefold dimenfion*, includes length, breadth, and thicknefs. The Trine dimenfion is peculiar to bodies or folids.

TRINE, in Aftrology, is the afpect or fituation of one planet with refpect to another, when they are diftant

tant ⅓ part of the circle, or 4 signs, or 120 degrees. It is also called trigon, and is denoted by the character △.

TRINITY *Sunday*, is the next after Whitsunday; so called, because on that day was anciently held a festival (as it still continues to be in the Romish Church) in honour of the Holy Trinity.—The observance of this festival was first enjoined by the 6th canon of the council of Arles, in 1260; and John the 22d, who distinguished himself so much by his opinion concerning the beatific vision, it is said, fixed the office for this festival in 1334.

TRINODA, or TRINODIA *Terræ*, in some ancient writers, denotes the quantity of 3 perches of land.

TRINOMIAL, in Algebra, is a quantity, or a root, consisting of three parts or terms, connected together by the signs + or −: as $a + b - c$, or $x + y + z$.

TRIO, in Music, a part of a concert in which three persons sing; or rather a musical composition consisting of 3 parts.—Trios are the finest kind of musical composition, and please most in concerts.

TRIOCTILE, in Astrology, an aspect or situation of two planets, with regard to the earth, when they are 3 octants, or ⅜ of a circle, which is 135°, distant from each other.—This aspect, which some call the *sesquiquadrans*, is one of the new aspects added to the old ones by Kepler.

TRIONES, in Astronomy, a sort of constellation, or assemblage of 7 stars in the Ursa Major, popularly called *Charles's Wain*.—From the *Septem Triones* the north pole takes the denomination *Septentrio*.

TRIPARTITION, is a division by 3, or the taking of the 3d part of any number or quantity.

TRIPLE, threefold. See RATIO and SUBTRIPLE.

TRIPLE, in Music, is one of the species of measure or time, and is taken from hence, that the whole, or half measure, is divisible into 3 equal parts, and is beaten accordingly.

TRIPLICATE *Ratio*, is the ratio which cubes, or any similar solids, bear to each other; and is the cube of the simple ratio, or this twice multiplied by itself. Thus 1 to 8 is the Triplicate ratio of 1 to 2, and 1 to 27 Triplicate of 1 to 3.

TRIPLICITY, or TRIGON, with Astrologers, is a division of the 12 signs, according to the number of the 4 elements, earth, water, air, fire; each division consisting of 3 signs, making the earthly Triplicity, the watery Triplicity, the airy Triplicity, and the fiery Triplicity.

Triplicity is sometimes confounded with trine aspect; though they are, strictly speaking, very different things; as Triplicity is only used with regard to the signs, and trine with regard to the planets. The signs of Triplicity are those which are of the same nature, and not those that are in trine aspect: thus Aries, Leo, and Sagittary are signs of Triplicity, because those signs are, by these writers, all supposed fiery.

The signs in each of the four Triplicities, are as follow:

Earthly.	*Watery.*	*Airy.*	*Fiery.*
♉ Taurus.	♋ Cancer.	♊ Gemini.	♈ Aries.
♍ Virgo.	♏ Scorpio.	♎ Libra.	♌ Leo.
♑ Capricorn.	♓ Pisces.	♒ Aquarius.	♐ Sagittary.

TRIS DIAPASON, or *Triple Diapason Chord*, in Music, is what is otherwise called a *triple eighth*.

TRISECTION, the dividing a thing into three equal parts. The term is chiefly used in Geometry, for the division of an angle into three equal parts. The *Trisection of an angle* geometrically, is one of those great problems whose solution has been so much sought for by mathematicians, for 2000 years past; being, in this respect, on a footing with the famous quadrature of the circle, and the duplicature of the cube.

The Ancients Trisected an angle by means of the conic sections, and the book of Inclinations; and Pappus enumerates several ways of doing it, in the 4th book of his Mathematical Collections, prop. 31, 32, 33, 34, 35, &c. He farther observes, that the problem of Trisecting an angle, is a solid problem, or a problem of the 3d degree, being expressed by the resolution of a cubic equation, in which way it has been resolved by Vieta, and others of the Moderns. See his Angular Sections, with those of other authors, and the Trisection in particular by cubic equations, as in Guisne's Application of Algebra to Geometry, in l'Hospital's Conic Sections, and in Emerson's Trigonometry, book 1, sec. 4. The cubic equation by which the problem of Trisection is resolved, is as follows: Let c denote the chord of a given arc, or angle, and x the cord of the 3d part of the same, to the radius 1; then is

$$x^3 - 3x = -c,$$

by the resolution of which cubic equation is found the value of x, or the chord of the 3d part of the given arc or angle, whose chord is c; and the resolution of this equation, by Cardan's rule, gives the chord

$$x = \sqrt[3]{\frac{-c + \sqrt{c^2 - 4}}{2}} + \frac{1}{\sqrt[3]{\dfrac{-c + \sqrt{c^2 - 4}}{2}}},$$

$$\text{or } x = \sqrt[3]{\frac{-c + \sqrt{c^2 - 4}}{2}} + \sqrt[3]{\frac{-c - \sqrt{c^2 - 4}}{2}}$$

TRISPAST, or TRISPASTON, in Mechanics, a machine with 3 pulleys, or an assemblage of 3 pulleys, for raising great weights; being a lower species of the polyspaston.

TRITE, in Music, the 3d musical chord in the system of the Ancients.

TRITONE, in Music, a false concord, consisting of three tones, or a greater third, and a greater tone. Its ratio or proportion in numbers, is that of 45 to 32.

TROCHILE, in Architecture, is that hollow ring, or cavity, which runs round a column next to the tore.

TROCHLEA, in Mechanics, one of the mechanic powers, more usually called the pulley.

TROCHOID, in the Higher Geometry, a curve described by a point in any part of the radius of a wheel, during its rotatory and progressive motions. This is the same curve as what is more usually called the *Cycloid*, where the construction and properties of it are shewn.

TRONE *Weight*, was the same with what we now call *Troy Weight*.

TRONE *Pound*, in Scotland, contains 20 Scotch ounces. Or because it is usual to allow one to the score, the Trone-pound is commonly 21 ounces.

TRONE-*Stone*, in Scotland, according to Sir John Skene, contains $19\frac{1}{2}$ pounds.

TROPHY, in Architecture, an ornament which represents the trunk of a tree, charged or encompassed all around with arms or military weapons, both offensive and defensive.

TROPICAL, something relating to the Tropics. As, TROPICAL-*Winds*. See WIND, and TRADE-*Winds*.

TROPICAL *Year*, the space of time during which the sun passes round from a tropic, till his return to it again. See YEAR.

TROPICS, in Astronomy, two fixed circles of the sphere, drawn parallel to the equator, through the solstitial points, or at such distance from the equator, as is equal to the sun's greatest recess or declination, or to the obliquity of the ecliptic.

Of the two Tropics, that on the north side of the equator, passes through the first point of Cancer, and is therefore called the *Tropic of Cancer*. And the other on the south side, passing through the first point of Capricorn, is called the *Tropic of Capricorn*.

To determine the distance between the two Tropics, and thence the sun's greatest declination, or the obliquity of the ecliptic; observe the sun's meridian altitude, both in the summer and winter solstice, and subtract the latter from the former, so shall the remainder be the distance between the two Tropics; and the half of this will be the quantity of the greatest declination, or the obliquity of the ecliptic; the medium of which is now $23^\circ 28'$ nearly.

TROPICS, in Geography, are two lesser circles of the globe, drawn parallel to the equator through the beginnings of Cancer and Capricorn, being in the planes of the celestial Tropics, and consequently at $23^\circ 28'$ distance either way from the equator.

TROY-*Weight*, anciently called *Trone-weight*, is supposed to be taken from a weight of the same name in France, and that from the name of the town of Troyes there.

The original of all weights used in England, was a corn or grain of wheat gathered out of the middle of the ear, and, when well dried, 32 of them were to make one pennyweight, 20 pennyweights 1 ounce, and 12 ounces 1 pound Troy. Vide Statutes of 51 Hen. III; 31 Ed. I. and 12 Hen. VII.

But afterward it was thought sufficient to divide the said pennyweight into 24 equal parts, called grains, being the least weight now in common use; so that the divisions of Troy weight now are these:

24 grains	=	1 pennyweight	*dwt.*
20 pennyweights	=	1 ounce	*oz.*
12 ounces	=	1 pound	*lb.*

By Troy-weight are weighed jewels, gold, silver, and all liquors.

TRUCKS, among Gunners, are the small wooden wheels fixed on the axletrees of gun carriages, especially those for ship service, to move them about by.

TRUE *Conjunction*, in Astronomy. See *True* CONJUNCTION.

TRUE *Place of a Planet or Star*, is a point in the heavens shewn by a right line drawn from the centre of the earth, through the centre of the star or planet.

TRUMPET, *Listening or Hearing*, is an instrument invented by Joseph Landini, to assist the hearing of persons dull of that faculty, or to assist us to hear persons who speak at a great distance.

Instruments of this kind are formed of tubes, with a wide mouth, and terminating in a small canal, which is applied to the ear. The form of these instruments evidently shews how they conduce to assist the hearing; for the greater quantity of the weak and languid pulses of the air being received and collected by the large end of the tube, are reflected to the small end, where they are collected and condensed; thence entering the ear in this condensed state, they strike the tympanum with a greater force than they could naturally have done from the ear alone.

Hence it appears, that a speaking Trumpet may be applied to the purpose of a hearing Trumpet, by turning the wide end towards the sound, and the narrow end to the ear.

Speaking TRUMPET, is a tube of a considerable length, from 6 to 15 feet, used for speaking with to make the voice be heard to a greater distance.

This tube, which is made of tin, is straight throughout its length, but opening to a large aperture outwards, and the other end terminating in a proper shape and size to receive both the lips in the act of speaking, the speaker pushing his voice or the sound outwards, by which means it may be heard at the distance of a mile or more.

The invention of this Trumpet is held to be modern, and has been ascribed to Sir Samuel Moreland, who called it the *tuba stentorophonica*, and in a work of the same name, published at London in 1671, that author gave an account of it, and of several experiments made with it. With one of these instruments, of $5\frac{1}{2}$ feet long, 21 inches diameter at the greater end, and 2 inches at the smaller, tried at Deal-Castle, the speaker was heard to the distance of 3 miles, the wind blowing from the shore.

But it seems that Kircher has a better title to the invention; for it is certain that he had such an instrument before ever Moreland thought of his. That author, in his Phonurgia Nova, published in 1673, says, that the tromba, published last year in England, he invented 24 years before, and published in his Mesurgia. He adds, that Jac. Albanus Ghibbisius and Fr. Eschinardus ascribe it to him; and that G. Schottus testifies of him, that he had such an instrument in his chamber in the Roman

Roman college, with which he could call to, and receive answers from the porter.

But, considering how famous the tube or horn of Alexander the Great was, it is rather strange that the Moderns should pretend to the invention. With his stentorophonic horn or tube he used to speak to his army, and make himself be distinctly heard, it is said, 100 stadia or furlongs. A figure of this tube is preserved in the Vatican; and it is nearly the same as that now in use. See STENTOROPHONIC.

The principle of this instrument is obvious; for as sound is stronger in proportion to the density of the air, it follows that the voice in passing through a tube, or Trumpet, must be greatly augmented by the constant reflection and agitation of the air through the length of the tube, by which it is condensed, and its action on the external air greatly increased at its exit from the tube.

It has been found, that a man speaking through a tube of 4 feet long, may be understood at the distance of 500 geometrical paces; with a tube 16⅔ feet, at the distance of 1800 paces; and with a tube 24 feet long, at more than 2500 paces.

Although some advantage in heightening the sound, both in speaking and hearing, be derived from the shape of the tube, and the width of the outer end, yet the effect depends chiefly upon its length. As to the form of it, some have asserted that the best figure is that which is formed by the revolution of a parabola about its axis; the mouth-piece being placed in the focus of the parabola, and consequently the sonorous rays reflected parallel to the axis of the tube. But Mr. Martin observes, that this parallel reflection is by no means essential to increasing the sound: on the contrary, it prevents the infinite number of reflections and reciprocations of sound, in which, according to Newton, its augmentation chiefly consists; the augmentation of the impetus of the pulses of air being proportional to the number of repercussions from the sides of the tube, and therefore to its length, and to such a figure as is most productive of them. Hence he infers, that the parabolic Trumpet is the most unfit of any for this purpose; and he endeavours to shew, that the logarithmic or logistic curve gives the best form, viz, by a revolution about its axis. Martin's Philos. Brit. vol. 2, pa. 248, 3d edit.

But Cassegrain is of opinion that an hyperbola, having the axis of the tube for an asymptote, is the best figure for this instrument. Musschenb. Intr. ad Phil. Nat. tom. 2, pa. 926, 4to.

For other constructions of Speaking Trumpets, by Mr. Conyers, see Philos. Trans. numb. 141, for 1678.

TRUNCATED *Pyramid* or *Cone*, is the frustum of one, being the part remaining at the bottom, after the top is cut off by a plane parallel to the base. See FRUSTUM.

TRUNNIONS, of a piece of ordnance, are those knobs or short cylinders of metal on the sides, by which it rests on the cheeks of the carriage.

TRUNNION-*Ring*, is the ring about a cannon, next before the Trunnions.

TSCHIRNHAUSEN (ERNFROY WALTER), an ingenious mathematician, lord of Killingswald and of Stolzenberg in Lusatia, where he was born in 1651. After having served as a volunteer in the army of Holland in 1672, he travelled into most parts of Europe, as England, Germany, Italy, France, &c. He went to Paris for the third time in 1682; where he communicated to the Academy of Sciences, the discovery of the curves called, from him, Tschirnhausen's Caustics; and the Academy in consequence elected the inventor one of its foreign members. On returning to Italy, he was desirous of perfecting the science of optics; for which purpose he established two glass-works, from whence resulted many new improvements in dioptrics and physics, particularly the noted burning-glass which he presented to the regent.—It was to him too that Saxony owed its porcelane manufactory.

Content with the enjoyment of literary fame, Tschirnhausen refused all other honours that were offered him. Learning was his sole delight. He searched out men of talents, and gave them encouragement. He was often at the expence of printing the useful works of other men, for the benefit of the public; and died, beloved and regretted, the 11th of September 1708.

Tschirnhausen wrote, *De Medicina Mentis & Corporis*, printed at Amsterdam in 1687. And the following memoirs were printed in the volumes of the Academy of Sciences.

1. Observations on Burning Glasses of 3 or 4 feet diameter: vol. 1699.

2. Observations on the Glass of a Telescope, convex on both sides, of 32 feet focal distance; 1700.

3. On the Radii of Curvature, with the finding the Tangents, Quadratures, and Rectifications of many curves; 1701.

4. On the Tangents of Mechanical Curves; 1702.

5. On a method of Quadratures; 1702.

TUBE, a pipe, conduit, or canal; being a hollow cylinder, either of metal, wood, glass, or other matter, for the conveyance of air, or water, &c.

The term is chiefly applied to those used in physics, astronomy, anatomy, &c. On other ordinary occasions, we more usually say *pipe*.

In the memoirs of the French Academy of Sciences, Varignon has given a treatise on the proportions for the diameters of tubes, to give any particular quantities of water. The result of his paper gives these two analogies, viz, that the diminutions of the velocity of water, occasioned by its friction against the sides of Tubes, are as the diameters; the Tubes being supposed equally long: and the quantities of water issuing out at the Tubes, are as the square roots of their diameters, deducting out of them the quantity that each is diminished.

TUBE, in Astronomy, is sometimes used for telescope; but more properly for that part of it into which the lenses are fitted, and by which they are directed and used.

TUESDAY, the 3d day of the week, fo called from Tuefco, one of the Saxon Gods, fimilar to Mars; for which reafon the aftronomical mark for this day of the week, is ♂.

TUMBREL, is a kind of carriage with two wheels, ufed either in Hufbandry for dung, or in Artillery to carry the tools of the pioneers, &c, and fometimes likewife the money of an army.

TUN, is a meafure for liquids, as wine, oil, &c.

The Englifh Tun contains 2 pipes, or 4 hogfheads, or 252 gallons.

TUNE, or TONE, in Mufic, is that property of founds by which they come under the relation of acute and grave.

If two or more founds be compared together in this relation, they are either equal or unequal in the degree of Tune: fuch as are equal, are called *unifons*. The unequal conftitute what are called *intervals*, which are the differences of Tone between founds.

Sonorous bodies are found to differ in Tone: 1ft, According to the different kinds of matter; thus the found of a piece of gold, is much graver than that of a piece of filver of the fame fhape and dimenfions. 2d, According to the different quantities of the fame matter in bodies of the fame figure; as a folid fphere of brafs of 1 foot diameter, founds acuter than a fphere of brafs of 2 feet diameter.

But the meafures of Tone are only to be fought in the relations of the motions that are the caufe of found, which are moft difcernible in the vibration of chords. Now, in general, we find that in two chords, all things being equal, excepting the tenfion, the thicknefs, or the length, the Tones are different; which difference can only be in the velocity of their vibratory motions, by which they perform a different number of vibrations in the fame time; as it is known that all the fmall vibrations of the fame chord are performed in equal times. Now the frequenter or quicker thofe vibrations are, the more acute is the Tone; and the flower and fewer they are in the fame fpace of time, by fo much the more grave is the Tone. So that any given note of a Tune is made by one certain meafure of velocity of vibrations, that is, fuch a certain number of vibrations of a chord or ftring, in fuch a certain fpace of time, conftitutes a determinate Tone.

This theory is ftrongly fupported by the beft and lateft writers on mufic, Holder, Malcolm, Smith, &c, both from reafon and experience. Dr. Wallis, who owns it very reafonable, adds, that it is evident the degrees of acutenefs are reciprocally as the lengths of the chords; though, he fays, he will not pofitively affirm that the degrees of acutenefs anfwer the number of vibrations, as their only true caufe: but his diffidence arifes from hence, that he doubts whether the thing has been fufficiently confirmed by experiment.

TUNNAGE. See TONNAGE.

TURN, is ufed for a circular motion; in which fenfe it agrees with revolution.

TURN, in Clock or Watch-work, particularly denotes the revolution of a wheel or pinion.

In calculation, the number of Turns which the pinion hath, is denoted in common arithmetic thus, 5) 60 (12, where the pinion 5, playing in a wheel of 60, moves round 12 times in one Turns of the wheel. Now by knowing the number of Turns which any pinion hath, in one Turn of the wheel it works in, you may eafily find how many Turns a wheel or pinion has at a greater diftance; as the contrat-wheel, crown-wheel, &c, by multiplying together the quotients, and the number produced is the number of Turns, as in the example here annexed: the firft of

5)	55	(11
5)	45	(9
5)	40	(8

thefe three numbers has 11 Turns, the next 9, and the laft 8; if you multiply 11 by 9, it produces 99; that is, in one Turn of the wheel 55, there are 99 Turns of the fecond pinion 5, or the wheel 40, which runs concentrical or on the fame arbor with the fecond pinion 5: and if you again multiply 99 by the laft quotient 8, it produces 792, which is the number of Turns the third pinion 5 hath. See CLOCK-*work*, and PINION.

TURNING *to windward*, in Sea Language, denotes that operation in failing when a fhip endeavours to make a progrefs againft the direction of the wind, by a compound courfe, inclined to the place of her deftination.—This method of navigation is otherwife called *plying to windward*.

TUSCAN *Order*, in Architecture, is the firft, the fimpleft, and the ftrongeft or moft maffive of any. Its column has 7 diameters in height; and its capital, bafe, and entablement, have no ornaments, and but few mouldings.

TWELFTH-*Day*, the feftival of the Epiphany, or the manifeftation of Chrift to the Gentiles, fo called, as being the Twelfth day, exclufive, from the nativity or Chriftmas-day; of courfe it falls always on the 6th day of January.

TWILIGHT, in Aftronomy, is that faint light which is perceived before the fun-rifing, and after fun-fetting. The Twilight is occafioned by the earth's atmofphere refracting the rays of the fun, and reflecting them among its particles.

The depreffion of the fun below the horizon, at the beginning of the morning, and end of the evening Twilight, has been varioufly ftated, at different feafons, and by different obfervers: by Alhazen it was obferved to be 19°; by Tycho 17°; by Rothman 24°; by Stevinus 18°; by Caffini 15°; by Riccioli, at the time of the equinox in the morning 16°, in the evening 20½°; in the fummer folftice in the morning 21° 25′, and in the winter 17° 15′. Whence it appears that the caufe of the Twilight is variable; but, on a medium, about 18° of the fun's depreffion will ferve tolerably well for our latitude, for the beginning and end of Twilight, and according to which Dr. Long, (in his Aftronomy, vol. 1, pa. 258) gives the following Table, of the duration of Twilight, in different latitudes, and for feveral different declinations of the fun.

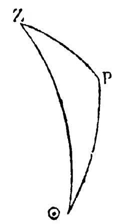
Latitude.

Latitude.	0	10	20	30	40	45	50	52½	55	60	65	70	75	80	85	90
☉ Enters	h m	h m	h m	h m	h m	h m	h m	h m	h m	h m	h m	h m	h m	h m	h m	h m
♋	1 18	1 21	1 28	1 41	2 8	2 39	w n	w n	w n	w n	w n	c d	c d	c d	c d	c d
♊ ♌	1 16	1 19	1 25	1 36	1 58	2 19	3 3	w n	w n	w n	w n	c d	c d	c d	c d	c d
♉ ♍	1 13	1 15	1 20	1 28	1 43	1 55	2 12	2 25	2 41	3 55	w n	w n	w n	c d	c d	c d
♈ ♎	1 12	1 13	1 17	1 24	1 35	1 44	1 55	2 2	2 10	2 33	3 8	4 18	w n	w n	w n	w n
♓ ♏	1 13	1 14	1 18	1 24	1 35	1 43	1 51	2 0	2 8	2 27	2 56	8 41	5 2	17 32	w n	w n
♒ ♐	1 16	1 17	1 21	1 28	1 40	1 49	2 1	2 8	2 18	2 43	3 26	11 38	11 14	10 32	8 38	c n
♑	1 18	1 19	1 23	1 30	1 43	1 53	2 6	2 15	2 26	2 57	4 4	10 24	9 30	7 46	c n	c n

Where *c d* signify that it is then continual day, *c n* continual night, and *w n* that the Twilight lasts the whole night.

Prob.—To find the Beginning or End of Twilight.

In this problem, there are given the sides of an oblique spherical triangle, to find an angle; viz, given the side ZP the colatitude of the place; P☉ the codeclination, or polar distance; and Z☉ the zenith distance, which is always equal to 108°, viz, 90° from the zenith to the horizon, and 18° more for the sun's distance below the horizon. For example, suppose the place London in latitude 51° 32′, and the time the 1st of May, when the sun's declination is 15° 12′ north. Here then ZP = 38° 28′ the complement of 51° 32′, and P☉ = 74° 48′, the complement of 15° 12′. Then the calculation is as follows.



$$
\begin{array}{rcl}
P☉ & = & 74°\ 48' \\
PZ & = & 38\ \ 28 \\
\hline
P☉ - PZ & = & 36\ \ 20 = D \\
Z☉ & = & 108\ \ 00 \\
\hline
Z☉ + D & = & 144\ \ 20 \\
 & 2\,) & \\
Z☉ - D & = & 71\ \ 40
\end{array}
\quad
\begin{array}{l}
72°\ 10' = \tfrac{1}{2}\ \overline{Z☉ + D} \\
35\ \ 50 = \tfrac{1}{2}\ \overline{Z☉ - D}
\end{array}
$$

Then,

Co-ar. sin. polar dist.	= 74° 48′	- 0·01547
Co-ar. sin. colat. -	= 38 28	- 0·20617
Sine ½ $\overline{Z☉ + D}$ -	= 72 10	- 9·97861
Sine ½ $\overline{Z☉ - D}$ -	= 35 50	- 9·76747
Sum of these four logs -	-	19·96772
Half sum gives	74° 28½′ -	9·98386

Which doubled gives 148 57 for the angle ZPO.

This 148° 57′ reduced to time, at the rate of 15° per hour, gives $9^h\ 55^m\ 48^s$, either before or after noon; that is, the twilight begins at $2^h\ 4^m\ 12^s$ in the morning, and ends at $9^h\ 55^m\ 48^s$ in the evening on the given day at London.

TWINKLING *of the Stars*, denotes that tremulous motion which is observed in the light proceeding from the fixed stars.

This Twinkling in the stars has been variously accounted for. Alhazen, a Moorish philosopher of the 12th century, considers refraction as the cause of this phenomenon.

Vitello, in his Optics, (composed before the year 1270) pa. 449, ascribes the Twinkling of the stars to the motion of the air, in which the light is refracted; and he observes, in confirmation of this hypothesis, that they Twinkle still more when they are viewed in water put into motion.

Dr. Hook (Microgr. pa. 231, &c) ascribes this phenomenon to the inconstant and unequal refraction of the rays of light, occasioned by the trembling motion of the air and interspersed vapours, in consequence of variable degrees of heat and cold in the air, producing correspondign variations in its density, and also of the action of the wind, which must cause the successive rays to fall upon the eye in different directions, and consequently upon different parts of the retina at different times, and also to hit and miss the pupil alternately; and this also is the reason, he says, why the limbs of the sun, moon, and planets appear to wave or dance.

These tremors of the air are manifest to the eye by the tremulous motion of shadows cast from high towers; and by looking at objects through the smoke of a chimney, or through steams of hot water, or at objects situated beyond hot sands, especially if the air be moved transversely over them. But when stars are seen through telescopes that have large apertures; they Twinkle but little, and sometimes not at all. For, as Newton has observed, (Opt. pa. 98) the rays of light which pass through different parts of the aperture, tremble each of them apart, and by means of their various, and contrary tremors, fall at one and the same time

time upon different points in the bottom of the eye, and their trembling motions are too quick and confused to be separately perceived. And all these illuminated points constitute one broad lucid point, composed of those many trembling points confusedly and insensibly mixed with one another by very short and swift tremors, and so cause the star to appear broader than it is, and without any trembling of the whole.

Dr. Jurin, in his Essay upon Distinct and Indistinct Vision, has recourse to Newton's hypothesis of fits of easy refraction and reflection for explaining the Twinkling of the stars: thus, he says, if the middle part of the image of a star be changed from light to dark, and the adjacent ring at the same time be changed from dark to light, as must happen from the least motion of the eye towards or from the star, this will occasion such an appearance as Twinkling.

Mr. Michell (Philos. Trans. vol. 57, pa. 262) supposes that the arrival of fewer or more rays at one time, especially from the smaller or more remote fixed stars, may make such an unequal impression on the eye, as may at least have some share in producing this effect: since it may be supposed that even a single particle of light is sufficient to make a sensible impression on the organs of sight; so that very few particles arriving at the eye in a second of time, perhaps not more than three or four, may be sufficient to make an object constantly visible. See Light.

Hence, he says, it is not improbable that the number of the particles of light which enter the eye in a second of time, even from Syrius himself, may not exceed 3 or 4 thousand, and from stars of the 2d magnitude they may probably not exceed 100. Now the apparent increase and diminution of the light, which we observe in the Twinkling of the stars, seem to be repeated at intervals not very unequal, perhaps about 4 or 5 times in a second. He therefore thought it reasonable to suppose, that the inequalities which will naturally arise from the chance of the rays coming sometimes a little denser, and sometimes a little rarer, in so small a number of them, as must fall upon the eye in the 4th or 5th part of a second, may be sufficient to account for this appearance.

Since these observations were published however, Mr. Michell (as we are informed by Dr. Priestley in his Hist. of Light, pa. 495) has entertained some suspicion, that the unequal density of light does not contribute to this effect in so great a degree as he had imagined; especially as he has observed that even Venus does sometimes Twinkle. This he once observed her to do remarkably when she was about 6 degrees high, though Jupiter, which was then about 16 degrees high, and was sensibly less luminous, did not Twinkle at all. If, notwithstanding the great number of rays which doubtless come to the eye from such a surface as this planet presents, its appearance be liable to be affected in this manner, it must be owing to such undulations in the atmosphere, as will probably render the effect of every other cause altogether insensible.

Musschenbroek suspects (Introd. ad Phil. Nat. vol. 2, sect. 1741, pa. 707) that the Twinkling of the stars arises from some affection of the eye, as well as the state of the atmosphere. For, says he, in Holland, when the weather is frosty, and the sky very clear, the stars Twinkle most manifestly to the naked eye, though not in telescopes; and since he does not suppose there is any great exhalation, or dancing of the vapour, at that time, he questions whether the vivacity of the light, affecting the eye, may not be concerned in the phenomenon.

But this philosopher might have satisfied himself with respect to this hypothesis, by looking at the stars near the zenith, when the light traverses but a small part of the atmosphere, and therefore might be expected to affect the eye most sensibly. For he would have found that they do not Twinkle near so much as they do near the horizon, when much more of their light is intercepted by the atmosphere.

Some astronomers have lately endeavoured to explain the Twinkling of the fixed stars, by the extreme minuteness of their apparent diameter; so that they suppose the sight of them is intercepted by every mote that floats in the air. To this purpose Dr. Long observes (Astron. vol. 1, pa. 170) that our air near the earth is so full of various kinds of particles, which are in continual motion, that some one or other of them is perpetually passing between us and any star we look at, which makes us every moment alternately see it and lose sight of it: and this Twinkling of the stars, he says, is greatest in those that are nearest the horizon, because they are viewed through a great quantity of thick air, where the intercepting particles are most numerous; whereas stars that are near the zenith do not Twinkle so much, because we do not look at them through so much thick air, and therefore the intercepting particles, being fewer, come less frequently before them. With respect to the planets, it is observed that, because they are much nearer to us than the stars, they have a sensible apparent magnitude, so that they are not covered by the small particles floating in the atmosphere, and therefore do not Twinkle, but shine with a steady light.

The fallacy of this hypothesis appears from the observation of Mr. Michell, that no object can hide a star from us that is not large enough to exceed the apparent diameter of the star, by the diameter of the pupil of the eye; so that if a star were even a mathematical point, or of no diameter, the interposing object must still be equal in size to the pupil of the eye; and indeed it must be large enough to hide the star from both eyes at the same time.

The principal cause therefore of the Twinkling of the stars, is now acknowledged to be the unequal refraction of light, in consequence of inequalities and undulations in the atmosphere.

Besides a variation in the quantity of light, it may here be added, that a momentary change of colour has likewise been observed in some of the fixed stars. Mr. Melville (Edinb. Essays, vol. 2, pa. 81) says, that when one looks steadfastly at Sirius, or any bright star, not much elevated above the horizon, its colour seems not to be constantly white, but appears tinctured, at every Twinkling, with red and blue. Mr. Melville could not entirely satisfy himself as to the cause of this phenomenon;

nomenon; obferving that the feparation of the colours by the refractive power of the atmofphere, is probably too fmall to be perceived. Mr. Michell's hypothefis above mentioned, though not adequate to the explication of the Twinkling of the ftars, may pretty well account for this circumftance. For the red and blue rays being much fewer than thofe of the intermediate colours, and therefore much more liable to inequalities from the common effect of chance, a fmall excefs or defect in either of them will make a very fenfible difference in the colour of the ftars.

TYCHONIC *Syftem*, or *Hypothefis*, is an order or arrangement of the heavenly bodies, of an intermediate nature between the Copernican and Ptolomaic; and is fo called from its inventor Tycho Brahe. See SYSTEM.

TYMPAN, or TYMPANUM, in Architecture, is the area of a pediment, being that part which is on a level with the naked of the frize. Or it is the fpace included between the three cornices of a triangular pediment, or the two cornices of a circular one.

TYMPAN is alfo ufed for that part of a pedeftal called the *trunk* or *dye*.

TYMPAN, among Joiners, is alfo applied to the pannels of doors.

TYMPAN *of an Arch*, is a triangular fpace or table in the corners of fides of an arch, ufually hollowed and enriched, fometimes with branches of laurel, olive-tree, or oak; or with trophies, &c; fometimes with flying figures, as fame, &c; or fitting figures, as the cardinal virtues.

TYMPAN, in Mechanics, is a kind of wheel placed round an axis, or cylindrical beam, on the top of which are two levers, or fixed ftaves, for more eafily turning the axis about, in order to raife a weight. The Tympanum is much the fame with the peritrochium; but that the cylinder of the axis of the peritrochium is much fhorter and lefs than the cylinder of the Tympanum.

TYMPANUM of a machine, is alfo ufed for a hollow wheel, in which people or animals walk, to turn it; fuch as that of fome cranes, calenders, &c.

TYR, in the Ethiopian Calendar, the name of the 5th month of the Ethiopian year. It commences on the 25th of December of the Julian year.

TYSHAS, among the Ethiopians, the name of the 4th month of their year, commencing the 27th of November in the Julian year.

U AND V.

V Is a numeral letter, in the Roman numeration, denoting 5 or five. And with a dafh over the top thus $\overline{V}$, it denoted 5000.

VACUUM, in Phyfics, a fpace empty or devoid of all matter.

Whether there be any fuch thing in nature as an abfolute Vacuum; or whether the univerfe be completely full, and there be an abfolute plenum; is a queftion that has been agitated by the philofophers of all ages.

The Ancients, in their controverfies, diftinguifhed two kinds; a *Vacuum coacervatum*, and a *Vacuum interfperfum*, or *diffeminatum*.

VACUUM *Coacervatum*, is conceived as a confiderably large fpace deftitute of matter; fuch, for inftance, as there would be, fhould God annihilate all the air, and other bodies, within the walls of a chamber.

The exiftence of fuch a Vacuum is maintained by the Pythagoreans, Epicureans, and the Atomifts or Corpufcularians; moft of whom affert, that fuch a Vacuum actually exifts without the limits of the fenfible world. But the modern Corpufcularians, who hold a *Vacuum coacervatum*, deny that appellation; as conceiving that fuch a Vacuum muft be infinite, eternal, and uncreated.

According then to the later philofophers, there is no Vacuum coacervatum without the bounds of the fenfible world; nor would there be any other Vacuum, provided God fhould annihilate divers contiguous bodies, than what amounts to a mere privation, or nothing; the dimenfions of fuch a fpace, which the Ancients held to be real, being by thefe held to be mere negations; that is, in fuch a place there is fo much length, breadth, and depth wanting, as a body muft have to fill it. To fuppofe then that when all the matter in a chamber is annihilated, there fhould yet be real dimenfions, is to fuppofe, fay they, corporeal dimenfions without body; which is abfurd.

The Cartefians however deny any *Vacuum coacervatum* at all, and affert that if God fhould immediately annihilate all the matter, for example in a chamber, and prevent the ingrefs of any other matter, the confequence would be, that the walls would become contiguous, and include no fpace at all. They add, that if there be no matter in a chamber, the walls cannot be conceived otherwife than as contiguous; thofe things being

being said to be contiguous, between which there is not any thing intermediate: but if there be no body between, there is, say they, no extension between; extension and body being the same thing: and if there be no extension between, then the walls are contiguous; and where is the Vacuum?——But this reasoning, or rather quibbling, is founded on the mistake, that body and extension are the same thing.

VACUUM *Disseminatum*, or *Interspersum*, is that supposed to be naturally interspersed in and among bodies, in the interstices between different bodies, and in the pores of the same body.

It is this kind of Vacuum which is chiefly contested among the modern philosophers; the Corpuscularians strenuously asserting it; and the Peripatetics and Cartesians as tenaciously denying it. See CARTESIAN and LEIBNITZIAN.

The great argument urged by the Peripatetics against a Vacuum interspersum, is; that there are divers bodies frequently seen to move contrary to their own nature and inclination; and that for no other apparent reason, but to avoid a Vacuum: whence they conclude, that nature abhors a Vacuum; and give us a new class of motions ascribed to the *fuga vacui* or nature's flying a Vacuum. Such, they say, is the rise of water in a syringe, upon the drawing up of the piston; and such is the ascent of water in pumps, and the swelling of the flesh in a cupping glass, &c.—But since the weight, elasticity, &c, of the air have been ascertained by sure experiments, those motions and effects are universally, and justly, ascribed to the gravity and pressure of the atmosphere.

The Cartesians deny, not only the actual existence, but even the possibility of a Vacuum; and that on this principle, that extension being the essence of matter, or body, wherever extension is, there is matter; but mere space, or vacuity, is supposed to be extended; therefore it is material. Whoever asserts an empty space, say they, conceives dimensions in that space, i. e. he conceives an extended substance in it; and therefore he denies a Vacuum, at the same time that he admits it.—But Descartes, if we may believe some accounts, rejected a Vacuum from a complaisance to the taste which prevailed in his time, against his own first sentiments; and among his familiar friends he used to call his system his philosophical romance.

On the other hand, the corpuscular authors prove, not only the possibility, but the actual existence, of a Vacuum, from divers considerations; particularly from the consideration of motion in general; and that of the planets, comets, &c, in particular; as also from the fall of bodies; from the vibration of pendulums; from rarefaction and condensation; from the different specific gravities of bodies; and from the divisibility of matter into parts.

1. First, there could be no linear or progressive motion without a Vacuum; for if all space were full of matter, no body could be moved out of its place, for want of another place unoccupied, to move into. And this argument was stated even by Lucretius.

2. The motions of the planets and comets also prove a Vacuum. Thus, Newton argues, "that there is no such fluid medium as æther," (to fill up the porous parts of all sensible bodies, and so make a plenum), seems probable; because the planets and comets proceed with so regular and lasting a motion, through the celestial spaces; for hence it appears that those celestial spaces are void of all sensible resistance, and consequently of all sensible matter. Consequently if the celestial regions were as dense as water, or as quicksilver, they would resist almost as much as water or quicksilver; but if they were perfectly dense, without any interspersed vacuity, though the matter were ever so fluid and subtle, they would resist more than quicksilver does: a perfectly solid globe, in such a medium, would lose above half its motion, in moving 3 lengths of its diameter; and a globe not perfectly solid, such as the bodies of the planets and comets are, would be stopped still sooner. Therefore, that the motion of the planets and comets may be regular, and lasting, it is necessary that the celestial spaces be void of all matter; except perhaps some few and much rarefied effluvia of the planets and comets, and the passing rays of light."

3. The same great author also deduces a Vacuum from the consideration of the weights of bodies; thus: "All bodies about the earth gravitate towards it; and the weights of all bodies, equally distant from the earth's centre, are as the quantities of matter in those bodies. If the æther therefore, or any other subtile matter, were altogether destitute of gravity, or did gravitate less than in proportion to the quantity of its matter; because (as Aristotle, Descartes, and others, argue) it differs from other bodies only in the form of matter; the same body might, by the change of its form, gradually be converted into a body of the same constitution with those which gravitate most in proportion to the quantity of matter: and, on the other hand, the heaviest bodies might gradually lose their gravity, by gradually changing their form; and so the weights would depend upon the forms of bodies, and might be changed with them; which is contrary to all experiment."

4. The descent of bodies proves, that all space is not equally full; for the same author goes on, "If all spaces were equally full, the specific gravity of that fluid with which the region of the air would, in that case, be filled, would not be less than the specific gravity of quicksilver or gold, or any other the most dense body; and therefore neither gold, nor any other body, could descend in it. For bodies do not descend in a fluid, unless that fluid be specifically lighter than the body. But by the air-pump we can exhaust a vessel, till even a feather shall fall with a velocity equal to that of gold in the open air; and therefore the medium through which this feather falls, must be much rarer than that through which the gold falls in the other case. The quantity of matter therefore in a given space may be diminished by rarefaction: and why may it not be diminished ad infinitum? Add, that we conceive the solid particles of all bodies to be of the same density; and that they are only rarefiable by means of their pores; and hence a Vacuum evidently follows."

5. "That there is a Vacuum, is evident too from the vibrations of pendulums: for since those bodies, in places out of which the air is exhausted, meet with no resistance to retard their motion, or shorten their vibrations; it is evident that there is no sensible matter in those spaces, or in the occult pores of those bodies."

6. That

6. That there are interfperfed vacuities, appears from matter's being actually divided into parts, and from the figures of thofe parts; for, on fuppofition of an abfolute plenum, we do not conceive how any part of matter could be actually divided from that next adjoining, any more than it is poffible to divide actually the parts of abfolute fpace from one another: for by the actual divifion of the parts of a continuum from one another, we conceive nothing elfe underftood, but the placing of thofe parts at a diftance from one another, which in the continuum were at no diftance from one another: but fuch divifions between the parts of matter muft imply vacuities between them.

7. As for the figures of the parts of bodies, upon the fuppofition of a plenum, they muft either be all rectilinear, or all concavo-convex; otherwife they would not adequately fill fpace; which we do not find to be true in fact.

8. The denying a Vacuum fuppofes what it is impoffible for any one to prove to be true, viz, that the material world has no limits.

However, we are told by fome, that it is impoffible to conceive a Vacuum. But this furely muft proceed from their having imbibed Defcartes's doctrine, that the effence of body is conftituted by extenfion; as it would be contradictory to fuppofe fpace without extenfion. To fuppofe that there are fluids penetrating all bodies and replenifhing fpace, which neither refift nor act upon bodies, merely in order to avoid admitting a Vacuum, is feigning two forts of matter, without any neceffity or foundation; or is tacitly giving up the queftion.

Since then the effence of matter does not confift in extenfion, but in folidity, or impenetrability, the univerfe may be faid to confift of folid bodies moving in a Vacuum: nor need we at all fear, left the phenomena of nature, moft of which are plaufibly accounted for from a plenum, fhould become inexplicable when the plenitude is fet afide. The principal ones, fuch as the tides; the fufpenfion of the mercury in the barometer; the motion of the heavenly bodies, and of light, &c, are more eafily and fatisfactorily accounted for from other principles.

VACUUM *Boileanum*, is ufed to exprefs that approach to a real Vacuum, which we arrive at by means of the air-pump. Thus, any thing put in a receiver fo exhaufted, is faid to be put *in vacuo:* and thus moft of the experiments with the air-pump are faid to be performed *in vacuo*, or *in vacuo Boileano*.

Some of the principal phenomena obferved of bodies in vacuo, are; that the heavieft and lighteft bodies, as a guinea and a feather, fall here with equal velocity: —that fruits, as grapes, cherries, peaches, apples, &c, kept for any time in vacuo, retain their nature, frefhnefs, colour, &c, and thofe withered in the open air recover their plumpnefs in vacuo:—all light and fire become immediately extinct in vacuo:—little or no found is heard from a bell rung in vacuo:—a bladder half full of air, will diftend the bladder, and lift up 40 pound weight in vacuo:—moft animals foon expire in vacuo.

By experiments made in 1704, Dr. Derham found that animals which have two ventricals, and no foramen ovale, as birds, dogs, cats, mice, &c, die in lefs than half a minute; counting from the firft exfuction: a mole died in one minute; a bat lived 7 or 8. Infects, as wafps, bees, grafshoppers, &c, feemed dead in two minutes; but after being left in vacuo 24 hours, they came to life again in the open air: fnails continued 24 hours in vacuo, without appearing much incommoded. —Seeds planted in vacuo do not grow: Small beer dies, and lofes all its tafte, in vacuo: And air rufhing through mercury into a Vacuum, throws the mercury in a kind of fhower upon the receiver, and produces a great light in a dark room.

The air-pump can never produce a perfect Vacuum; as is evident from its ftructure, and the manner of its working: in effect, every exfuction only takes away a part of the air; fo that there is ftill fome left after any finite number of exfuctions. For the air-pump has no longer any effect but while the fpring of the air remaining in the receiver is able to lift up the valves; and when the rarefaction is come to that degree, you can come no nearer to a Vacuum; unlefs perhaps the air valves can be opened mechanically, independent of the fpring of the air, as it is faid they are in fome new improved air-pumps.

Torricellian VACUUM, is that made in the barometer tube, between the upper end and the top of the mercury. This is perhaps never a perfect and entire Vacuum; as all fluids are found to yield or to rife in elaftic vapours, on the removal of the preffure of the atmofphere. See TORRICELLIAN, and BAROMETER.

VALVE, in Hydraulics, Pneumatics, &c, is a kind of lid or cover to a tube or veffel, contrived to open one way; but which, the more forcibly it is preffed the other way, the clofer it fhuts the aperture: fo that it either admits the entrance of a fluid into the tube, or veffel, and prevents its return; or permits it to efcape, and prevents its re-entrance.

Valves are of great ufe in the air-pump, and other wind machines; in which they are ufually made of pieces of bladder. In hydraulic engines, as the emboli of pumps, they are moftly of ftrong leather, of a round figure, and fitted to fhut the apertures of the barrels or pipes. Sometimes they are made of two round pieces of leather enclofed between two others of brafs; having divers perforations, which are covered with another piece of brafs, moveable upwards and downwards, on a kind of axis, which goes through the middle of them all. Sometimes they are made of brafs, covered over with leather, and furnifhed with a fine fpring, which gives way upon a force applied againft it; but upon the ceafing of that, returns the Valve over the aperture. See PUMP. See alfo Defaguliers' Exper. Philof. vol. 2, p. 156, and p. 180.

VANE, in a fhip, &c, a thin flip of fome kind of matter, placed on high in the open air, turning eafily round on an axis or fpindle, and veered about by the wind, to fhew its direction or courfe.

VANES, in Mathematical or Philofophical Inftruments, are fights made to flide and move upon crofsftaves, fore-ftaves, quadrants, &c.

VAPOUR, in Meteorology, a watery exhalation raifed up either by the heat of the fun, or any other heat, as fire, &c. Vapour is confidered as a thin veficle of water, or other humid matter, filled or inflated with air; which, being rarefied to a certain degree by the action of heat, afcends to fome height in the atmo-

atmosphere, where it is suspended, till it returns in form of rain, snow, or the like. An assemblage of a number of particles or vesicles of vapour, constitutes what is called a cloud.

Some use the term Vapour indifferently, for all fumes emitted, either from moist bodies, as fluids of any kind; or from dry bodies, as sulphur, &c. But Newton, and other authors, better distinguish between humid and dry fumes, calling the latter *exhalations*.

For the manner in which Vapours are raised, and again precipitated, see CLOUD, DEW, RAIN, BAROMETER, and particularly EVAPORATION.

It may here be added, with respect to the principles of solution adopted to account for evaporation, and largely illustrated under that article, that Dr. Halley, about the beginning of the present century, seems to have been acquainted with the solvent power of air on water; for he says, that supposing the earth to be covered with water, and the sun to move diurnally round it, the air would of itself imbibe a certain quantity of aqueous Vapours, and retain them like salts dissolved in water; and that the air warmed by the sun would sustain a greater proportion of Vapours, as warm water will hold more dissolved salts; which would be discharged in dews, similar to the precipitation of salts on the cooling of liquors. Philos. Trans. Abr. vol. 2, p. 127.

Mr. Eeles, in 1755, endeavoured to account for the ascent of Vapour and exhalation, and their suspension in the atmosphere, by means of the electric fire. The sun, he acknowledges, is the great agent in detaching Vapour and exhalations from their masses, whether he acts immediately by himself, or by his rendering the electric fire more active in its vibrations: but their subsequent ascent he attributes entirely to their being rendered specifically lighter than the lower air, by their conjunction with electrical fire: each particle of Vapour, with the electrical fluid that surrounds it, occupying a greater space than the same weight of air. Mr. Eeles also endeavours to shew, that the ascent and descent of Vapour, attended by this fire, are the cause of all the winds, and that they furnish a satisfactory solution of the general phenomena of the weather and barometer. Philos. Trans. vol. 49, pa. 124.

Dr. Darwin, in 1757, published remarks on the theory of Mr. Eeles, with a view of confuting it; and attempting to account for the ascent of Vapours, by considering the power of expansion which the constituent parts of some bodies acquire by heat, and also that some bodies have a greater affinity to heat, or acquire it sooner, and retain it longer, than others. On these principles, he thinks, it is easily understood how water, whose parts appear from the æolipile to be capable of immeasurable expansion, should by heat alone become specifically lighter than the common atmosphere. A small degree of heat is sufficient to detach or raise the Vapour of water from the mass to which it belongs; and the rays of the sun communicate heat only to those bodies by which they are refracted, reflected, or obstructed, whence, by their impulse, a motion or vibration is caused in the parts of such bodies. Hence he infers, that the sphericles of Vapour will, by refracting the solar rays, acquire a constant heat, though the surrounding atmosphere remain cold. If it be asked, how clouds are supported in the absence of the sun? It must be remembered, that large masses of Vapour must for a considerable time retain much of the heat they have acquired in the day; at the same time reflecting how small a quantity of heat was necessary to raise them, and that doubtless even a less will be sufficient to support them; as from the diminished pressure of the atmosphere at a given height, a less power may be able to continue them in their present state of rarefaction; and lastly, that clouds of particular shapes will be sustained or elevated by the motion they acquire from winds. Philos. Trans. vol. 50, p. 246.

For the Effect of Vapour in the Formation of Springs, &c, see SPRING, and RIVER.

The quantity of Vapour raised from the sea by the warmth of the sun, must be far greater than is commonly imagined. Dr. Halley has attempted to estimate it. For the result of his calculations, see EVAPORATION.

VARIABLE, in Geometry and Analytics, is a term applied by mathematicians, to such quantities as are considered in a Variable or changeable state, either increasing or decreasing. Thus, the abscisses and ordinates of an ellipsis, or other curve line, are Variable quantities; because these vary or change their magnitude together, the one at the same time with the other. But some quantities may be Variable by themselves alone, or while those connected with them are constant: as the abscisses of a parallelogram, whose ordinates may be considered as all equal, and therefore constant. Also the diameter of a circle, and the parameter of a conic section, are *constant*, while their abscisses are *Variable*.

Variable quantities are usually denoted by the last letters of the alphabet, z, y, x, &c; while the constant ones are denoted by the leading letters, a, b, c, &c.

Some authors, instead of *Variable* and *constant* quantities, use the terms *fluent* and *stable* quantities.

The indefinitely small quantity by which a Variable quantity is continually increased or decreased, in very small portions of time, is called the *differential*, or *increment* or *decrement*. And the rate of its increase or decrease at any point, is called its *fluxion*; while the Variable quantity itself is called the *fluent*. And the calculation of these, is the subject of the new *Methodus Differentialis*, or *Doctrine of Fluxions*.

VARENIUS (BERNARD), a learned Dutch geographer and physician, of the last century, who was author of the best mathematical treatise on Geography, intitled, *Geographia Universalis*, in qua affectiones generalis Telluris explicantur. This excellent work has been translated into all languages, and was honoured by an edition, with improvements, by Sir Isaac Newton, for the use of his academical students at Cambridge.

VARIATION, *of Quantities*, in Algebra. See CHANGES, and COMBINATION.

VARIATION, in Astronomy.—*The Variation of the Moon*, called by Bulliald, the *Reflection of her Light*, is the third inequality observed in the moon's motion; by which, when out of the quadratures, her true place differs from her place twice equated. See PLACE, EQUATION, &c.

Newton makes the moon's variation to arise partly from the form of her orbit, which is an ellipsis; and partly

partly from the inequality of the ſpaces, which the moon deſcribes in equal times, by a radius drawn to the earth.

To find the Greateſt Variation. Obſerve the moon's longitude in the octants; and to the time of obſervation compute the moon's place twice equated; then the difference between the computed and obſerved place, is the greateſt Variation.

Tycho makes the greateſt Variation 40′ 30″; and Kepler makes it 51′ 49″.—But Newton makes the greateſt Variation, at a mean diſtance between the ſun and the earth, to be 35′ 10″: at the other diſtances, the greateſt Variation is in a ratio compounded of the duplicate ratio of the times of the moon's ſynodical revolution directly, and the triplicate ratio of the diſtance of the ſun from the earth inverſely. And therefore in the ſun's apogee, the greateſt Variation is 33′ 14″, and in his perigee 37′ 11″; provided that the eccentricity of the ſun be to the tranſverſe ſemidiameter of the orbis magnus, as $16\frac{15}{16}$ to 1000. Or, taking the mean motions of the moon from the ſun, as they are ſtated in Dr. Halley's tables, then the greateſt Variation at the mean diſtance of the earth from the ſun will be 35′ 7″, in the apogee of the ſun 33′ 27″, and in his perigee 36′ 51″. Philoſ. Nat. Princ. pr. 29, lib. 3.

VARIATION, in Geography, Navigation, &c, a term applied to the deviation of the magnetic needle, or compaſs, from the true north point, either towards the eaſt or weſt; called alſo the *declination*. Or the Variation of the compaſs is properly defined, the angle which a magnetic needle, ſuſpended at liberty, makes with the meridian line on an horizontal plane; or an arch of the horizon, comprehended between the true and the magnetic meridians.

In the ſea-language, the Variation is uſually called *north-eaſting*, or *north-weſting*.

All magnetic bodies are found to range themſelves, in ſome ſort, according to the meridian; but they ſeldom agree preciſely with it: in one place they decline, from the north toward the eaſt, in another toward the weſt; and that too differently at different times.

The Variation of the compaſs could not long remain a ſecret, after the invention of the compaſs itſelf: accordingly Ferdinand, the ſon of Columbus, in his life written in Spaniſh, and printed in Italian at Venice in 1571, aſſerts, that his father obſerved it on the 14th of September 1492: though others ſeem to attribute the diſcovery of it to Sebaſtian Cabat, a Venetian, employed in the ſervice of our king Henry VII, about the year 1500.—It now appears however, that this Variation or declination of the needle was known even ſome centuries earlier, though it does not appear that the uſe of the needle itſelf in navigation was then known. For it ſeems there is in the library of the univerſity of Leyden, a ſmall manuſcript tract on the Magnet, in Latin, written by one Peter Adſiger, bearing date the 8th of Auguſt 1269; in which the declination of the needle is particularly mentioned. Mr. Cavallo has printed the chief part of this letter in the Supplement to his Treatiſe on Magnetiſm, with a tranſlation; and I think it is to be wiſhed he had printed the whole of ſo curious a paper. The curioſity of this letter, ſays Mr. Cavallo, conſiſts in its containing almoſt all that is at preſent known of the ſubject, at leaſt the moſt remarkable parts of it, mixed however with a good deal of abſurdity. The laws of magnetic attraction, and of the communication of that power to iron, the directive property of the natural magnet, as well as of the iron that has been touched by it, and even the declination of the magnetic needle, are clearly and unequivocally mentioned in it.

As this Variation differs in different places, Gonzales d'Oviedo found there was none at the Azores; from whence ſome geographers thought fit in their maps to make the firſt meridian paſs through one of theſe iſlands: it not being then known that the Variation altered in time. See MAGNET; alſo Gilbert De Magnete, Lond. 1600, p. 4 and 5; or Purchas's Pilgrims, Lond. 1625, book 2, ſect. 1.

Various are the hypotheſes that have been framed to account for this extraordinary phenomenon: we ſhall only notice ſome of the latter, and more probable: juſt premiſing, that Robert Norman, the inventor of the Dipping needle, diſputes againſt Cortes's notion, that the Variation was cauſed by a point in the heavens; contending that it ſhould be ſought for in the earth, and propoſes how to diſcover its place.

The firſt is that of Gilbert (De Magnete, lib. 4, p. 151 &c), which is followed by Cabeus, &c. This notion is, that it is the earth, or land, that draws the needle out of its meridian direction: and hence they argue, that the needle varied more or leſs, as it was more or leſs diſtant from any great continent; and conſequently that if it were placed in the middle of an ocean, equally diſtant from equal tracts of land on each ſide, eaſtward and weſtward, it would not decline either to the one or the other, but point exactly north and ſouth. Thus, ſay they, in the Azores iſlands, which are equally diſtant from Africa on the eaſt, and America on the weſt, there is no Variation: but as you ſail from thence towards Africa, the needle begins to decline toward the eaſt, and that ſtill more and more till you reach the ſhore. If you proceed ſtill farther eaſtward, the declination gradually diminiſhes again, by reaſon of the land left behind on the weſt, which continues to draw the needle. The ſame holds till you arrive at a place where the tracts of land on each ſide are equal; and there again the Variation will be nothing. But the misfortune is, the law does not hold univerſally; for multitudes of obſervations of the Variation, in different parts, made and collected by Dr. Halley, overturn the whole theory.

Others therefore have recourſe to the frame and compages of the earth, conſidered as interſperſed with rocks and ſhelves, which being generally found to run towards the polar regions, the needle comes to have a general tendency that way; but it ſeldom happens that their direction is exactly in the meridian, and the needle has conſequently, for the moſt part, ſome Variation.

Others hold that divers parts of the earth have different degrees of the magnetic virtue, as ſome are more intermixed with heterogeneous matters, which prevent the free action or effect of it, than others are.

Others again aſcribe all to magnetic rocks and iron mines, which, affording more of the magnetic matter than other parts, draw the needle more.

 Laſtly,

Laftly, others imagine that earthquakes, or high tides, have difturbed and diflocated feveral confiderable parts of the earth, and fo changed the magnetic axis of the globe, which was originally the fame with the axis of the earth itfelf.

But none of thefe theories can be the true one; for ftill that great phenomenon, the *Variation of the Variation*, i. e. the continual change of the declination, in one and the fame place, is not accountable for, on any of thefe foundations, nor is it even confiftent with them.

Doctor Hook communicated to the Royal Society, in 1674, a theory of the Variation; the fubftance of which is, that the magnet has its peculiar pole, diftant 10 degrees from the pole of the earth, about which it moves, fo as to make a revolution in 370 years: whence the Variation, he fays, has altered of late about 10 or 11 minutes every year, and will probably fo continue to do for fome time, when it will begin to proceed flower and flower, till at length it become ftationary and retrograde, and fo return back again. Birch's Hift. of the Royal Society, vol. 3, p. 131.

Dr. Halley has given a new fyftem, the refult of numerous obfervations, and even of a number of voyages made at the public expence on this account. The light which this author has thrown upon this obfcure part of natural hiftory, is very great, and of important confequence in navigation, &c. In this fyftem he has reduced the feveral Variations in divers places to a precife rule, or order, which before appeared all precarious and arbitrary.

His theory will therefore deferve a more ample detail. The obfervations it is built upon, as laid down in the Philof. Tranf. number 148, or Abr. vol. 2, p. 610, are as follow:

Obferved Variations of the Needle in divers places, and at divers times.

Upon

Upon these observed Variations Dr. Halley makes several remarks, as to the Variation in different parts of the world at the time of his writing, eastward and westward; and the situation and direction of the lines or places of no Variation: from the whole he deduces the following theory.

Dr. *Halley's Theory of the Variation of the Needle.* That the whole globe of the earth is one great magnet, having four magnetical poles, or points of attraction; near each pole of the equator two; and that in those parts of the world which lie nearly adjacent to any one of these magnetic poles, the needle is governed by it; the nearest pole being always predominant over the more remote.

The pole which at present is nearest to us, he conjectures to lie in or near the meridian of the Land's-end of England, and not above 7° from the north pole: by this pole, the Variations in all Europe and Tartary, and the North Sea, are chiefly governed; though still with some regard to the other northern pole, whose situation is in the meridian passing about the middle of California, and about 15° from the north pole of the world, to which the needle has chiefly respect in all North America, and in the two oceans on either side of it, from the Azores westward to Japan, and farther.

The two southern magnetic poles, he imagines, are rather more distant from the south pole of the world; the one being about 16° from it, on a meridian 20° to the westward of the Magellanic Streights, or 95° west from London: this pole commands the needle in all South America, in the Pacific Ocean, and the greatest part of the Ethiopic Ocean. The other magnetic pole seems to have the greatest power, and the largest dominion of all, as it is the most remote from the pole of the world, being little less than 20° distant from it, in the meridian which passes through New Holland, and the island Celebes, about 120° east from London: this pole is predominant in the south part of Africa, in Arabia, and the Red Sea, in Persia, India, and its islands, and all over the Indian sea, from the Cape of Good Hope eastward, to the middle of the Great South Sea that divides Asia from America.

Such, he observes, seems to be the present disposition of the magnetic virtue thoughout the whole globe of the earth. It is then shewn how this hypothesis accounts for all the Variations that have been observed of late, and how it answers to the several remarks drawn from the table.

It is there inferred that from the whole it appears, that the direction of the needle, in the temperate and frigid zones, depends chiefly upon the counterpoise of the forces of two magnetic poles of the same nature: as also why, under the same meridian, the Variation should be in one place $29\frac{1}{2}$ degrees west, and in another $20\frac{1}{2}$ degrees east.

In the torrid zone, and particularly about the equator, respect must be had to all the four poles, and their positions must be well considered, otherwise it will not be easy to determine what the Variation should be, the nearest pole being always strongest; yet so however as to be sometimes counterbalanced by the united forces of two more remote ones. Thus, in sailing from St. Helena, by the isle of Ascension, to the equator, on the north-west course, the Variation is very little easterly, and unalterable in that whole track; because the South-American pole (which is much the nearest in the aforesaid places), requiring a great easterly variation, is counterpoised by the contrary attraction of the North-American and the Asiatic south poles; each of which singly is, in these parts, weaker than the American south pole; and upon the north-west course the distance from this latter is very little varied; and as you recede from the Asiatic south pole, the balance is still preserved by an access towards the North-American pole. In this case no notice is taken of the European north pole; its meridian being a little removed from those of these places, and of itself requiring the same Variations which are here found.

After the same manner may the Variations in other places about the equator be accounted for, upon Dr. Halley's hypothesis.

To observe the Variation of the Needle. Draw a meridian line, as directed under MERIDIAN; then a stile being erected in the middle of it, place a needle upon it, and draw the right line which it hangs over. Thus will the quantity of the Variation appear.

Or thus: As the former method of finding the Variation cannot be applied at sea, others have been devised, the principal of which are as follow. Suspend a thread and plummet over the compass, till the shadow pass through the centre of the card; observe the rhumb, or point of the compass which the shadow touches when it is the shortest. For the shadow is then a meridian line; and consequently the Variation is shewn.

Or thus: Observe the point of the compass upon which the sun, or some star, rises and sets; bisect the arch intercepted between the rising and setting, and the line of bisection will be the meridian line; consequently the Variation is had as before. The same may also be obtained from two equal altitudes of the same star, observed either by day or night. Or thus: Observe the rhumb upon which the sun or star rises and sets; and from the latitude of the place find the eastern or western amplitude: to the difference between the amplitude, and the distance of the rhumb observed, from the eastern rhumb of the card, is the Variation sought.

Or thus: Observe the altitude of the sun, or some star S, whose declination is known; and note the rhumb in the compass to which it then corresponds. Then in the triangle ZPS, are known three sides, viz, PZ the colatitude, PS the codeclination, and ZS the coaltitude; the angle PZS is thence found by spherical trigonometry; the supplement to which, viz AZS, is the azimuth from the south. Then the difference between the azimuth and the observed distance of the rhumb from the south, is the Variation sought. See *Azimuth* COMPASS.

The use of the Variation is to correct the courses a ship has steered by the compass, which must always be done before they are worked, or calculated.

VARIATION

VARIATION *of the Variation*, is a gradual and continual change in the Variation, observed in any place, by which the quantity of the Variation is found to be different at different times.

This Variation, according to Henry Bond (in his *Longitude found*, Lond. 1670, pa. 6) "was first found to decrease by Mr. John Mair; 2dly, by Mr. Edmund Gunter: 3dly, by Mr. Henry Gellibrand; 4thly, by myself (Henry Bond) in 1640; and lastly, by Dr. Robert Hook, and others, in 1665;" which they found out by comparing together observations made at the same place, at different times. The discovery was soon known abroad; for Kircher, in his treatise intitled Magnes, first printed at Rome in 1641, says that our countryman Mr. John Greaves had informed him of it, and then he gives a letter of Mersenne's, containing a distinct account of it.

This continual change in the Variation, is gradual and universal, as appears by numerous observations. Thus, the Variation was,

At Paris, according to Orontius Finæus,

in 1550	-	8°	0′E.
in 1640	-	3	0 E.
in 1660	-	0	0
in 1681	-	2	2W.
in 1759	-	18	10W.
in 1760	-	18	20W.

M. De la Lande (Exposition du Calcul Astronomique) observes, that the Variation has changed, at Paris, 26° 20′ in the space of 150 years, allowing that in 1610 the Variation was 8° E: and since 1740 the needle, which was always used by Maraldi, is more than 3° advanced toward the west, beyond what it was at that period; which is a change after the rate nearly of 9′½ per year.

At Cape d'Agulhas, in 1600, it had no Variation; (whence the Portuguese gave it that name);

in 1622	it was	2°	W.
in 1675	-	8	W.
in 1692	-	11	W.

which is a change of nearly 8′ per year.

At St. Helena, the Variation,	in 1600 was	8°	0′E.
	in 1623	- 6	0 E.
	in 1677	- 0	40 E.
	in 1692	. 1	0 W.

which is a change of nearly 5′½ per year.

At Cape Comorin, the Variation,

in 1620 was	14°	20′W.
in 1680 -	8	44 W.
in 1688 -	7	30 W.

which is a change of nearly 6′¼ per year.

At London, the Variation,	in 1580 was	11°	15′E.
	in 1622 -	6	0 E.
	in 1634 -	4	5 E.
	in 1657 -	0	0
	in 1672 -	2	30 W.
	in 1692 -	6	0 W.
	in 1723 -	14	17 W.
	in 1747 -	17	40 W.
	in 1780 -	22	41 W.

which is a change after the rate of 10′ per year, upon a course of exactly 200 years. See Philos. Trans. No. 148 and No. 383, or Abr. vol. 2, p. 615, and vol. 7, p. 290; and Philos. Trans. vol. 45, p. 280, and vol. 66, p. 393. On the subject of the Variation, see also Norman's New Attractive 1614; Burrows's Discovery of the Variation 1581; Bond's Longitude found, 1676; &c.

Mr. Thomas Harding, in the Transactions of the Royal Irish Academy, vol. 4, has given observations on the Variation of the magnetic needle, at Dublin, which are rather extraordinary: He says the change in the Variation at that place is *uniform*. That from the year 1657, in which the Variation was nothing (the same as at London in that year), it has been going on at the medium rate of 12′ 20″ annually, and was in May 1791, 27° 23′ west: exceeding that at London now by 3 or 4 degrees. He brings proof of his assertion of the uniformity of the Variation, from different authentic records, and states the operations by which it is calculated. He concludes with recommending accuracy in marking the existing Variation when maps are made, as not only conducing to the exact definition of boundaries, but as laying the best foundation for a discovery of the longitude by sea or land.

Theory of the Variation of the Variation. According to Dr. Halley's theory, this change in the Variation of the compass, is supposed owing to the difference of velocity in the motions of the internal and external parts of the globe. From the observations that have been cited, it seems to follow, that all the magnetical poles have a motion westward, but yet not exactly round the axis of the earth, for then the Variations would continue the same in the same parallel of latitude, contrary to experience.

From the disagreement of such a supposition with experiments therefore, the learned author of the theory invented the following hypothesis: The external parts of the globe he considers as the shell, and the internal as a nucleus, or inner globe; and between the two he conceives a fluid medium. That inner earth having the same common centre and axis of diurnal rotation, may revolve with our earth every 24 hours: Only the outer sphere having its turbinating motion somewhat swifter or slower than the internal ball; and a very minute difference in length of time, by many repetitions, becoming sensible; the internal parts will gradually recede from the external, and they will appear to move, either eastward or westward, by the difference of their motions.

Now, supposing such an internal sphere, having such a motion, the two great difficulties in the former hypothesis are easily solved; for if this exterior shell of earth be a magnet, having its pole at a distance from the poles of diurnal rotation; and if the internal nucleus be likewise a magnet, having its poles in two other places, distant also from the axis; and these latter, by a slow gradual motion, change their place in respect of the external, a reasonable account may then be given of the four magnetical poles before mentioned, and also of the changes of the needle's Variation.

The author thinks that two of these poles are fixed, and the other two moveable; viz, that the fixed poles are the poles of the external cortex or shell of the earth;

earth; and the other the poles of the magnetical nucleus, included and moveable within the former. From the observations he infers, that the motion is westwards, and consequently, that the nucleus has not precisely attained the same velocity with the exterior parts in their diurnal rotation; but so very nearly equals it, that in 365 revolutions the difference is scarcely sensible.

That there is any difference of this kind, arises from hence, that the impulse by which the diurnal motion was impressed on the earth, was given to the external parts, and from thence in time communicated to the internal; but so as not yet perfectly to equal the velocity of the first motion impressed on the superficial parts of the globe, and still preserved by them.

As to the precise period, observations are wanting to determine it, though the author thinks we may reasonably conjecture that the American pole has moved westward 46° in 90 years, and that its whole period is performed in about 700 years.

Mr. Whiston, in his New Laws of Magnetism, raises several objections against this theory. See MAGNETISM.

M. Euler, too, the son of the celebrated mathematician of that name, has controverted and censured Dr. Halley's theory. He thinks, that two magnetic poles, placed on the surface of the earth, will sufficiently account for the Variation: and he then endeavours to shew, how we may determine the declination of the needle, at any time, and on every part of the globe, from this hypothesis. For the particulars of this reasoning, see the Histoire de l'Academie des Sciences & Belles Lettres of Berlin, for 1757; also Mr. Cavallo's Treatise on Magnetism, p. 117.

Variation of the Needle by Heat and Cold.—There is a small Variation of the Variation of the magnetic needle, amounting only to a few minutes of a degree in the same place, at different hours of the same day, which is only discoverable by nice observations. Mr. George Graham made several observations of this kind in the years 1722 and 1723, professing himself altogether ignorant of the cause of the phenomena he observed. Philos. Trans. No. 383, or Abr. vol. 7, p. 290.

About the year 1750, Mr. Wargentin, secretary of the Swedish Academy of Sciences, took notice both of the regular diurnal Variation of the needle, and also of its being disturbed at the time of the aurora borealis, as recorded in the Philos. Trans. vol. 47, p. 126.

About the year 1756, Mr. Canton commenced a series of observations, amounting to near 4000, with an excellent Variation-compass, of about 9 inches diameter. The number of days on which these observations were made, was 603, and the Diurnal Variation on 574 of them was regular, so as that the absolute Variation of the needle westward was increasing from about 8 or 9 o'clock in the morning, till about 1 or 2 in the afternoon, when the needle became stationary for some time; after that, the absolute Variation westward was decreasing, and the needle came back again to its former situation, or nearly so, in the night, or by the next morning. The Diurnal Variation is irregular when the needle moves slowly eastward in the latter part of the morning, or westward in the latter part of the afternoon; also when it moves much either way after night, or suddenly both ways in a short time. These irregularities seldom happen more than once or twice in a month, and are always accompanied, as far as Mr. Canton observed, with an aurora borealis.

Mr. Canton lays down and evinces, by experiment, the following principle, viz, that the attractive power of the magnet (whether natural or artificial) will decrease while the magnet is heating, and increase while it is cooling. He then proceeds to account for both the regular and irregular Variation. It is evident, he says, that the magnetic parts of the earth in the north, on the east side, and on the west side of the magnetic meridian, equally attract the north end of the needle. If then the eastern magnetic parts be heated faster by the sun in the morning, than the western parts, the needle will move westward, and the absolute Variation will increase: when the attracting parts of the earth on each side of the magnetic meridian have their heat increasing equally, the needle will be stationary, and the absolute Variation will then be greatest; but when the western magnetic parts are either heating faster, or cooling slower, than the eastern, the needle will move eastward, or the absolute Variation will decrease; and when the eastern and western magnetic parts are cooling equally fast, the needle will again be stationary, and the absolute Variation will then be least.

By this theory, the Diurnal Variation in the summer ought to exceed that in winter; and accordingly it is found by observation, that the Diurnal Variation in the months of June and July is almost double of that in December and January.

The irregular Diurnal Variation must arise from some other cause than that of heat communicated by the sun; and here Mr. Canton has recourse to subterranean heat, which is generated without any regularity as to time, and which will, when it happens in the north, affect the attractive power of the magnetic parts of the earth on the north end of the needle. That the air nearest the earth will be most warmed by the heat of it, is obvious; and this has been often noticed in the morning, before day, by means of thermometers at different distances from the ground. Philos. Trans. vol. 48, pa. 526.

Mr. Canton has annexed to his paper on this subject, a complete year's observations; from which it appears, that the Diurnal Variation increases from January to June, and decreases from June to December. Philos. Trans. vol. 51, pa. 398.

It has also been observed, that different needles, especially if touched with different loadstones, will differ a few minutes in their Variation. See Poleni Epist. Phil. Trans. num. 421.

Dr. Lorimer (in the Supp. to Cavallo's Magnetism) adduces some ingenious observations on this subject. It must be allowed, says he, according to the observations of several ingenious gentlemen, that the collective magnetism of this earth arises from the magnetism of all the ferruginous bodies contained in it, and that the magnetic poles should therefore be considered as the centres of the powers of those magnetic substances. These poles must therefore change their places according as the magnetism of such substances is affected, and if with-

with Mr. Canton we allow, that the general cauſe of the Diurnal Variation ariſes from the ſun's heat in the forenoon and afternoon of the ſame day, it will naturally occur, that the ſame cauſe, being continued, may be ſufficient to produce the general Variation of the magnetic needle for any number of years. For we muſt conſider, that ever ſince any attentive obſervations have been made on this ſubject, the natural direction of the magnetic needle in Europe has been conſtantly moving, from weſt to eaſt, and that in other parts of the world it has continued its motion with equal conſtancy.

As we muſt therefore admit, ſays Dr. Lorimer, that the heat in the different ſeaſons depends chiefly on the ſun, and that the months of July and Auguſt are commonly the hotteſt, while January and February are the coldeſt months of the year; and that the temperature of the other months falls into the reſpective intermediate degrees; ſo we muſt conſider the influence of heat upon magnetiſm to operate in the like manner, viz. that for a ſhort time it ſcarcely manifeſts itſelf; yet in the courſe of a century, the conſtancy and regularity of it becomes ſufficiently apparent. It would therefore be idle to ſuppoſe, that ſuch an influence could be derived from an uncertain or fortuitous cauſe. But if it be allowed to depend upon the conſtancy of the ſun's motion, and this appears to be a cauſe ſufficient to explain the phenomena, we ſhould (agreeably to Newton's firſt law of philoſophizing) look no farther.

As we therefore conſider, ſays he, the magnetic powers of the earth to be concentrated in the magnetic poles, and that there is a diurnal Variation of the magnetic needle, theſe poles muſt perform a ſmall diurnal revolution proportional to ſuch Variation, and return again to the ſame point nearly. Suppoſe then that the ſun in his diurnal revolution paſſes along the northern tropic, or along any parallel of latitude between it and the equator, when he comes to that meridian in which the magnetic pole is ſituated, he will be much nearer to it, than in any other; and in the oppoſite meridian he will of courſe be the fartheſt from it. As the influence of the ſun's heat will therefore act moſt powerfully at the leaſt, and leſs forcibly at the greateſt diſtance, the magnetic pole will conſequently deſcribe a figure ſomething of the elliptical kind; and as it is well known that the greateſt heat of the day is ſome time after the ſun has paſſed the meridian, the longeſt axis of this elliptical figure will lie north-eaſterly in the northern, and ſouth-eaſterly in the ſouthern hemiſphere. Again, as the influence of the ſun's heat will not from thoſe quarters have ſo much power, the magnetic poles cannot be moved back to the very ſame point, from which they ſet out; but to one which will be a little more northerly and eaſterly, or more ſoutherly and eaſterly, according to the hemiſpheres in which they are ſituated. The figures therefore which they deſcribe, may more properly be termed elliptoidal ſpirals.

In this manner the Variation of the magnetic needle in the northern hemiſphere may be accounted for. But with reſpect to the ſouthern hemiſphere we muſt recollect, that though the lines of declination in the northern hemiſphere have conſtantly moved from weſt to eaſt, yet in the ſouthern hemiſphere, it is equally certain that they have moved from eaſt to weſt, ever ſince any obſervations have been made on the ſubject. Hence then the lines of magnetic declination, or Halleyan curves, as they are now commonly called, appear to have a contrary motion in the ſouthern hemiſphere, to what they have in the northern; though both the magnetic poles of the earth move in the ſame direction, that is from weſt to eaſt.

In the northern hemiſphere there was a line of no Variation, which had eaſt Variation on its eaſtern ſide, and weſt Variation on its weſtern ſide. This line evidently moved from weſt to eaſt during the two laſt centuries; the lines of eaſt Variation moving before it, while the lines of weſt Variation followed it with a proportional pace. Theſe lines firſt paſſed the Azores or Weſtern Iſlands, then the meridian of London, and after a certain number of years ſtill later, they paſſed the meridian of Paris. But in the ſouthern hemiſphere there was another line of no Variation, which had eaſt Variation on its weſtern ſide, and weſt Variation on its eaſtern; the lines of eaſt Variation moving before it, while thoſe of the weſt Variation followed it. This line of no Variation firſt paſſed the Cape des Aiguilles, and then the Cape of Good Hope; the lines of 5°, 10°, 15°, and 20° weſt Variation following it, the ſame as was the caſe in the northern hemiſphere, but in the contrary direction.

We may juſt farther mention the idea of Dr. Gowin Knight, which was, that this earth had originally received its magnetiſm, or rather that its magnetical powers had been brought into action, by a ſhock, which entered near the ſouthern tropic, and paſſed out at the northern one. His meaning appears to have been, that this was the courſe of the magnetic fluid, and that the magnetic poles were at firſt diametrically oppoſite to each other. Though, according to Mr. Canton's doctrine, they would not have long continued ſo; for from the intenſe heat of the ſun in the torrid zone, according to the principles already explained, the north pole muſt have ſoon retired to the north-eaſtward, and the ſouth pole to the ſouth-eaſtward. It is alſo curious to obſerve, that on account of the ſouthern hemiſphere being colder upon the whole than the northern hemiſphere, the magnetic poles would have moved with unequal pace: that is, the north magnetic pole would have moved farther in any given time to the north-eaſt, than the ſouth magnetic pole could have moved to the ſouth-eaſt. And, according to the opinions of the moſt ingenious authors on this ſubject, it is generally allowed, that at this time the north magnetic pole is conſiderably nearer to the north pole of the earth, than the ſouth magnetic pole is to the ſouth pole of the earth.

It may farther be added, that ſeveral ingenious ſea officers are of opinion, that in the weſtern parts of the Engliſh Channel the Variation of the magnetic needle has already begun to decreaſe; having in no part of it ever amounted to 25°. There are however other perſons who aſſert that the Variation is ſtill increaſing in the Channel, and as far weſtward as the 15th degree of longitude and 51° of latitude, at which place they ſay that it amounts to about 30°.

Of the Variation Chart. Doctor Halley having collected a multitude of obſervations made on the Variation of the needle in many parts of the world, was hence enabled to draw, on a Mercator's chart, certain lines, ſhewing the Variation of the compaſs in all theſe places

places over which they passed, in the year 1700, when he published the first chart of this kind, called the *Variation Chart*.

From the construction of this chart it appears, that the longitude of any of those places may be found by it, when the latitude and the Variation in that place are known. Thus, having found the Variation of the compass, draw a parallel of latitude on the chart through the latitude found by observation; and the point where it cuts the curved line, whose Variation is the same with that observed, will be the ship's place. A similar project of thus finding the longitude, from the known latitude and inclination or dip of the needle, was before proposed by Henry Bond, in his treatise intitled, The Longitude Found, printed in 1676.

This method however is attended with two considerable inconveniences: 1st, That wherever the Variation lines run east and west, or nearly so, this way of finding the longitude becomes imperfect, as their intersection with the parallel of latitude must be very indefinite: and among all the trading parts of the world, this imperfection is at present found chiefly on the western coasts of Europe, between the latitudes of 45° and 53°; and on the eastern shores of North America, with some parts of the Western Ocean and Hudson's Bay, lying between the said shores: but for the other parts of the world, a Variation Chart may be attended with considerable benefit. However, the Variation curves, when they run east and west, may sometimes be applied to good purpose in correcting the latitude, when meridian observations cannot be had, as it often happens on the northern coasts of America, in the Western Ocean, and about Newfoundland; for if the Variation can be obtained exactly, then the east and west curve, answering to the Variation in the chart, will shew the latitude.

2dly, As the deviation of the magnetical meridian, from the true one, is subject to continual alteration, therefore a chart to which the Variation lines are fitted for any year, must in time become useless, unless new lines, shewing the state of the Variation at that time, be drawn on the chart: but as the change in the Variation is very slow, therefore new Variation Charts published every 7 or 8 years, will answer the purpose tolerably well. And thus it has happened that Halley's Variation Chart has become useless, for want of encouragement to renew it from time to time.

However, in the year 1744, Mr. William Mountaine and Mr. James Dodson published a new Variation Chart, adapted for that year, which was well received; and several instances of its great utility having been communicated to them, they fitted the Variation lines anew for the year 1756, and in the following year published the 3d Variation Chart, and also presented to the Royal Society a curious paper concerning the Variation of the magnetic needle, with a set of tables annexed, containing the result of upwards of 50 thousand observations, in six periodical reviews, from the year 1700 to 1756 inclusive, and adapted to every 5 degrees of latitude and longitude in the more frequented oceans; which paper and tables were printed in the Transactions for the year 1757.

From these tables of observations, such extraordinary and whimsical irregularities occur in the Variation, that we cannot think it wholly under the direction of one general and uniform law; but rather conclude, with Dr. Gowen, in the 87th prop. of his Treatise upon Attraction and Repulsion, that it is influenced by various and different magnetic attractions, perhaps occasioned by the heterogeneous compositions in the great magnet, the earth.

Many other observations on the Variation of the magnetic needle, are to be found in several volumes of the Philos. Trans. See particularly vol. 48, p. 875; vol. 50, p. 329; vol. 56, p. 220; and vol. 61, p. 422.

VARIATION *Compass*. See COMPASS.

VARIATION *of Curvature*, in Geometry, is used for that inequality or change which takes place in the curvature of all curves except the circle, by which their curvature is more or less in different parts of them. And this Variation constitutes the quality of the curvature of any line.

Newton makes the index of the inequality, or Variation of Curvature, to be the ratio of the fluxion of the radius of curvature to the fluxion of the curve itself: and Maclaurin, to avoid the perplexity that different notions, connected with the same terms, occasion to learners, has adopted the same definition: but he suggests, that this ratio gives rather the Variation of the ray of curvature, and that it might have been proper to have measured the Variation of Curvature rather by the ratio of the fluxion of the curvature itself to the fluxion of the curve; so that, the curvature being inversely as the radius of curvature, and consequently its fluxion as the fluxion of the radius itself directly, and the square of the radius inversely, its Variation would have been directly as the measure of it according to Newton's definition, and inversely as the square of the radius of curvature.

According to this notion, it would have been measured by the angle of contact contained by the curve and circle of curvature, in the same manner as the curvature itself is measured by the angle of contact contained by the curve and tangent. The reason of this remark may appear from this example: The Variation of curvature, according to Newton's explication, is uniform in the logarithmic spiral, the fluxion of the radius of curvature in this figure being always in the same ratio to the fluxion of the curve; and yet, while the spiral is produced, though its curvature decreases, it never vanishes; which must appear a strange paradox to those who do not attend to the import of Newton's definition. Newton's Method of Fluxions and Inf. Series, pa. 76. Maclaurin's Flux. art. 386. Philos. Trans. num. 468, pa. 342.

The Variation of curvature at any point of a conic section, is always as the tangent of the angle contained by the diameter that passes through the point of contact, and the perpendicular to the curve at the same point, or to the angle formed by the diameter of the section, and of the circle of curvature. Hence the Variation of curvature vanishes at the extremities of either axis, and is greatest when the acute angle, contained by the diameter, passing through the point of contact and the tangent, is least.

When the conic section is a parabola, the Variation is as

as the tangent of the angle, contained by the right line drawn from the point of contact to the focus, and the perpendicular to the curve. See CURVATURE.

From Newton's definition may be derived practical rules for the Variation of curvature, as follows:

1. Find the radius of curvature, or rather its fluxion; then divide this fluxion by the fluxion of the curve, and the quotient will give the Variation of curvature; exterminating the fluxions when necessary, by the equation of the curve, or perhaps by expressing their ratio by help of the tangent, or ordinate, or subnormal, &c.

2. Since $\frac{\dot z^3}{-\dot x\ddot y}$, or $\frac{\dot z^3}{-\ddot y}$ (putting $\dot x = 1$) denotes the radius of curvature of any curve z, whose abscis is x, and ordinate y; if the fluxion of this be divided by $\dot z$, and $\dot z$ and $\ddot z$ be exterminated, the general value of the Variation will come out $\frac{-3\dot y\ddot y^2 + \dddot y(1+\dot y^2)}{\ddot y^2}$; then substituting the values of $\dot y$, $\ddot y$, $\dddot y$ (found from the equation of the curve) into this quantity, it will give the Variation sought.

Ex. Let the curve be the parabola, whose equation is $ax = y^2$. Here then $2y\dot y = a\dot x = a$, and $\dot y = \frac{a}{2y}$; hence $\ddot y = \frac{-a\dot y}{2yy} = \frac{-aa}{4y^3}$, and $\dddot y = \frac{-3aa\dot y}{2y^4} = \frac{3a^3}{8y^5}$. Therefore $\frac{-3\dot y\ddot y^2 + \dddot y(1+\dot y^2)}{\ddot y^2} = -3\dot y + \dddot y \times \frac{1+\dot y^2}{\ddot y^2} = \frac{-3a}{2y} + \frac{3a^3}{8y^5} \times (1 + \frac{aa}{4yy}) \times \frac{16y^6}{a^4} = \frac{6y}{a}$, the Variation sought. Emerson's Flux. pa. 228.

VARIGNON (PETER), a celebrated French mathematician and priest, was born at Caen in 1654, and died suddenly in 1722, at 68 years of age. He was the son of an architect in middling circumstances, but had a college education, being intended for the church. An accident threw a copy of Euclid's Elements in his way, which gave him a strong turn to that kind of learning. The study of geometry led him to the works of Des Cartes on the same science, and there he was struck with that new light which has, from thence, spread over the world.

He abridged himself of the necessaries of life to purchase books of this kind, or rather considered them of that number, as indeed they ought to be. What contributed to heighten this passion in him was, that he studied in private: for his relations observing that the books he studied were not such as were commonly used by others, strongly opposed his application to them. As there was a necessity for his being an ecclesiastic, he continued his theological studies, yet not entirely sacrificing his favourite subject to them.

At this time the Abbé St. Pierre, who studied philosophy in the same college, became acquainted with him. A taste in common for rational subjects, whether physics or metaphysics, and continual disputations, formed the bonds of their friendship. They were mutually serviceable to each other in their studies. The Abbé, to enjoy Varignon's company with greater ease, lodged him with himself; thus, growing still more sensible of his merit, he resolved to give him a fortune, that he might fully pursue his genius, and improve his talents; and, out of only 18 hundred livres a year, which he had himself, he conferred 300 of them upon Varignon.

The Abbé, persuaded that he could not do better than go to Paris to study philosophy, settled there in 1686, with M. Varignon, in the suburbs of St. Jacques. There each studied in his own way; the Abbé applying himself to the study of men, manners, and the principles of government; whilst Varignon was wholly occupied with the mathematics.

I, says Fontenelle, who was their countryman, often went to see them, sometimes spending two or three days with them. They had also room for a couple of visitors, who came from the same province. We joined together with the greatest pleasure. We were young, full of the first ardour for knowledge, strongly united, and, what we were not then perhaps disposed to think so great a happiness, little known. Varignon, who had a strong constitution, at least in his youth, spent whole days in study, without any amusement or recreation, except walking sometimes in fine weather. I have heard him say, that in studying after supper, as he usually did, he was often surprised to hear the clock strike two in the morning; and was much pleased that four hours rest were sufficient to refresh him. He did not leave his studies with that heaviness which they usually create; nor with that weariness that a long application might occasion. He left off gay and lively, filled with pleasure, and impatient to renew it. In speaking of mathematics, he would laugh so freely, that it seemed as if he had studied for diversion. No condition was so much to be envied as his; his life was a continual enjoyment, delighting in quietness.

In the solitary suburb of St. Jacques, he formed however a connection with many other learned men; as Du Hamel, Du Verney, De la Hire, &c. Du Verney often asked his assistance in those parts of anatomy connected with mechanics: they examined together the positions of the muscles, and their directions; hence Varignon learned a good deal of anatomy from Du Verney, which he repaid by the application of mathematical reasoning to that subject.

At length, in 1687, Varignon made himself known to the public by a Treatise on New Mechanics, dedicated to the Academy of Sciences. His thoughts on this subject were, in effect, quite new. He discovered truths, and laid open their sources. In this work, he demonstrated the necessity of an equilibrium, in such cases as it happens in, though the cause of it is not exactly known. This discovery Varignon made by the theory of compound motions, and is what this essay turns upon.

This new Treatise on Mechanics was greatly admired by the mathematicians, and procured the author two considerable places, the one of Geometrician in the Academy of Sciences, the other of Professor of Mathematics in the College of Mazarine, to which he was the first person raised.

Varignon catched eagerly at the Science of Infinitesimals as soon as it appeared in the world, and became one of its most early cultivators. When that sublime and beautiful method was attacked in the Academy itself

ſelf (for it could not eſcape the fate of all innovations) he became one of its moſt zealous defenders, and in its favour he put a violence upon his natural character, which abhorred all contention. He ſometimes lamented, that this diſpute had interrupted him in his enquiries into the Integral Calculation ſo far, that it would be difficult for him to reſume his diſquiſition where he had left it off. He ſacrificed Infiniteſimals to the intereſt of Infiniteſimals, and gave up the pleaſure and glory of making a farther progreſs in them when called upon by duty to undertake their defence.

All the printed volumes of the Academy bear witneſs to his application and induſtry. His works are never detached pieces, but complete theories of the laws of motion, central forces, and the reſiſtance of mediums to motion. In theſe he makes ſuch uſe of his rules, that nothing eſcapes him that has any connection with the ſubject he treats.

Geometrical certainty is by no means incompatible with obſcurity and confuſion, and thoſe are ſometimes ſo great, that it is ſurpriſing a mathematician ſhould not miſs his way in ſo dark and perplexing a labyrinth. The works of M. Varignon never occaſion this diſagreeable ſurpriſe, he makes it his chief care to place every thing in the cleareſt light; he does not, as ſome great men do, conſult his eaſe by declining to take the trouble of being methodical, a trouble much greater than that of compoſition itſelf; he does not endeavour to acquire a reputation for profoundneſs, by leaving a great deal to be gueſſed by the reader.

He was perfectly acquainted with the hiſtory of mathematics. He learned it not merely out of curioſity, but becauſe he was deſirous of acquiring knowledge from every quarter. This hiſtorical knowledge is doubtleſs an ornament in a mathematician, but it is an ornament which is by no means without its utility. Indeed it may be laid down as a maxim, the more different ways the mind is occupied in, upon a ſubject, the more it improves.

Though Varignon's conſtitution did not ſeem eaſy to be impaired, aſſiduity and conſtant application brought upon him a ſevere diſeaſe in 1705. Great abilities are generally dangerous to the poſſeſſors. He was ſix months in danger, and three years in a languid ſtate, which proceeded from his ſpirits being almoſt entirely exhauſted. He ſaid that ſometimes when delirious with a fever, he thought himſelf in the midſt of a foreſt, where all the leaves of the trees were covered with algebraical calculations. Condemned by his phyſicians, his friends, and himſelf, to lay aſide all ſtudy, he could not, when alone in his chamber, avoid taking up a book of mathematics, which he hid as ſoon as he heard any perſon coming. He again reſumed the attitude and behaviour of a ſick man, and ſeldom had occaſion to counterfeit.

In regard to his character, Fontenelle obſerves, that it was at this time that a writing of his appeared, in which he cenſured Dr. Wallis for having advanced that there are certain ſpaces more than infinite, which that great geometrician aſcribes to hyperbolas. He maintained, on the contrary, that they were finite. The criticiſm was ſoftened with all the politeneſs and reſpect imaginable; but a criticiſm it was, though he had written it only for himſelf. He let M. Carré ſee it, when he was in a ſtate that rendered him indifferent about things of that kind; and that gentleman, influenced only by the intereſt of the ſciences, cauſed it to be printed in the memoirs of the Academy of Sciences, unknown to the author, who thus made an attack againſt his inclination.

He recovered from his diſeaſe; but the remembrance of what he had ſuffered did not make him more prudent for the future. The whole impreſſion of his *Project for a New Syſtem of Mechanics*, having been ſold off, he formed a deſign to publiſh a ſecond edition of it, or rather a work entirely new, though upon the ſame plan, but more extended. It muſt be eaſy to perceive how much learning he muſt have acquired in the interval; but he often complained, that he wanted time, though he was by no means diſpoſed to loſe any. Frequent viſits, either of French or of foreigners, ſome of whom went to ſee him that they might have it to ſay that they had ſeen him; and others to conſult him and improve by his converſation: works of mathematics, which the authority of ſome, or the friendſhip he had for others, engaged him to examine, and which he thought himſelf obliged to give the moſt exact account of; a literary correſpondence with all the chief mathematicians of Europe; all theſe obſtructed the book he had undertaken to write. Thus a man acquires reputation by having a great deal of leiſure time, and he loſes this precious leiſure as ſoon as he has acquired reputation. Add to this, that his beſt ſcholars, whether in the College of Mazarine or the Royal College (for he had a profeſſor's chair in both), ſometimes requeſted private lectures of him, which he could not refuſe. He ſighed for his two or three months of vacation, for that was all the leiſure time he had in the year; no ſooner were they come but he retired into the country, where his time was entirely his own, and the days ſeemed always quickly ended.

Notwithſtanding his great deſire of peace, in the latter part of his life he was involved in a diſpute. An Italian monk, well verſed in mathematics, attacked him upon the ſubject of tangents and the angle of contact in curves, ſuch as they are conceived in the arithmetic of infinites; he anſwered by the laſt memoir he ever gave to the Academy, and the only one which turned upon a diſpute.

In the laſt two years of his life he was attacked with an aſthmatic complaint. This diſorder increaſed every day, and all remedies were ineffectual. He did not however ceaſe from any of his cuſtomary buſineſs; ſo that, after having finiſhed his lecture at the College of Mazarine, on the 22d of December 1722, he died ſuddenly the following night.

His character, ſays Fontenelle, was as ſimple as his ſuperior underſtanding could require. He was not apt to be jealous of the fame of others: indeed he was at the head of the French mathematicians, and one of the beſt in Europe. It muſt be owned however, that when a new idea was offered to him, he was too haſty to object. The fire of his genius, the various inſights into every ſubject, made too impetuous an oppoſition to thoſe that were offered; ſo that it was not eaſy to obtain from him a favourable attention.

His works that were publiſhed ſeparately, were,

1. Project d'une Nouvelle Mechanique; 4to, Paris 1687.

2. Des

2. Des Nouvelles Conjectures sur la Pesanteur.

3. Nouvelle Mechanique ou Statique, 2 tom. 4to, 1725.

As to his memoirs in the volumes of the Academy of Sciences, they are far too numerous to be here particularized; they extend through almost all the volumes, down to his death in 1722.

VASA *Concordiæ*, in Hydraulics, are two vessels, so constructed, as that one of them, though full of wine, will not run a drop, unless the other, being full of water, do run also. Their structure and apparatus may be seen in Wolfius, Element. Mathes. tom. 3, Hydraul.

VAULT, in Architecture, an arched roof, so contrived, as that the several stones of which it consists, by their disposition into the form of a curve, mutually sustain each other; as the arches of bridges, &c.

Vaults are to be preferred, on many occasions, to soffits, or flat ceilings, as they give a greater rise and elevation, and are also more firm and durable.

The Ancients, Salmasius observes, had only three kinds of vaults: the first the *fornix*, made cradlewise; the 2d, the *testudo*, tortoise-wise, or oven-wise; the 3d, the *concha*, made shell-wise.

But the Moderns subdivide these three sorts into a great many more, to which they give different names, according to their figures and use: some are circular, others elliptical, &c.

Again, the sweeps of some are larger, and others less portions of a sphere: all above hemispheres are called *high*, or *surmounted Vaults*; all that are less than hemispheres, are *low*, or *surbased Vaults*, &c.

In some the height is greater than the diameter; in others it is less: there are others again quite flat, only made with haunses; others oven-like, and others growing wider as they lengthen, like a trumpet.

Of Vaults, some are *single*, others *double*, *cross*, *diagonal*, *horizontal*, *ascending*, *descending*, *angular*, *oblique*, *pendent*, &c, &c. There are also *Gothic* Vaults, with *pendentives*, &c.

Master VAULTS, are those which cover the principal parts of buildings; in contradistinction from the *less*, or subordinate Vaults, which only cover some small part; as a passage, a gate, &c.

Double VAULT, is such a one as, being built over another, to make the exterior decoration range with the interior, leaves a space between the convexity of the one, and the concavity of the other: as in the dome of St. Paul's at London, and that of St. Peter's at Rome.

VAULTS *with Compartiments*, are such whose sweep, or inner face, is enriched with pannels of sculpture, separated by platbands. These compartiments, which are of different figures, according to the Vaults, and are usually gilt on a white ground, are made with stucco, on brick Vaults; as in the church of St. Peter's at Rome; and with plaster, on timber Vaults.

Theory of VAULTS.—In a semicircular Vault, or arch, being a hollow cylinder cut by a plane through its axis, standing on two imposts, and all the stones that compose it, being cut and placed in such a manner, as that their joints, or beds, being prolonged, do all meet in the centre of the vault; it is evident that all the stones must be cut wedge-wise, or wider at top and above, than below; by virtue of which, they sustain each other, and mutually oppose the effort of their weight, which determines them to fall.

The stone in the middle of the Vault, which is perpendicular to the horizon, and is called the *key of the Vault*, is sustained on each side by the two contiguous stones, as by two inclined planes.

The second stone, which is on the right or left of the key-stone, is sustained by a third; which, by virtue of the figure of the Vault, is necessarily more inclined to the second, than the second is to the first; and consequently the second, in the effort it makes to fall, employs a less part of its weight than the first.

For the same reason, all the stones, reckoning from the keystone, employ still a less and less part of their weight to the last; which, resting on the horizontal plane, employs no part of its weight, or makes no effort to fall, as being entirely supported by the impost.

Now a great point to be aimed at in Vaults, is, that all the several stones make an equal effort to fall: to effect this, it is evident that as each stone, reckoning from the key to the impost, employs a still less and less part of its whole weight; the first only employing, for example, one-half; the 2d, one-third; the 3d, one-fourth; &c; there is no other way to make these different parts equal, but by a proportionable augmentation of the whole; that is, the second stone must be heavier than the first, the third heavier than the second, and so on to the last, which should be vastly heavier.

La Hire demonstrates what that proportion is, in which the weights of the stones of a semicircular arch must be increased, to be in equilibrio, or to tend with equal forces to fall; which gives the firmest disposition that a vault can have. Before him, the architects had no certain rule to conduct themselves by; but did all at random. Reckoning the degrees of the quadrant of the circle, from the keystone to the impost; the length or weight of each stone must be so much greater, as it is farther from the key. La Hire's rule is, to augment the weight of each stone above that of the key stone, as much as the tangent of the arch to the stone exceeds the tangent of the arch of half the key. Now the tangent of the last stone becomes infinite, and consequently the weight should be so too; but as infinity has no place in practice, the rule amounts to this, that the last stone be loaded as much as possible, and the others in proportion, that they may the better resist the effort which the Vault makes to separate them; which is called the *shoot* or *drift* of the Vault.

M. Parent, and other authors, have since determined the curve, or figure, which the extrados or outside of a Vault, whose intrados or inside is spherical, ought to have, that all the stones may be in equilibrio.

The above rule of La Hire's has since been found not accurate. See ARCH, and BRIDGE. See also my Treatise on the Principles of Bridges, and Emerson's Construction of Arches.

Key of a VAULT. See KEY, and VOUSSOIR.

Reins or *fillings up of a* VAULT, are the sides which sustain it.

Pendentive of a VAULT. See PENDENTIVE.

Impost of a VAULT, is the stone upon which is laid the first voussoir, or arch-stone of the Vault.

VEADAR,

VEADAR, in Chronology, the 13th month of the Jewish ecclesiastical year, answering commonly to our March; this month is intercalated, to prevent the beginning of Nisan from being removed to the end of February.

VECTIS, in Mechanics, one of the simple mechanical powers, more usually called the LEVER.

VECTOR, or *Radius Vector*, in Astronomy, is a line supposed to be drawn from any planet moving round a centre, or the focus of an ellipse, to that centre, or focus. It is so called, because it is that line by which the planet seems to be carried round its centre; and with which it describes areas proportional to the times.

VELOCITY, or *Swiftness*, in Mechanics, is that affection of motion, by which a moving body passes over a certain space in a certain time. It is also called celerity; and it is always proportional to the space moved over in a given time, when the Velocity is uniform, or always the same during that time.

Velocity is either *uniform* or *variable*. *Uniform*, or equal *Velocity*, is that with which a body passes always over equal spaces in equal times. And it is *variable*, or *unequal*, when the spaces passed over in equal times are unequal; in which case it is either *accelerated* or *retarded* Velocity; and this acceleration, or retardation, may also be equal or unequal, i. e. uniform or variable, &c. See ACCELERATION, and MOTION.

Velocity is also either *absolute* or *relative*. *Absolute Velocity* is that we have hitherto been considering, in which the Velocity of a body is considered simply in itself, or as passing over a certain space in a certain time. But *relative* or *respective Velocity*, is that with which bodies approach to, or recede from one another, whether they both move, or one of them be at rest. Thus, if one body move with the absolute Velocity of 2 feet per second, and another with that of 6 feet per second; then if they move directly towards each other, the relative velocity with which they approach is that of 8 feet per second; but if they move both the same way, so that the latter overtake the former, then the relative Velocity with which that overtakes it, is only that of 4 feet per second, or only half of the former; and consequently it will take double the time of the former before they come in contact together.

VELOCITY *in a Right Line*.—When a body moves with a uniform Velocity, the spaces passed over by it, in different times, are proportional to the times; also the spaces described by two different uniform Velocities, in the same time, are proportional to the Velocities; and consequently, when both times and Velocities are unequal, the spaces described are in the compound ratio of the times and Velocities. That is, $S \propto TV$, and $s \propto tv$; or $S : s :: TV : tv$. Hence also, $V : v :: \frac{S}{T} : \frac{s}{t}$, or the Velocity is as the space directly and the time reciprocally.

But in uniformly accelerated motions; the last degree of Velocity uniformly gained by a body in beginning from rest, is proportional to the time; and the space described from the beginning of the motion, is as the product of the time and Velocity, or as the square of the Velocity, or as the square of the time. That is, in uniformly accelerated motions, $v \propto t$, and $s \propto tv$ or $\propto v^2$ or $\propto t^2$. And, in fluxions, $\dot{s} = v\dot{t}$.

VELOCITY *of Bodies moving in Curves*.—According to Galileo's system of the fall of heavy bodies, which is now universally admitted among philosophers, the Velocities of a body falling vertically are, at each moment of its fall, as the square roots of the heights from whence it has fallen; reckoning from the beginning of the descent. And hence he inferred, that if a body descend along an inclined plane, the Velocities it has, at the different times, will be in the same ratio: for since its Velocity is all owing to its fall, and it only falls as much as there is perpendicular height in the inclined plane, the Velocity should be still measured by that height, the same as if the fall were vertical.

The same principle led him also to conclude, that if a body fall through several contiguous inclined planes, making any angles with each other, much like a stick when broken, the Velocity would still be regulated after the same manner, by the vertical heights of the different planes taken together, considering the last Velocity as the same that the body would acquire by a fall through the same perpendicular height.

This conclusion it seems continued to be acquiesced in, till the year 1672, when it was demonstrated to be false, by James Gregory, in a small piece of his intitled *Tentamina quædam Geometrica de Motu Penduli & Projectorum*. This piece has been very little known, because it was only added to the end of an obscure and pseudonymous piece of his, then published, to expose the errors and vanity of Mr. Sinclair, professor of natural philosophy at Glasgow. This little jeu d'esprit of Gregory is intitled, *The great and new Art of Weighing Vanity: or a discovery of the Ignorance and Arrogance of the great and new Artist, in his Pseudo-Philosophical writings: by M. Patrick Mathers, Arch-Bedal to the University of S. Andrews*. In the *Tentamina*, Gregory shews what the real Velocity is, which a body acquires by descending down two contiguous inclined planes, forming an obtuse angle, and that it is different from the Velocity a body acquires by descending perpendicularly through the same height; also that the Velocity in quitting the first plane, is to that with which it enters the second, and in this latter direction, as radius to the cosine of the angle of inclination between the two planes.

This conclusion however, Gregory observes, does not apply to the motions of descent down any curve lines, because the contiguous parts of curve lines do not form any angle between them, and consequently no part of the Velocity is lost by passing from one part of the curve to the other; and hence he infers, that the Velocities acquired in descending down a continued curve line, are the same as by falling perpendicularly through the same height. This principle is then applied, by the author, to the motion of pendulums and projectiles.

Varignon too, in the year 1693, followed in the same track, shewing that the Velocity lost in passing from one right lined direction to another, becomes indefinitely small in the course of a curve line; and that therefore the doctrine of Galileo holds good for the descent of bodies down a curve line, viz, that the Velocity

 acquired

acquired at any point of the curve, is equal to that which would be acquired by a fall through the same perpendicular altitude.

The nature of every curve is abundantly determined by the ratio of the ordinates to the corresponding abscisses; and the essence of curves in general may be conceived as consisting in this ratio, which may be varied in a thousand different ways. But this same ratio will be also that of two simple Velocities, by whose joint effect a body may describe the curve in question; and consequently the essence of all curves, in general, is the same thing as the concourse or combination of all the forces which, taken two by two, may move the same body. Thus we have a most simple and general equation of all possible curves, and of all possible Velocities. By means of this equation, as soon as the two simple Velocities of a body are known, the curve resulting from them is immediately determined.

It may be observed, in particular, according to this equation, that an uniform Velocity, combined with a Velocity that always varies as the square roots of the heights, the two produce the particular curve of a parabola, independent of the angle made by the directions of the two forces that give the Velocities; and consequently a cannon ball, shot either horizontally or obliquely to the horizon, must always describe a parabola, were it not for the resistance of the air.

Circular VELOCITY. See CIRCULAR.

Initial VELOCITY, in Gunnery, denotes the Velocity with which military projectiles issue from the mouth of the piece by which they are discharged. This, it is now known, is much more considerable than was formerly apprehended. For the method of estimating it, and the result of a variety of experiments, by Mr. Robins, and myself, &c, see the articles GUN, GUNNERY, PROJECTILE, and RESISTANCE.

Mr. Robins had hinted in his New Principles of of Gunnery, at another method of measuring the Initial Velocities of military projectiles, viz, from the arc of vibration of the gun itself, in the act of expulsion, when it is suspended by an axis like a pendulum. And Mr. Thompson, in his experiments (Philos. Trans. vol. 71, p. 229) has pursued the same idea at considerable length, in a number of experiments, from whence he deduces a rule for computing the Velocity, which is somewhat different from that of Mr. Robins, but which agrees very well with his own experiments.

This rule however being drawn only from the experiments with a musket barrel, and with a small charge of powder, and besides being different from that in the theory as proposed by Robins; it was suspected that it would not hold good when applied to cannon, or other large pieces of ordnance, of different and various lengths, and to larger charges of powder. For this reason, a great multitude of experiments, as related in my Tracts, vol. 1, were instituted with cannon of various lengths and charged with many different quantities of powder; and the Initial Velocities of the shot were computed both from the vibration of a ballistic pendulum, and from the vibration of the gun itself; but the consequence was, that these two hardly ever agreed together, and in many cases they differed by almost 400 feet per second in the Velocity. A brief abstract for a comparison between these two methods, is contained in the following tablet, viz.

Comparison of the Velocities by the Gun and Pendulum.

Gun No.	2 Ounces.			4 Ounces.			8 Ounces.			16 Ounces.		
	Velocity by		Diff.	Velocity by		Diff.	Velocity by		Diff.	Velocity by		Diff.
	Gun	Pend.		Gun	Pend.		Gun	Pend.		Gun	Pend.	
1	830	780	50	1135	1100	35	1445	1430	15	1345	1377	−32
2	863	835	28	1203	1180	23	1521	1580	−59	1485	1656	−171
3	919	920	−1	1294	1300	−6	1631	1790	−159	1680	1998	−318
4	929	970	−41	1317	1370	−53	1669	1940	−271	1730	2106	−376

In this table, the first column shews the number of the gun, as they were of different lengths; viz, the length of number 1 was 30½ inches, number 2 was 40½ inches, number 3 was 60 inches, and number 4 was 83 inches, nearly. After the first column, the rest of the table is divided into four spaces, for the four charges, 2, 4, 8, 16 ounces of powder: and each of these is divided into three columns: in the first of the three is the Velocity of the ball as determined from the vibration of the gun; in the second is the Velocity as determined from the vibration of the pendulum; and in the third is the difference between the two, being so many feet per second, which is marked with the negative sign, or −, when the former Velocity is too little, otherwise it is positive.

From the comparison contained in this table, it appears, in general, that the Velocities, determined by the two different ways, do not agree together; and that therefore the method of determining the Velocity of the ball from the recoil of the gun, is not generally true, although Mr. Robins and Mr. Thompson had suspected it to be so; and consequently that the effect of the inflamed powder on the recoil of the gun, is not exactly the same when it is fired without a ball, as when it is fired with one. It also appears, that this difference is no ways regular, neither is the different

guns with the same charge of powder, nor in the same gun with different charges: That with very small charges, the Velocity by the gun is greater than that by the pendulum; but that the latter always gains upon the former, as the charge is increased, and soon becomes equal to it; and afterwards goes on to exceed it more and more: That the particular charge, at which the two Velocities become equal, is different in the different guns; and that this charge is less, or the equality sooner takes place, as the gun is longer. And all this, whether we use the actual Velocity with which the ball strikes the pendulum, or the same increased by the Velocity lost by the resistance of the air, in its flight from the gun to the pendulum.

VENTILATOR, a machine by which the noxious air of any close place, as an hospital, gaol, ship, chamber, &c, may be discharged and changed for fresh air.

The noxious qualities of bad air have been long known; and Dr. Hales and others have taken great pains to point out the mischiefs arising from foul air, and to prevent or remedy them. That philosopher proposed an easy and effectual one, by the use of his Ventilators; the account of which was read before the Royal Society in May 1741; and a farther account of it may be seen in his Description of Ventilators, printed at London in 8vo, 1743; and still farther in part 2, p. 32, printed in 1758; where the uses and applications of them are pointed out for ships, and prisons, &c. For what is said of the foul air of ships may be applied to that of gaols, mines, workhouses, hospitals, barracks, &c. In mines, Ventilators may guard against the suffocations, and other terrible accidents arising from damps. The air of gaols has often proved infectious; and we had a fatal proof of this, by the accident that happened some years since at the Old Bailey sessions. After that, Ventilators were used in the prison, which were worked by a small windmill, placed on the top of Newgate; and the prison became more healthy.

Dr. Hales farther suggests, that Ventilators might be of use in making salt; for which purpose there should be a stream of water to work them; or they might be worked by a windmill, and the brine should be in long narrow canals, covered with boards of canvas, about a foot above the surface of the brine, to confine the stream of air, so as to make it act upon the surface of the brine, and carry off the water in vapours. Thus it might be reduced to a dry salt, with a saving of fuel, in winter and summer, or in rainy weather, or any state of the air whatever. Ventilators, he apprehends, might also serve for drying linen hung in low, long, narrow galleries, especially in damp or rainy weather, and also in drying woollen cloths, after they are fulled or dyed; and in this case, the Ventilators might be worked by the fulling water-mill. Ventilators might also be an useful appendage to malt and hop kilns; and the same author is farther of opinion, that a ventilation of warm dry air from the adjoining stove, with a cautious hand, might be of service to trees and plants in green-houses; where it is well known that air full of the rancid vapours which perspire from the plants, is very unkindly to them, as well as the vapours from human bodies are to men: for fresh air is as necessary to the healthy state of vegetables, as of animals.—Ventilators are also of excellent use for drying corn, hops, and malt.—Gunpowder may be thoroughly dried, by blowing air up through it by means of Ventilators; which is of great advantage to the strength of it. These Ventilators, even the smaller ones, will also serve to purify most easily, and effectually, the bad air of a ship's well, before a person is sent down into it, by blowing air through a trunk, reaching near the bottom of it. And in a similar manner may stinking water, and ill-tasted milk, &c, be sweetened, viz, by passing a current of air through them, from bottom to top, which will carry the offensive particles along with it.

For these and other uses to which they might be applied, as well as for a particular account of the construction and disposition of Ventilators in ships, hospitals, prisons, &c, and the benefits attending them, see Hales's Treatise on Ventilators, part 2 passim; and the Philos. Trans. vol. 49, p. 332.

The method of drawing off air from ships by means of fire-pipes, which some have preferred to Ventilators, was published by Sir Robert Moray in the Philos. Trans. for 1665. These are metal pipes, about $2\frac{1}{2}$ inches diameter, one of which reaches from the fire-place to the well of the ship, and other three branches go to other parts of the ship; the stove hole and ash hole being closed up, the fire is supplied with air through these pipes. The defects of these, compared with Ventilators, are particularly examined by Dr. Hales, ubi supra, p. 113.

In the latter part of the year 1741, M. Triewald, military architect to the king of Sweden, informed the secretary to the Royal Society, that he had in the preceding spring invented a machine for the use of ships of war, to draw out the foul air from under their decks, which exhausted 36172 cubic feet of air in an hour, or at the rate of 21732 tuns in 24 hours. In 1742 he sent one of these to France, which was approved of by the Academy of Sciences at Paris, and the navy of France was ordered to be furnished with the like Ventilators.

Mr. Erasmus King proposed to have Ventilators worked by the fire engines, in mines. And Mr. Fitzgerald has suggested an improved method of doing this, which he has also illustrated by figures. See Philos. Trans. vol. 50, p. 727.

There are various ways of Ventilation, or changing the air of rooms. Mr. Tidd contrived to admit fresh air into a room, by taking out the middle upper sash pane of glass, and fixing in its place a frame box, with a round hole in its middle, about 6 or 7 inches diameter; in which hole are fixed, behind each other, a set of sails of very thin broad copper-plates, which spread over and cover the circular hole, so as to make the air which enters the room, and turning round these sails, to spread round in thin sheets sideways; and so not to incommode persons, by blowing directly upon them, as it would do if it were not hindered by the sails.

This method however is very unseemly and disagreeable in good rooms: and therefore, instead of it, the late ingenious Mr. John Whitehurst substituted another; which was, to open a small square or rectangular hole in the party wall of the room, in the upper part near the cieling, at a corner or part distant from the fire

fire; and before it he placed a thin piece of metal or paſteboard &c, attached to the wall in its lower part juſt below the hole, but declining from it upwards, ſo as to give the air, that enters by the hole, a direction upwards againſt the cieling, along which it ſweeps and diſperſes itſelf through the room, without blowing in a current againſt any perſon. This method is very uſeful to cure ſmoky chimneys, by thus admitting conveniently freſh air. A picture placed before the hole prevents the ſight of it from diſfiguring the room. This, and many other methods of Ventilating, he meant to have publiſhed, and was occupied upon, when death put an end to his uſeful labours. Theſe have ſince been publiſhed, viz in 1794, 4to, by Dr. Willan.

VENUS, in Aſtronomy, one of the inferior planets, but the brighteſt and to appearance the largeſt of all the planets; and is deſigned by the mark ♀, ſuppoſed to be a rude repreſentation of a female figure, with her trailing robe.

Venus is eaſily diſtinguiſhed from all the other planets, by her whiteneſs and brightneſs, in which ſhe exceeds all the reſt, even Jupiter himſelf, and which is ſo conſiderable, that in a duſky place ſhe cauſes an object to project a ſenſible ſhadow, and ſhe is often viſible in the day-time. Her place in the ſyſtem is the ſecond from the ſun, viz, between Mercury and the earth, and in magnitude is about equal to the earth, or rather a little larger according to Dr. Herſchel's obſervations.

As Venus moves round the ſun, in a circle beneath that of the earth, ſhe is never ſeen in oppoſition to him, nor indeed very far from him; but ſeems to move backward and forward, paſſing him from ſide to ſide, to the diſtance of about 47 or 48 degrees, both ways, which is her greateſt elongation.

When ſhe appears weſt of the ſun, which is from her inferior conjunction to her ſuperior, ſhe riſes before him, or is a morning ſtar, and is called *Phoſphorus*, or *Lucifer*, or the *Morning Star*; and when ſhe is eaſtwards from the ſun, which is from her ſuperior conjunction to her inferior, ſhe ſets after him, or is an evening ſtar, and is called *Heſperus*, or *Veſper*, or the *Evening ſtar*: being each of thoſe in its turn for 290 days.

The real diameter of Venus is nearly equal to that of the earth, being about 7900 miles; her apparent mean diameter ſeen from the earth 59″, ſeen from the ſun, or her horizontal parallax, 30″; but as ſeen from the earth 18″·79 according to Dr. Herſchel: her diſtance from the ſun 70 million of miles; her eccentricity $\frac{7}{1000}$ths of the ſame, or 490,000 miles; the inclination of her orbit to the plane of the ecliptic 3° 23′; the points of their interſection or nodes are 14° of ♊ and ♐; the place of her aphelion ♒ 4° 20′; her axis inclined to her orbit 75° 0′; her periodical courſe round the ſun 224 days 17 hours; the diurnal rotation round her axis very uncertain, being according to Caſſini only 23 hours, but according to the obſervations of Bianchini it is in 24 days 8 hours; though Dr. Herſchel thinks it cannot be ſo much. See alſo PLANETS.

Venus, when viewed through a teleſcope, is rarely ſeen to ſhine with a full face, but has phaſes and changes juſt like thoſe of the moon, being increaſing, decreaſing, horned, gibbous, &c: her illuminated part being conſtantly turned toward the ſun, or directed toward the eaſt when ſhe is a morning ſtar, and toward the weſt when an evening ſtar.

Theſe different phaſes of Venus were firſt diſcovered by Galileo; who thus fulfilled the prediction of Copernicus: for when this excellent aſtronomer revived the ancient Pythagorean ſyſtem, aſſerting that the earth and planets move round the ſun, it was objected that in ſuch a caſe the phaſes of Venus ſhould reſemble thoſe of the moon; to which Copernicus replied, that ſome time or other that reſemblance would be found out. Galileo ſent an account of the firſt diſcovery of theſe phaſes in a letter, written from Florence in 1611, to William de Medici, the duke of Tuſcany's ambaſſador at Prague; deſiring him to communicate it to Kepler. The letter is extant in the preface to Kepler's Dioptries, and a tranſlation of it in Smith's Optics, p. 416. Having recited the obſervations he had made, he adds, "We have hence the moſt certain, ſenſible deciſion and demonſtration of two grand queſtions, which to this day have been doubtful and diſputed among the greateſt maſters of reaſon in the world. One is, that the planets in their own nature are opake bodies, attributing to Mercury what we have ſeen in Venus: and the other is, that Venus neceſſarily moves round the ſun; as alſo Mercury and the other planets; a thing well believed indeed by Pythagoras, Copernicus, Kepler, and myſelf, but never yet proved, as now it is, by ocular inſpection upon Venus."

Caſſini and Campani, in the years 1665 and 1666, diſcovered ſpots in the face of Venus: from the appearances of which the former aſcertained her motion round her axis; concluding that this revolution was performed in leſs than a day; or at leaſt that the biggeſt ſpot which he obſerved, finiſhed its period either by revolution or libration in about 23 hours. And de la Hire, in 1700, through a teleſcope of 16 feet, diſcovered ſpots in Venus; which he found to be larger than thoſe in the moon.

The next obſervations of the ſame kind that occur are thoſe of ſignior Binanchini at Rome, in 1726, 1727, 1728, who, with Campani's glaſſes, diſcovered ſeveral dark ſpots in the diſc of Venus, of which he gave an account and a repreſentation in his book entitled Heſperi et Phoſphori Nova Phenomena, publiſhed at Rome in 1728. From ſeveral ſucceſſive obſervations Bianchini concludes, that a rotation of Venus about her axis was not completed in 23 hours, as Caſſini imagined, but in 24¼ days; that the north pole of this rotation faced the 20th degree of Aquarius, and was elevated 15° above the plane of the ecliptic, and that the axis kept parallel to itſelf, during the planet's revolution about the ſun. Caſſini the ſon, though he admits the accuracy of Bianchini's obſervations, diſputes the concluſion drawn from them, and finally obſerves, that if we ſuppoſe the period of the rotation of Venus to be 23 h. 20 min. it agrees equally well with the obſervations both of his father and Bianchini; but if ſhe revolve in 24 d. 8 h. then his father's obſervations muſt be rejected as of no conſequence.

In the Philoſ. Tranſ. 1792, are publiſhed the reſults of a courſe of obſervations on the planet Venus, begun in the year 1780, by Mr. Schroeter, of Lilienthal, Bremen. From theſe obſervations, the author infers, that

that Venus has an atmosphere in some respects similar to that of our earth, but far exceeding that of the moon in density, or power to weaken the rays of the sun: that the diurnal period of this planet is probably much longer than that of other planets: that the moon also has an atmosphere, though less dense and high than that of Venus: and that the mountains of this planet are 5 or 6 times as high as those on the earth.

Dr. Herschel too, between the years 1777 and 1793, has made a long series of observations on this planet, accounts of which are given in the Philos. Trans. for 1793. The results of these observations are: that the planet revolves about its axis, but the time of it is uncertain: that the position of its axis is also very uncertain: that the planet's atmosphere is very considerable: that the planet has probably hills and inequalities on its surface, but he has not been able to see much of them, owing perhaps to the great density of its atmosphere; as to the mountains of Venus, no eye, he says, which is not considerably better than his, or assisted by much better instruments, will ever get a sight of them: and that the apparent diameter of Venus, at the mean distance from the earth, is 18″·79; from whence it may be inferred, that this planet is somewhat larger than the earth, instead of being less, as former astronomers have imagined.

Sometimes Venus is seen in the disc of the sun, in form of a dark round spot. These appearances, called Transits, happen but seldom, viz, when the earth is about her nodes at the time of her inferior conjunction. One of these transits was seen in England in 1639 by Mr. Horrox and Mr. Crabtree; and two in the present century, viz, the one June 6, 1761, and the other in June 1769. There will not happen another of them till the year 1874. See PARALLAX.

Except such transits as these, Venus exhibits the same appearances to us regularly every 8 years; her conjunctions, elongations, and times of rising and setting, being very nearly the same, on the same days, as before.

In 1672 and 1686, Cassini, with a telescope of 34 feet, thought he saw a satellite move round this planet, at the distance of about $\frac{3}{5}$ of Venus's diameter. It had the same phases as Venus, but without any well defined form; and its diameter scarce exceeded $\frac{1}{4}$ of the diameter of Venus. Dr. Gregory (Astron. lib. 6, prop. 3) thinks it more than probable that this was a satellite; and supposes that the reason why it is not more frequently seen, is the unfitness of its surface to reflect the rays of the sun's light; as is the case of the spots in the moon; for if the whole disc of the moon were composed of such, he thinks she could not be seen so far as to Venus.

Mr. Short, in 1740, with a reflecting telescope of 16½ inches focus, perceived a small star near Venus: with another telescope of the same focus, magnifying 50 or 60 times, and fitted with a micrometer, he found its distance from Venus about 10′; and with a magnifying power of 240, he observed the star assume the same phase with Venus; its diameter seemed to be about [illegible] less, of the diameter of Venus; its [illegible] and vivid, but exceeding sharp and [illegible] viewed it, for the space of an hour, but never had the good fortune to see it after the first morning. Philos. Trans. number 459, p. 646, or Abr. vol. 8, p. 208.

M. Montaign, of Limoges in France, preparing for observing the transit of 1761, discovered in the preceding month of May a small star, about the distance of 20′ from Venus, the diameter of it being about $\frac{1}{4}$ of that of the planet. Others have also thought they saw a like appearance. And indeed it must be acknowledged, that Venus may have a satellite, though it is difficult for us to see it. Its enlightened side can never be fully turned towards us, but when Venus is beyond the sun; in which case Venus herself appears little bigger than an ordinary star, and therefore her satellite may be too small to be perceived at such a distance. When she is between us and the sun, her moon has its dark side towards us; and when Venus is at her greatest elongation, there is but half the enlightened side of the moon turned toward us, and even then it may be too far distant to be seen by us. But it was presumed, that the two transits of 1761, and 1769, would afford opportunity for determining this point; and yet we do not find, although many observers directed their attention to this object, that any satellite was then seen in the sun's disc; unless we except two persons, viz, an anonymous writer in the London Chronicle of May 18, who says that he saw the satellite of Venus on the sun the day of the transit, at St. Neot's in Huntingdonshire; that it moved in a track parallel to that of Venus, but nearer the ecliptic; that Venus quitted the sun's disc at 31 minutes after 8, and the satellite at 6 minutes after 9; and M. Montaign at Limoges, whose account of his observations is in the Memoirs of the Academy of Paris, from whence the following certificate is extracted:—CERTIFICATE. "We having examined, by order of the Academy, the remarks of M. Baudouin on a new observation of the satellite of Venus, made at Limoges the 11th of May by M. Montaign. This fourth observation, of great importance for the theory of the satellite, has shewn that its revolution must be longer than appeared by the first three observations. M. Baudouin believes it may be fixed at 12 days; as to its distance, it appears to him to be 50 semidiameters of Venus; whence he infers that the mass of Venus is equal to that of the earth. This mass of Venus is a very essential element to astronomy, as it enters into many computations, and produces different phenomena: &c.

Signed L'Abbé De La Caille,
De La Lande."

VERBERATION, in Physics, a term used to express the cause of sound, which arises from a Verberation of the air, when struck, in divers manners, by the several parts of the sonorous body first put into a vibratory motion.

VERNAL, something belonging to the spring season: as vernal signs, vernal equinox, &c.

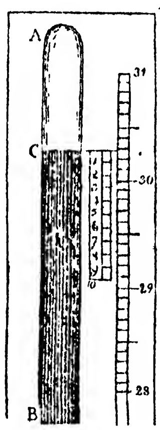
VERNIER, is a scale, or a division, well adapted for the gradation of mathematical instruments, so called from its inventor Peter Vernier, a gentleman of Franche Comté, who communicated the discovery to the world in a small tract, entitled La Construction, l'Usage, et les Proprietez du Quadrant Nouveau de Mathematique &c, printed at Brussels in 1631. This was

was an improvement on the method of division proposed by Jacobus Curtius, printed by Tycho in Clavius's Astrolabe, in 1593. Vernier's method of division, or dividing plate, has been very commonly, though erroneously, called by the name of Nonius; the method of Nonius being very different from that of Vernier, and much less convenient.

When the relative unit of any line is so divided into many small equal parts, those parts may be too numerous to be introduced, or if introduced, they may be too close to one another to be readily counted or estimated; for which reason there have been various methods contrived for estimating the aliquot parts of the small divisions, into which the relative unit of a line may be commodiously divided; and among those methods, Vernier's has been most justly preferred to all others. For the history of this, and other inventions of a similar nature, see Robins's Math. Tracts, vol. 2, p 265, &c.

Vernier's scale is a small moveable arch, or scale, sliding along the limb of a quadrant, or any other graduated scale, and divided into equal parts, that are one less in number than the divisions of the portion of the limb corresponding to it. So, if we want to subdivide the graduations on any scale into for ex. 10 equal parts; we must make the Vernier equal in length to 11 of those graduations of the scale, but dividing the same length of the Vernier itself only into 10 equal parts; for then it is evident that each division on the Vernier will be $\frac{1}{10}$th part longer than the gradations on the instrument, or that the division of the former is equal to $\frac{11}{10}$ of the degree on the latter, as that gains 1 in 10 upon this.

Thus let AB be a part of the upper end of a barometer tube, the quicksilver standing at the point C; from 28 to 31 is a part of the scale of inches, viz, from 28 inches to 31 inches, divided into 10ths of inches; and the middle piece, from 1 to 10, is the Vernier, that slides up and down in a groove, and having 10 of its divisions equal to 11 tenths of the inches, for the purpose of subdividing every 10th of the inch into 10 parts, or, the inches into centesms or 100th parts. In practice, the method of counting is by observing (when the Vernier is set with its index at top pointing exactly against the upper surface of the mercury in the tube) which division of the Vernier it is that exactly, or nearest, coincides with a division in the scale of 10ths of inches, for that will shew the number of 100ths, over the 10ths of inches next below the index at top. So, in the annexed figure, the top of the Vernier is between 2 and 3 tenths above the 30 inches of the barometer; and because the 8th division of the Vernier is seen to coincide with a division of the scale, this shews that it is 8 centesms more; so that the height of the quicksilver altogether, is 30·28, that is, 30 inches, and 28 hundredths, or 2 tenths and 8 hundredths.



If the scale were not inches and 10ths, but degrees of a quadrant, &c, then the 8 would be $\frac{8}{10}$ of a degree, or 48′; or if every division on the scale be 10 minutes, then the Vernier will subdivide it into single minutes, and the 8 will then be 8 minutes. And so for any other case.

By altering the number of divisions, either in the degrees or in the Vernier, or in both, an angle can be observed to many different degrees of accuracy. Thus, if a degree on a quadrant be divided into 12 parts, each being 5 minutes, and the length of the Vernier be 21 such parts, or $1^\circ\frac{3}{4}$, and divided into 20 parts, then

$$\frac{1}{12} \times \frac{1}{20} = \frac{1^\circ}{240} = \frac{1'}{4} = 15'',$$

is the smallest division the Vernier will measure to: Or, if the length of the Vernier be $2^\circ\frac{7}{12}$, and divided into 30 parts, then

$$\frac{1}{12} \times \frac{1}{30} = \frac{1^\circ}{360} = \frac{1'}{6} = 10'',$$

is the smallest part in this case: Also

$$\frac{1}{12} \times \frac{1}{50} = \frac{1^\circ}{600} = \frac{1'}{10} = 6'',$$

is the smallest part when the Vernier extends $4^\circ\frac{1}{4}$. See Robertson's Navigation, book 5, p. 279.

For the method of applying the Vernier to a quadrant, see *Hadley's* QUADRANT. And for the application of it to a telescope, and the principles of its construction, see Smith's Optics, book 3, sect. 861.

VERSED-*Sine*, of an arch, is the part of the diameter intercepted between the sine and the commencement of the arc; and it is equal to the difference between the radius and the cosine. See *Versed*-SINE. And for *coversed sine*, see COVERSED-*Sine*.

VERTEX *of an Angle*, is the angular point, or the point where the legs or sides of the angle meet.

VERTEX *of a Figure*, is the uppermost point, or the vertex of the angle opposite to the base.

VERTEX *of a Curve*, is the extremity of the axis or diameter, or it is the point where the diameter meets the curve; which is also the vertex of the diameter.

VERTEX *of a Glass*, in Optics, the same as its pole.

VERTEX is also used, in Astronomy, for the point of the heavens vertically or perpendicularly over our heads, also called the zenith.

VERTEX, *Path of the*. See PATH.

VERTICAL, something relating to the vertex or highest point. As,

VERTICAL *Point*, in Astronomy, is the same with vertex, or zenith.—Hence a star is said to be Vertical, when it happens to be in that point which is perpendicularly over any place.

VERTICAL *Circle*, is a great circle of the sphere, passing through the zenith and nadir of a place.—The Vertical circles are also called *azimuths*. The meridian of any place is a Vertical circle, viz, that particular one which passes through the north or south point of the horizon.—All the Vertical circles intersect one another in the zenith and nadir.

The use of the Vertical circles is to estimate or measure the height of the stars &c, and their distances from the zenith, which is reckoned on these circles; and to find their eastern and western amplitude, by observing how many degrees the Vertical, in which the star rises or sets, is distant from the meridian.

Prime VERTICAL, is that Vertical circle, or azimuth, which passes through the poles of the meridian; or which is perpendicular to the meridian, and passes through the equinoctial points.

Prime VERTICALS, in Dialling. See PRIME *Verticals*.

VERTICAL *of the Sun*, is the Vertical which passes through the centre of the sun at any moment of time.—Its use is, in Dialling, to find the declination of the plane on which the dial is to be drawn, which is done by observing how many degrees that Vertical is distant from the meridian, after marking the point or line of the shadow upon the plane at any times.

VERTICAL *Dial*. See *Vertical* DIAL.

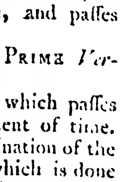
VERTICAL *Line*, in Dialling, is a line in any plane perpendicular to the horizon.——This is best found and drawn on an erect and reclining plane, by steadily holding up a string and plummet, and then marking two points of the shadow of the thread on the plane, a good distance from one another: and drawing a line through these marks.

VERTICAL *Line*, in Conics, is a line drawn on the Vertical plane, and through the vertex of the cone.

VERTICAL *Line*, in Perspective. See *Vertical* LINE.

VERTICAL *Plane*, in Conics, is a plane passing through the vertex of a cone, and parallel to any conic section.

VERTICAL *Plane*, in Perspective. See PLANE and PERSPECTIVE.



VERTICAL *Angles*, or *Opposite Angles*, in Geometry, are such as have their legs or sides continuations of each other, and which consequently have the same vertex or angular point. So the angles *a* and *b* are Vertical angles; as also the angles *c* and *d*.

VERTICITY, is that property of the magnet or loadstone, or of a needle &c touched with it, by which it turns or directs itself to some peculiar point, as to its pole.—The attraction of the magnet was known long before its Verticity.

VERU, a comet, according to some writers, resembling a spit, being nearly the same as the lonchites, only its head is rounder, and its train longer and sharper pointed.

VESPER, in Astronomy, called also *Hesperus*, and the *Evening Star*, is the planet Venus, when she is eastward of the sun, and consequently sets after him, and shines as an evening star.

VESPERTINE, in Astronomy, is when a planet is descending to the west after sun-set, or shines as an evening star.

VIA LACTEA, in Astronomy, the milky way, or Galaxy. See GALAXY.

VIA SOLIS, or *sun's way*, is used among astronomers, for the ecliptic line, or path in which the sun seems always to move.

VIBRATION, in Mechanics, a regular reciprocal motion of a body, as, for example, a pendulum, which being freely suspended, swings or vibrates from side to side.

Mechanical authors, instead of Vibration, often use the term *oscillation*, especially when speaking of a body that thus swings by means of its own gravity or weight.

The Vibrations of the same pendulum are all isochronal; that is, they are performed in an equal time, at least in the same latitude; for in lower latitudes they are found to be slower than in higher ones. See PENDULUM. In our latitude, a pendulum $39\frac{1}{8}$ inches long, vibrates seconds, making 60 Vibrations in a minute.

The Vibrations of a longer pendulum take up more time than those of a shorter one, and that in the subduplicate ratio of the lengths, or the ratio of the square roots of the lengths. Thus, if one pendulum be 40 inches long, and another only 10 inches long, the former will be double the time of the latter in performing a Vibration; for $\sqrt{40} : \sqrt{10} :: \sqrt{4} : \sqrt{1}$, that is as 2 to 1. And because the number of Vibrations, made in any given time, is reciprocally as the duration of one Vibration, therefore the number of such Vibrations is in the reciprocal subduplicate ratio of the lengths of the pendulums.

M. Monton, a priest of Lyons, wrote a treatise, expressly to shew, that by means of the number of Vibrations of a given pendulum, in a certain time, may be established an universal measure throughout the whole world; and may fix the several measures that are in use among us, in such a manner, as that they might be recovered again, if at any time they should chance to be lost, as is the case of most of the ancient measures, which we now only know by conjecture.

The VIBRATIONS *of a Stretched Chord*, or *String*, arise from its elasticity; which power being in this case similar to gravity, as acting uniformly, the Vibrations of a chord follow the same laws as those of pendulums. Consequently the Vibrations of the same chord equally stretched, though they be of unequal lengths, are isochronal, or are performed in equal times; and the squares of the times of Vibration are to one another inversely as their tensions, or powers by which they are stretched.

The Vibrations of a spring too are proportional to the powers by which it is bent. These follow the same laws as those of the chord and pendulum; and consequently are isochronal; which is the foundation of spring watches.

VIBRATIONS are also used in *Physics*, &c, and for several other regular alternate motions. Sensation, for instance, is supposed to be performed by means of the vibratory motion of the contents of the nerves, begun by external objects, and propagated to the brain.

This doctrine has been particularly illustrated by Dr. Hartley, who has extended it farther than any other writer, in establishing a new theory of our mental operations.

The same ingenious author also applies the doctrine of Vibrations to the explanation of muscular motion, which he thinks is performed in the same general manner as sensation and the perception of ideas. For a particular account of his theory, and the arguments by which it is supported, see his Observations on Man, vol. 1.

The several sorts and rays of light, Newton conceives to make Vibrations of divers magnitudes; which, according to those magnitudes, excite sensations of several colours; much after the same manner as Vibrations of air, according to their several magnitudes, excite sensations of several sounds. See the article COLOUR.

Heat, according to the same author, is only an accident of light, occasioned by the rays putting a fine, subtile, ethereal medium, which pervades all bodies, into a vibrative motion, which gives us that sensation. See HEAT.

From the Vibrations or pulses of the same medium, he accounts for the alternate fits of easy reflexion and easy transmission of the rays.

In the Philosophical Transactions it is observed, that the butterfly, into which the silk-worm is transformed, makes 130 Vibrations or motions of its wings, in one coition.

VIETA (FRANCIS), a very celebrated French mathematician, was born in 1540 at Fontenai, or Fontenaile-Comté, in Lower Poitou, a province of France. He was Master of Requests at Paris, where he died in 1603, being the 63d year of his age. Among other branches of learning in which he excelled, he was one of the most respectable mathematicians of the 16th century, or indeed of any age. His writings abound with marks of great originality, and the finest genius, as well as intense application. His application was such, that he has sometimes remained in his study for three days together, without eating or sleeping. His inventions and improvements in all parts of the mathematics were very considerable. He was in a manner the inventor and introducer of Specious Algebra, in which letters are used instead of numbers, as well as of many beautiful theorems in that science, a full explanation of which may be seen under the article ALGEBRA. He made also considerable improvements in geometry and trigonometry. His angular sections are a very ingenious and masterly performance: by these he was enabled to resolve the problem of Adrian Roman, proposed to all mathematicians, amounting to an equation of the 45th degree. Romanus was so struck with his sagacity, that he immediately quitted his residence of Wirtzbourg in Franconia, and came to France to visit him, and solicit his friendship. His Apollonius Gallus, being a restoration of Apollonius's tract on Tangencies, and many other geometrical pieces to be found in his works, shew the finest taste and genius for true geometrical speculations.—He gave some masterly tracts on Trigonometry, both plane and spherical, which may be found in the collection of his works, published at Leyden in 1646, by Schooten, besides another large and separate volume in folio, published in the author's life-time at Paris in 1579, containing extensive trigonometrical tables, with the construction and use of the same, which are particularly described in the introduction to my Logarithms, pa. 4 &c. To this complete treatise on Trigonometry, plane and spherical, are subjoined several miscellaneous problems and observations, such as, the quadrature of the circle, the duplication of the cube, &c. Computations are here given of the ratio of the diameter of a circle to the circumference, and of the length of the sine of 1 minute, both to a great many places of figures; by which he found that the sine of 1 minute is

between 2908881959
and 2908882056;

also the diameter of a circle being 1000 &c, that the perimeter of the inscribed and circumscribed polygon of 393216 sides, will be as follows, viz, the

perim. of the inscribed polygon . 31415926535
perim. of the circumscribed polygon 31415926537

and that therefore the circumference of the circle lies between those two numbers.

Vieta having observed that there were many faults in the Gregorian Calendar, as it then existed, he composed a new form of it, to which he added perpetual canons, and an explication of it, with remarks and objections against Clavius, whom he accused of having deformed the true Lelian reformation, by not rightly understanding it.

Besides those, it seems a work greatly esteemed, and the loss of which cannot be sufficiently deplored, was his *Harmonicon Cœleste*, which, being communicated to father Mersenne, was, by some perfidious acquaintance of that honest-minded person, surreptitiously taken from him, and irrecoverably lost, or suppressed, to the great detriment of the learned world. There were also, it is said, other works of an astronomical kind, that have been buried in the ruins of time.

Vieta was also a profound decipherer, an accomplishment that proved very useful to his country. As the different parts of the Spanish monarchy lay very distant from one another, when they had occasion to communicate any secret designs, they wrote them in ciphers and unknown characters, during the disorders of the league: the cipher was composed of more than 500 different characters, which yielded their hidden contents to the penetrating genius of Vieta alone. His skill so disconcerted the Spanish councils for two years, that they published it at Rome, and other parts of Europe, that the French king had only discovered their ciphers by means of magic.

VINCULUM, in Algebra, a mark or character, either drawn over, or including, or some other way accompanying, a factor, divisor, dividend, &c, when it is compounded of several letters, quantities, or terms, to connect them together as one quantity, and shew that they are to be multiplied, or divided, &c, together.

Vieta, I think, first used the bar or line over the quantities, for a Vinculum, thus $\overline{a+b}$; and Albert Girard the parenthesis thus $(a+b)$; the former way being now chiefly used by the English, and the latter by most other Europeans. Thus $\overline{a+b} \times c$, or $(a+b) \times c$, denotes the product of c and the sum $a+b$ considered as one quantity. Also $\sqrt{a+b}$, or $\sqrt{(a+b)}$, denotes the square root of the sum $a+b$. Sometimes the mark : is set before a compound factor, as a Vinculum, especially when it is very long, or an infinite series; thus $3a \times : 1 - 2x + 3x^2 - 4x^3 + 5x^5$ &c.

VINDEMIATRIX, or VINDEMIATOR, a fixed star of the third magnitude, in the northern wing of the constellation Virgo.

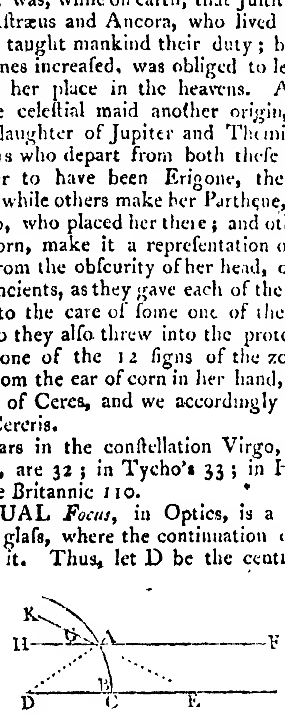
VIRGO,

VIRGO, in Astronomy, one of the signs or constellations of the zodiac, which the sun enters about the 21st or 22d of August; being one of the 48 old constellations, and is mentioned by the astronomers of all ages and nations, whose works have reached us. Anciently the figure was that of a girl, almost naked, with an ear of corn in her hand, evidently to denote the time of harvest among the people who invented this sign, whoever they were. But the Greeks much altered the figure, with clothes, wings, &c, and variously explained the origin of it by their own fables: thus, they tell us that the virgin, now exalted into the skies, was, while on earth, that Justitia, the daughter of Astræus and Ancora, who lived in the golden age, and taught mankind their duty; but who, when their crimes increased, was obliged to leave the earth, and take her place in the heavens. Again, Hesiod gives the celestial maid another origin, and says she was the daughter of Jupiter and Themis. There are also others who depart from both these accounts, and make her to have been Erigone, the daughter of Icarius: while others make her Parthene, the daughter of Apollo, who placed her there; and others, from the ear of corn, make it a representation of Ceres; and others, from the obscurity of her head, of Fortune.

The ancients, as they gave each of the 12 months of the year to the care of some one of the 12 principal deities, so they also threw into the protection of each of these one of the 12 signs of the zodiac. Hence Virgo, from the ear of corn in her hand, naturally fell to the lot of Ceres, and we accordingly find it called Signum Cereris.

The stars in the constellation Virgo, in Ptolomy's catalogue, are 32; in Tycho's 33; in Hevelius's 50; and in the Britannic 110.

VIRTUAL *Focus*, in Optics, is a point in the axis of a glass, where the continuation of a refracted ray meets it. Thus, let D be the centre, and DBE



the axis of the glass AB; upon which falls the ray FA. Now this ray will not proceed straight forward, as AH, after passing the glass, but will take the course AK, being deflected from the perpendicular AD. If then the refracted ray KA be produced, by AE, to the axis at E, this point E Mr. Molineux calls the *Virtual focus*, or *point of divergence*.

VIS, a Latin word, signifying force, or power; adopted by writers on physics, to express divers kinds of natural powers or faculties.

The term Vis is either active or passive: the *Vis activa* is the power of producing motion; the *Vis passiva* is that of receiving or losing it. The *Vis activa* is again subdivided into *Vis viva* and *Vis mortua*.

VIS *Absoluta*, or *absolute force*, is that kind of centripetal force which is measured by the motion that would be generated by it in a given body, at a given distance, and depends on the efficacy of the cause producing it.

VIS *Acceleratrix*, or *accelerating force*, is that centripetal force which produces an accelerated motion, and is proportional to the velocity which it generates in a given time; or it is as the motive or absolute force directly, and as the quantity of matter moved inversely.

VIS *Impressa* is defined by Newton to be the action exercised on any body to change its state, either of rest or moving uniformly in a right line.

This force consists altogether in the action; and has no place in the body after the action is ceased: for the body perseveres in every new state by the *Vis inertiæ* alone.

This Vis impressa may arise from various causes; as from percussion, pression, and centripetal force.

VIS *Inertiæ*, or power of inactivity, is defined by Newton to be a power implanted in all matter, by which it resists any change endeavoured to be made in its state, that is, by which it becomes difficult to alter its state, either of rest or motion.

This power then agrees with the *Vis resistendi*, or power of resisting, by which every body endeavours, as much as it can, to persevere in its own state, whether of rest or uniform rectilinear motion; which power is still proportional to the body, or to the quantity of matter in it, the same as the weight or gravity of the body; and yet it is quite different from, and even independent of the force of gravity, and would be and act just the same if the body were devoid of gravity. Thus, a body by this force resists the same in all directions, upwards or downwards or obliquely; whereas gravity acts only downwards.

Bodies only exert this power in changes brought on their state by some *Vis impressa*, force impressed on them. And the exercise of this power is, in different respects, both resistance and impetus; resistance, as the body opposes a force impressed on it to change its state; and impetus, as the same body endeavours to change the state of the resisting obstacle. Phil. Nat. Princ. Math. lib. 1.

The *Vis inertiæ*, the same great author elsewhere observes, is a passive principle, by which bodies persist in their motion or rest, and receive motion, in proportion to the force impressing it, and resist as much as they are resisted. See RESISTANCE.

VIS *Insita*, or *innate force* of matter, is a power of resisting, by which every body, as much as in it lies, endeavours to persevere in its present state, whether of rest or of moving uniformly forward in a right line. This force is always proportional to the quantity of matter in the body, and differs in nothing from the Vis inertiæ, but in our manner of conceiving it.

VIS *Centripeta*. See CENTRIPETAL *Force*.

VIS *Motrix*, or *moving force* of a centripetal body, is the tendency of the whole body towards the centre, resulting from the tendency of all the parts, and is proportional to the motion which it generates in a given time; so that the Vis motrix is to the Vis acceleratrix, as the motion is to the celerity: and as the quantity of motion in a body is estimated by the product of the velocity into the quantity of matter, so the Vis motrix arise

arises from the Vis acceleratrix multiplied by the quantity of matter.

The followers of Leibnitz use the term *Vis motrix* for the force of a body in motion, in the same sense as the Newtonians use the term *Vis inertiæ*; this latter they allow to be inherent in a body at rest; but the former, or Vis motrix, a force inherent in the same body only whilst in motion, which actually carries it from place to place, by acting upon it always with the same intensity in every physical part of the line which it describes.

Vis *Mortua*, and Vis *Viva*, in Mechanics, are terms used by Leibnitz and his followers for force, which they distinguish into two kinds, *Vis mortua*, and *Vis viva*; understanding by the former any kind of pressure, or an endeavour to move, not sufficient to produce actual motion, unless its action on a body be continued for some time; and by the latter, that force or power of acting which resides in a body in motion.

VISIBLE, something that is an object of vision or sight, or the property of a thing seen.

The Cartesians say that light alone is the proper object of vision. But according to Newton, colour alone is the proper object of sight; colour being that property of light by which the light itself is Visible, and by which the images of opake bodies are painted on the retina.

As to the Situation and Place of Visible Objects:

Philosophers in general had formerly taken for granted, that the place to which the eye refers any Visible object, seen by reflection or refraction, is that in which the visual ray meets a perpendicular from the object upon the reflecting or the refracting plane. That this is the case with respect to plane mirrors is universally acknowledged; and some experiments with mirrors of other forms seem to favour the same conclusion, and thus afford reason for extending the analogy to all cases of vision. If a right line be held perpendicularly over a convex or concave mirror, its image seems to make one line with it. The same is the case with a right line held perpendicularly within water; for the part which is within the water seems to be a continuation of that which is without. But Dr. Barrow called in question this method of judging of the place of an object, and so opened a new field of inquiry and debate in this branch of science. This, with other optical investigations, he published in his Optical Lectures, first printed in 1674. According to him, we refer every point of an object to the place from which the pencils of light issue, or from which they would have issued, if no reflecting or refracting substance intervened. Pursuing this principle, Dr. Barrow proceeded to investigate the place in which the rays issuing from each of the points of an object, and that reach the eye after one reflection or refraction, meet; and he found that when the refracting surface was plane, and the refraction was made from a denser medium into a rarer, those rays would always meet in a place between the eye and a perpendicular to the point of incidence. If a convex mirror be used, the case will be the same; but if the mirror be plane, the rays will meet in the perpendicular, and beyond it if it be concave. He also determined, according to these principles, what form the image of a right line will take when it is presented in different manners to a spherical mirror, or when it is seen through a refracting medium.

Dr. Barrow however notices an objection against the maxim above mentioned, concerning the supposed place of visible objects, and candidly owns that he was not able to give a satisfactory solution of it. The objection is this: Let an object be placed beyond the focus of a convex lens, and if the eye be close to the lens, it will appear confused, but very near to its true place. If the eye be a little withdrawn, the confusion will increase, and the object will seem to come nearer; and when the eye is very near the focus, the confusion will be very great, and the object will seem to be close to the eye. But in this experiment the eye receives no rays but those that are converging; and the point from which they issue is so far from being nearer than the object, that it is beyond it; notwithstanding which the object is conceived to be much nearer than it is, though no very distinct idea can be formed of its precise distance.

The first person who took much notice of Dr. Barrow's hypothesis, and the difficulty attending it, was Dr. Berkeley, who (in his Essay on a New Theory of Vision, p. 30) observes, that the circle formed upon the retina, by the rays which do not come to a focus, produce the same confusion in the eye, whether they cross one another before they reach the retina, or tend to it afterwards; and therefore that the judgment concerning distance will be the same in both the cases, without any regard to the place from which the rays originally issued; so that in this case, by receding from the lens, as the confusion increases, which always accompanies the nearness of an object, the mind will judge that the object comes nearer. See *Apparent* Distance.

M. Bouguer (in his Traité d'Optique, p. 104) adopts Barrow's general maxim, in supposing that we refer objects to the place from which the pencils of rays seemingly converge at their entrance into the pupil. But when rays issue from below the surface of a vessel of water, or any other refracting medium, he finds that there are always two different places of this seeming convergence: one of them of the rays that issue from it in the same vertical circle, and therefore fall with different degrees of obliquity upon the surface of the refracting medium; and another of those that fall upon the surface with the same degree of obliquity, entering the eye laterally with respect to one another. He says, sometimes one of these images is attended to by the mind, and sometimes the other; and different images may be observed by different persons. And he adds, that an object plunged in water affords an example of this duplicity of images.

G. W. Krafft has ably supported Barrow's opinion, that the place of any point seen by reflection from the surface of any medium, is that in which rays issuing from it, infinitely near to one another, would meet; and considering the case of a distant object viewed in a concave mirror, by an eye very near it, when the image, according to Euclid and other writers, would be between the eye and the object, and Barrow's rule cannot be applied, he says that in this case the speculum may

be confidered as a plane, the effect being the fame, only that the image is more obfcure. Com. Petrepol. vol. 12, p. 252, 256. See Prieftley's Hift. of Light &c, p. 89, 688.

From the principle above illuftrated feveral remarkable phenomena of vifion may be accounted for: as—That if the diftance between two Vifible objects be an angle that is infenfible, the diftant bodies will appear as if contiguous: whence, a continuous body being the refult of feveral contiguous ones, if the diftances between feveral Vifibles fubtend infenfible angles, they will appear one continuous body; which gives a pretty illuftration of the notion of a continuum.—Hence alfo parallel lines, and long viftas, confifting of parallel rows of trees, feem to converge more and more the farther they are extended from the eye; and the roofs and floors of long extended alleys feen, the former to defcend, and the latter to afcend, and approach each other; becaufe the apparent magnitudes of their perpendicular intervals are perpetually diminifhing, while at the fame time we miftake their diftance.

As to the Different Diftances of Vifible Objects:

The mind perceives the diftance of Vifible objects, 1ft, From the different configurations of the eye, and the manner in which the rays ftrike the eye, and in which the image is impreffed upon it. For the eye difpofes itfelf differently, according to the different diftances it is to fee; viz, for remote objects the pupil is dilated, and the cryftalline brought nearer the retina, and the whole eye is made more globous; on the contrary, for near objects, the pupil is contracted, the cryftalline thruft forwards, and the eye lengthened. The mode of performing this however, has greatly divided the opinions of philofophers. See Prieftley's Hift. of Light &c, p. 638—652, where the feveral opinions of Defcartes, Kepler, La Hire, are Le Roi, Porterfield, Jurin, Muffchenbroek, &c, ftated and examined.

Again, the diftance of Vifible objects is judged of by the angle the object makes; from the diftinct or confufed reprefentation of the objects; and from the brifknefs or feeblenefs, or the rarity or denfity of the rays.

To this it is owing, 1ft, That objects which appear obfcure or confufed, are judged to be more remote; a principle which the painters make ufe of to caufe fome of their figures to appear farther diftant than others on the fame plane. 2d, To this it is likewife owing, that rooms whofe walls are whitened, appear the fmaller; that fields covered with fnow, or white flowers, fhew lefs than when clothed with grafs; that mountains covered with fnow, in the night time, appear the nearer, and that opake bodies appear the more remote in the twilight.

The Magnitude of Vifible Objects.

The quantity or magnitude of Vifible objects, is known chiefly by the angle contained between two rays drawn from the two extremes of the object to the centre of the eye. An object appears fo large as is the angle it fubtends; or bodies feen under a greater angle appear greater; and thofe under a lefs angle lefs, &c. Hence the fame thing appears greater or lefs as it is nearer the eye or farther off. And this is called the apparent magnitude.

But to judge of the real magnitude of an object, we muft confider the diftance; for fince a near and a remote object may appear under equal angles, though the magnitudes be different, the diftance muft neceffarily be eftimated, becaufe the magnitude is great or fmall according as the diftance is. So that the real magnitude is in the compound ratio of the diftance and the apparent magnitude; at leaft when the fubtended angle, or apparent magnitude, is very fmall; otherwife, the real magnitude will be in a ratio compounded of the diftance and the fine of the apparent magnitude, nearly, or nearer ftill its tangent.

Hence, objects feen under the fame angle, have their magnitudes in the fame ratio as their diftances. The chord of an arc of a circle appears of equal magnitude from every point in the circumference, though one point be vaftly nearer than another. Or if the eye be fixed in any point in the circumference, and a right line be moved round fo as its extremes be always in the periphery, it will appear of the fame magnitude in every pofition. And the reafon is, becaufe the angle it fubtends is always of the fame magnitude. And hence alfo, the eye being placed in any angle of a regular polygon, the fides of it will all appear of equal magnitude; being all equal chords of a circle defcribed about it.

If the magnitude of an object directly oppofite to the eye be equal to its diftance from the eye, the whole object will be diftinctly feen, or taken in by the eye, but nothing more. And the nearer you approach an object, the lefs part you fee of it.

The leaft angle under which an ordinary object becomes vifible, is about one minute of a degree.

Of the Figure of Vifible Objects.

This is eftimated chiefly from our opinion of the fituation of the feveral parts of the object. This opinion of the fituation, &c, enables the mind to apprehend an external object under this or that figure, more juftly than any fimilitude of the images in the retina, with the object can; the images being often elliptical, oblong, &c, when the objects they exhibit to the mind are circles, or fquares, &c.

The laws of vifion, with regard to the figures of Vifible objects, are,

1. That if the centre of the eye be exactly in the direction of a right line, the line will appear only as a point.

2. If the eye be placed in the direction of a furface, it will appear only as a line.

3. If a body be oppofed directly towards the eye, fo as only one plane of the furface can radiate on it, the body will appear as a furface.

4. A remote arch, viewed by an eye in the fame plane with it, will appear as a right line.

5. A fphere, viewed at a diftance, appears a circle.

6. Angular figures, at a diftance, appear round.

7. If the eye look obliquely on the centre of a regular figure, or a circle, the true figure will not be feen; but the circle will appear oval, &c.

VISIBLE *Horizon*, *Place*, *&c.* See the substantives.

VISION, is the act of seeing, or of perceiving external objects by the organ of sight.

When an object is so disposed, that the rays of light, coming from all parts of it, enter the pupil of the eye, and present its image on the retina, that object is then seen. This is proved by experiment; for if the eye of any animal be taken out, and the skin and fat be carefully stripped off from the back part of it, till only the thin membrane, which is called the retina, remains to terminate it behind, and any object be placed before the front of the eye, the picture of that object will be seen figured as with a pencil on that membrane. There are thousands of experiments which prove that this is the mechanical effect of Vision, or seeing, but none of them all appear so conveniently as this, which is made with the very eye itself of an animal; an eye of an ox newly killed shews this happily, and with very little trouble. It will indeed appear singular in this, that the object is inverted, in the picture thus drawn of it, in the eye; and the case is the same in the eye of a living person.

Various other opinions however have been held concerning the means of Vision among philosophers.

The Platonists and Stoics held Vision to be effected by the emission of rays out of the eyes; conceiving that there was a sort of light thus darted out; which, with the light of the external air, taking hold as it were of the objects, rendered them visible; and thus returning back again to the eye, altered and new modified by the contact of the object, made an impression on the pupil, which gave the sensation of the object.

Our own countryman, Roger Bacon, distinguished as he was in many respects, also assents to the opinion that visual rays proceed from the eye; giving this reason for it, that every thing in nature is qualified to discharge its proper functions by its own powers, in the same manner as the sun, and other celestial bodies. Opus Majus, pa. 289.

The Epicureans held, that Vision is performed by the emanation of corporeal species or images from objects; or a sort of atomical effluvia continually flying off from the intimate parts of objects, to the eye.

The Peripatetics hold, with Epicurus, that Vision is performed by the reception of species; but they differ from him in the circumstances; for they will have the species (which they call *intentionales*) to be incorporeal. It is true, Aristotle's doctrine of Vision, delivered in his chapter De Aspectu, amounts to no more than this, that objects must have some intermediate body, that by this they may move the organ of sight. To which he adds, in another place, that when we perceive bodies, it is their species, not their matter, that we receive; as a seal makes an impression on wax, without the wax receiving any thing of the seal.

But this vague and obscure account the Peripatetics have thought fit to improve. Accordingly, what their master calls species, the disciples, understanding of real proper species, assert, that every visible object expresses a perfect image of itself in the air contiguous to it; and this image another, somewhat less, in the next air; and the third another; and so on till the last image arrives at the crystalline, which they hold for the chief organ of sight, or that which immediately moves the soul. These images they call *intentional species*.

The modern philosophers, as the Cartesians and Newtonians, give a better account of Vision. They all agree, that it is performed by rays of light reflected from the several points of objects received in at the pupil, refracted and collected in their passage, through the coats and humours, to the retina; and this striking, or making an impression, on so many points of it; which impression is conveyed, by the correspondent capillaments of the optic nerve, to the brain, &c.

Baptista Porta's experiments with the camera obscura, about the middle of the 16th century, convinced him that vision is performed by the intermission of something into the eye, and not by visual rays proceeding from the eye, as had been the general opinion before his time; and he was the first who fully satisfied himself and others upon this subject; though several philosophers still adhered to the old opinion.

As for the Peripatetic series or chain of images, it is a mere chimera; and Aristotle's meaning is better understood without than with them. In fact, setting these aside, the Aristotelian, Cartesian, and Newtonian doctrines of Vision, are very consistent with one another; for Newton imagines that Vision is performed chiefly by the vibrations of a fine medium (which penetrates all bodies) excited in the bottom of the eye by the rays of light, and propagated through the capillaments of the optic nerves, to the sensorium. And Des Cartes maintains, that the sun pressing the materia subtilis, with which the whole universe is every where filled, the vibrations and pulses of that matter reflected from objects, are communicated to the eye, and thence to the sensory: so that the action or vibration of a medium is equally supposed in all.

It is generally concluded then, that the images of objects are represented on the retina; which is only an expansion of the fine capillaments of the optic nerve, and from whence the optic nerve is continued into the brain. Now any motion or vibration, impressed on one extremity of the nerve, will be propagated to the other: hence the impulse of the several rays, sent from the several points of the object, will be propagated as they are on the retina (that is, in their proper colours, &c, or in particular vibrations, or modes of pressure, corresponding to them) to the place where those capillaments are interwoven into the substance of the brain. And thus is Vision brought to the common case of sensation.

Experience teaches us that the eye is capable of viewing objects at a certain distance, without any mental exertion. Beyond this distance, no mental exertion can be of any avail: but, within it, the eye possesses a power of adapting itself to the various occasions that occur, the exercise of which depends on the volition of the mind. How this is effected, is a problem that has very much engaged the attention of optical writers: but it is doubted whether it has yet been satisfactorily explained. The first theory for the solution of this problem is that of Kepler. He supposes that the ciliary processes contract the diameter of the eye, and lengthen its axis by a muscular power. But Mr. Thomas Young (in some ingenious Observations on Vision in the Philos. Trans. 1793) observes,

serves, that these processes neither appear to contain any muscular fibres, nor have any attachment by which they can be capable of performing this action.

Des Cartes ascribed this contraction and elongation to a muscularity of the crystalline, of which he supposed the ciliary processes to be the tendons: but he neither demonstrated this muscularity, nor sufficiently considered the connection with the ciliary processes.

De la Hire allows of no change in the eye, except the contraction and dilatation of the pupil: this opinion he founds on an experiment which Dr. Smith has shewn to be fallacious. Haller adopted his hypothesis, notwithstanding its inconsistency with the principles of optics and constant experience.

Dr. Pemberton supposes that the crystalline contains muscular fibres, by which one of its surfaces is flattened, while the other is made convex: but he has not demonstrated the existence of these fibres; and Dr. Jurin has proved that such a change as this is inadequate to the effect.

Dr. Porterfield conceives that the ciliary processes draw the crystalline forward, and make the cornea more convex. But the ciliary processes are incapable of this action; and it appears from Dr. Jurin's calculations, that a sufficient motion of this kind requires a very visible increase in the length of the axis of the eye; an increase which has never yet been observed.

Dr. Jurin maintains that the uvea, at its attachment to the cornea, is muscular; and that the contraction of this ring makes the cornea more convex. But this hypothesis is not sufficiently confirmed by observation.

Musschenbroek conjectures that the relaxation of this ciliary zone, which is nothing but the capsule of the vitreous humour where it receives the impression of the ciliary processes, permits the coats of the eye to push forward the crystalline and cornea. Such a voluntary relaxation however, Mr. Young observes, is wholly without example in the animal economy: besides, if it actually occurred, the coats of the eye could not act as he conceives; nor could they act in this manner without being observed. He adds, that the contraction of the ciliary zone is equally inadequate and unnecessary.

Mr. Young, having examined these theories, and some others of less moment, proceeds to investigate a more probable solution of this optical difficulty.——Adverting to the observation of Dr. Porterfield, that those who have been couched have not the power of accommodating the eye to different distances; and to the reflections of other writers on this subject; he was led to conclude that the rays of light, emitted by objects at a small distance, could only be brought to foci on the retina by a nearer approach of the crystalline to a spherical form; and he imagined that no other power was capable of producing this change, beside a muscularity of part, or of the whole of its capsule:—but, on closely examining first with the naked eye and then with a magnifier, the crystalline of an ox's eye turned out of its capsule, he discovered a structure which seemed to remove the difficulties that have long embarrassed this branch of optics.

"The crystalline of the ox, says he, is composed of various similar coats, each of which consists of six muscles, intermixed with a gelatinous substance, and attached to six membranous tendons. Three of the tendons are anterior, three posterior; their length is about two-thirds of the semidiameter of the coat; their arrangement is that of three equal and equidistant rays, meeting in the axis of the crystalline; one of the anterior is directed towards the outer angle of the eye, and one of the posterior towards the inner angle, so that the posterior are placed opposite to the middle of the interstices of the anterior: and planes passing through each of the six, and through the axis, would mark on either surface six regular equidistant rays. The muscular fibres arise from both sides of each tendon; they diverge till they reach the greatest circumference of the coat; and, having passed it, they again converge, till they are attached respectively to the sides of the nearest tendons of the opposite surface. The anterior or posterior portion of the six, viewed together, exhibits the appearance of three penniform-radiated muscles. The anterior tendons of all the coats are situated in the same planes, and the posterior ones the continuations of these planes beyond the axis. Such an arrangement of fibres can be accounted for on no other supposition than that of muscularity. This mass is inclosed in a strong membranous capsule, to which it is loosely connected by minute vessels and nerves; and the connection is more observable near its greatest circumference. Between the mass and its capsule is found a considerable quantity of an aqueous fluid, the liquid of the crystalline.

"When the will is exerted to view an object at a small distance, the influence of the mind is conveyed through the lenticular ganglion, formed from branches of the third and fifth pair of nerves by the filaments perforating the sclerotica, to the orbiculus ciliaris, which may be considered as an annular plexus of nerves and vessels; and thence by the ciliary processes to the muscle of the crystalline, which, by the contraction of its fibres, becomes more convex, and collects the diverging rays to a focus on the retina. The disposition of fibres in each coat is admirably adapted to produce this change; for, since the least surface that can contain a given bulk is that of a sphere (Simpson's Fluxions, pa. 486) the contraction of any surface must bring its contents nearer to a spherical form. The liquid of the crystalline seems to serve as a synovia in facilitating the motion, and to admit a sufficient change of the muscular part, with a smaller motion of the capsule.

Mr. Young proceeds to enquire whether these fibres can produce an alteration in the form of the lens sufficiently great to account for the known effects; and he finds, by calculation, that, supposing the crystalline to assume a spherical form, its diameter will be 642 thousandths of an inch, and its focal distance in the eye ·926. Then, disregarding the thickness of the cornea, we find (by Smith, art. 370) that such an eye will collect those rays on the retina, which diverge from a point at the distance of 12 inches and 8 tenths. This is a greater change than is necessary for an ox's eye; for if it be supposed capable of distinct vision at a distance somewhat less than 12 inches, yet it is probably far short of being able to collect parallel rays. The human crystalline is susceptible of a much greater change of form. The ciliary zone may admit of as much extension as this diminution of the diameter of the crystal-

line

ſine will require ; and its elaſticity will aſſiſt the cellular texture of the vitreous humour, and perhaps the gelatinous part of the cryſtalline, in reſtoring the indolent form.—Mr. Young apprehends that the ſole office of the optic nerve is to convey ſenſation to the brain; and that the retina does not contribute to ſupply the lens with nerves.—As the human cryſtalline reſembles that of the ox, it may reaſonably be preſumed that the action of both organs depends on the ſame general principles.

This theory of Mr. Young's however is ſtrongly oppoſed by Dr. Hoſack, (Philoſ. Tranſ. 1794, part 2, pa. 196). He conteſts the exiſtence of the muſcles, which Mr. Young has deſcribed, for ſeveral reaſons. Firſt, from the tranſparency they muſt poſſeſs; otherwiſe there would be ſome irregularity in the refraction of thoſe rays which paſs through the ſeveral parts, differing both in ſhape and denſity. Another circumſtance is the number of theſe muſcles. Mr. Young deſcribes 6 in each lamina; and as Leuwenhoek makes 2000 laminæ in all, therefore the number of muſcles muſt amount to 12 thouſand, the action of which, Dr. Hoſack apprehends, muſt exceed comprehenſion. But the exiſtence of theſe muſcles is ſtill more doubtful, if the accuracy of Dr. Hoſack's obſervations be admitted. With the aſſiſtance of the beſt glaſſes, and with the greateſt attention, he could not diſcover the ſtructure of the cryſtalline deſcribed by Mr. Young, but found it to be perfectly tranſparent. He firſt obſerved the lens in its viſcid ſtate, and then expoſed different lenſes to a moderate degree of heat, ſo that they became opaque and dry; and it was eaſy to ſeparate the diſtinct layers deſcribed by Mr. Young. Theſe were ſo numerous as not to admit of having, each of them, 6 muſcles. Another conſideration, which ſeems to prove that theſe layers poſſeſs no diſtinct muſcles, is that, in this opaque ſtate, they are not viſible, but conſiſt of an almoſt infinite number of concentric fibres, not divided into particular bundles, but ſimilar to as many of the fineſt hairs of equal thickneſs, arranged in ſimilar order. This regular ſtructure of layers, compoſed of concentric fibres, Dr. Hoſack thinks is much better adapted to the tranſmiſſion of the rays of light than the irregular ſtructure of muſcles. Beſides, it ought to be conſidered that the cryſtalline lens is not the moſt eſſential organ in viewing objects at different diſtances; and if this be the caſe, the power of the eye cannot be owing to any changes in this lens. It is a fact, ſays Dr. Hoſack, that we can, in a great degree, do without it; as is the caſe after couching or extraction, by which operation all its parts muſt be deſtroyed. Dr. Porterfield, however, and Mr. Young, on his authority, maintain that patients, after the operation of couching, have not the power of accommodating the eye to different diſtances of objects. On the whole, Dr. Hoſack concludes that no ſuch muſcles, as Mr. Young has deſcribed, exiſt, and that he muſt have been deceived by ſome other appearances that reſembled muſcles: neither will he allow the effects aſcribed to the ciliary proceſſes in changing the ſhape or ſituation of the lens.

Dr. Hoſack then proceeds to illuſtrate the ſtructure and uſe of the external muſcles of the eye; which are 6 in number, 4 called recti or ſtraight, and 2 oblique, and by means of which he thinks the buſineſs is effected. The common purpoſes to which theſe muſcles are ſubſervient are well known: but beſide theſe, Dr. Hoſack ſuggeſts that it is not inconſiſtent with the general laws of nature, nor even with the animal œconomy, to imagine that, from their combination, they ſhould have a different action and an additional uſe. In deſcribing the preciſe action of theſe muſcles, he ſuppoſes an object to be ſeen diſtinctly firſt at the diſtance of 6 feet; in which caſe the picture of it falls exactly on the retina. He then directs his attention to another object at the diſtance of 6 inches, as nearly as poſſible in the ſame line. While he is viewing this, he loſes ſight of the firſt object, though the rays proceeding from it ſtill fall on the eye; and hence he infers that the eye muſt have undergone ſome change; ſo that the rays meet either before or behind the retina. But, as rays from a more diſtant object concur ſooner than thoſe from a nearer one, the picture of the more remote object muſt fall before the retina, while the others form a diſtinct image upon it. But yet the eye continued in the ſame place; and therefore the retina muſt, by ſome means, have been removed to a greater diſtance from the fore-part of the eye, ſo as to receive the picture of the nearer object. This object, he contends, could not be ſeen diſtinctly, unleſs the retina were removed to a greater diſtance, or the refracting power of the media through which the rays paſſed were augmented:—but as the lens is the chief refracting medium, if we admit that this has no power of changing itſelf, we are under the neceſſity of adopting the firſt of theſe two ſuppoſitions.

The next object of inquiry is, how the external muſcles are capable of producing theſe changes. The recti are ſtrong, broad, and flat, and ariſe from the back part of the orbit of the eye; and, paſſing over the ball as over a pulley, they are inſerted by broad flat tendons at the anterior part of the eye. The oblique are inſerted towards the poſterior part by ſimilar tendons. When theſe different muſcles act jointly, the eye being in the horizontal poſition, and every muſcle in action contracting itſelf, the four recti by their combination muſt compreſs the various parts of the eye and lengthen its axis, while the oblique muſcles ſerve to keep the eye in its proper direction and ſituation. The convexity of the cornea, by means of its great elaſticity, is alſo increaſed in proportion to the degree of preſſure, and thus the rays of light paſſing through it are neceſſarily more converged. The elongation of the eye ſerves alſo to lengthen the media, in the aqueous, cryſtalline, and vitreous humours through which the rays paſs, ſo that their powers of refraction are proportionably increaſed. This is the general effect of the contraction of the external muſcles, according to Dr. Hoſack's ſtatement of it: to which it may be added, that we poſſeſs the ſame power of relaxing them in proportion to the greater diſtance of the object, till we arrive at the utmoſt extent of indolent Viſion. Dr. Hoſack alſo illuſtrates this hypotheſis by ſome experiments.

The miſrepreſentations of Viſion often depend upon the diſtance of the object. Thus, if an opake globe be placed at a moderate diſtance from the eye, the picture of it upon the retina will be a circle properly diverſified with light and ſhade, ſo that it will excite in the mind the ſenſation of a ſphere or globe; but, if the

the globe be placed at a great distance from the eye, the distance between those lights and shades, which form the picture of a globe, will be imperceptible, and the globe will appear no otherwise than as a circular plane. In a luminous globe, distance is not necessary in order to take off the representation of prominent and flat; an iron bullet, heated very red hot, and held but a few yards distance from the eye, appears a plane, not a prominent body; it has not the look of a globe, but of a circular plane. It is owing to this misrepresentation of Vision that we see the sun and moon flat by the naked eye, and the planets also, through telescopes, flat. It is in this light that astronomers, when they speak of the sun, moon, and planets, as they appear to our view, call them the discs of the sun, moon, and planets, which we see.

The nearer a globe is to the eye, the smaller segment of it is visible, the farther off the greater, and at a due distance the half; and, on the same principle, the nearer the globe is to the eye, the greater is its apparent diameter, that is, under the greater angle it will appear, the farther off the globe is placed, the less is its apparent diameter. This is a proposition of importance, for, on this principle, we know that the same globe, when it appears larger, is nearer to our eye, and, when smaller, is farther off from it. Therefore, as we know that the globes of the sun and moon continue always of the same size, yet appear sometimes larger, and sometimes smaller, to us, it is evident, that they are sometimes nearer, and sometimes farther off from the place whence we view them. Two globes, of different magnitude, may be made to appear of exactly the same diameter, if they be placed at different distances, and those distances be exactly proportioned to their diameters. To this it is owing, that we see the sun and moon nearly of the same diameter; they are, indeed, vastly different in real bulk, but, as the moon is placed greatly nearer to our eyes, the apparent magnitude of that little globe is nearly the same with that of the greater.

In this instance of the sun and moon (for there cannot be a more striking one) we see the misrepresentation of Vision in two or three several ways. The apparent diameters of these globes are so nearly equal, that, in their several changes of place, they do, at times, appear to us absolutely equal, or mutually greater than one another. This is often to be seen, but it is at no time so obvious, and so perfectly evinced, as in eclipses of the sun, which are total. In these we see the apparent magnitudes of the two globes vary so much according to their distances, that sometimes the moon is large enough exactly to cover the disc of the sun, sometimes it is larger, and a part of it every where extends beyond the disc of the sun; and, on the contrary, sometimes it is smaller, and, though the eclipse be absolutely central, yet it is annular, or a part of the sun's disc is seen in the middle of the eclipsed part, enlightened, and surrounding the opake body of the moon in form of a lucid ring.

When an object, which is seen above, without other objects of comparison, is of a known magnitude, we judge of its distance by its apparent magnitude; and custom teaches us to do this with tolerable accuracy. This is a practical use of the misrepresentation of Vision, and in the same manner, knowing that we see things, which are near us, distinctly, and those which are distant, confusedly, we judge of the distance of an object by the clearness, or confusion, in which we see it. We also judge yet more easily and truly of the distance of an object by comparing it to another seen at the same time, the distance of which is better known, and yet more by comparing it with several others, the distances of which are more or less known, or more or less easily judged of. These are the circumstances which assist us, even by the misrepresentation of Vision, to judge of distance; but, without one or more of these, the eye does not, in reality, enable us to judge concerning the distance of objects.

This misrepresentation, although it serves us on some occasions, yet is very limited in its effects. Thus, though it helps us greatly in distinguishing the distance of objects that are about us, both with respect to ourselves and them, and with respect to themselves with one another, yet it can do nothing with the very remote. We see that immense concave circle, in which we suppose the fixed stars to be placed, at all this vast remove from us, and no change of place that we could make to get nearer to it, would be of any avail for determining the distance of the stars from one another. If we look at three or four churches from a distance of as many miles, we see them stand in a certain position with regard to one another. If we advance a great deal nearer to them, we see that position differ, but, if we move forward only eight or ten feet, the difference is not seen.

Vision, in Optics. The laws of Vision, brought under mathematical demonstrations, make the subject of Optics, taken in the greatest latitude of that word: for, among mathematical writers, optics is generally taken, in a more restricted signification, for the doctrine of *direct Vision*; catoptrics, for the doctrine of *reflected Vision*; and dioptrics, for that of *refracted Vision*.

Direct or *Simple* Vision, is that which is performed by means of direct rays; that is, of rays passing directly, or in right lines, from the radiant point to the eye. Such is that explained in the preceding article Vision.

Reflected Vision, is that which is performed by rays reflected from speculums, or mirrors. The laws of which, see under Reflection, and Mirror.

Refracted Vision, is that which is performed by means of rays refracted, or turned out of their way, by passing through mediums of different density; chiefly through glasses and lenses. The laws of this, see under the article Refraction.

Arch of Vision. See Arch.

Distinct Vision, is that by which an object is seen distinctly. An object is said to be seen distinctly, when its outlines appear clear and well defined, and the several parts of it, if not too small, are plainly distinguishable, so that they can easily be compared one with another, in respect to their figure, size, and colour.

In order to such Distinct Vision, it had commonly been thought that all the rays of a pencil, flowing from a physical point of an object, must be exactly united in a physical, or at least in a sensible point of the retina. But Dr. Jurin has made it appear from experiments, that such an exact union of rays is not always necessary to

to Distinct Vision. He shews that objects may be seen with sufficient distinctness, though the pencils of rays issuing from the points of them do not unite precisely in the same point on the retina; but that since, in this case, pencils from every point either meet before they reach the retina, or tend to meet beyond it, the light that comes from them must cover a circular spot upon it, and will therefore paint the image larger than perfect Vision would represent it. Whence it follows, that every object placed either too near or too remote for perfect Vision, will appear larger than it is by a penumbra of light, caused by the circular spaces, which are illuminated by pencils of rays proceeding from the extremities of the object.

The smallest distance of perfect Vision, or that in which the rays of a single pencil are collected into a physical point on the retina in the generality of eyes, Dr. Jurin, from a number of observations, states at 5, 6, or 7 inches. The greatest distance of distinct and perfect Vision he found was more difficult to determine; but by considering the proportion of all the parts of the eye, and the refractive power of each, with the interval that may be discerned between two stars, the distance of which is known, he fixes it, in some cases, at 14 feet 5 inches; though Dr. Porterfield had restricted it to 27 inches only, with respect to his own eye.

For other observations on this subject, see Jurin's Essay on Distinct and Indistinct Vision, at the end of Smith's Optics; and Robins's Remarks on the same, in his Math. Tracts, vol. 2, pa. 278 &c. See also an ingenious paper on Vision in the Philos. Trans. 1793, pa. 169, by Mr. Thomas Young.

Field of VISION. See FIELD.

VISUAL, relating to sight, or seeing.

VISUAL *Angle*, is the angle under which an object is seen, or which it subtends. See ANGLE.

VISUAL *Line*. See LINE.

VISUAL *Point*, in Perspective, is a point in the horizontal line, where all the ocular rays unite. Thus, a person standing in a straight long gallery, and looking forward; the sides, floor, and cieling seem to meet and touch one another in this point, or common centre.

VISUAL *Rays*, are lines of light, conceived to come from an object to the eye.

VITELLIO, or VITELLO, a Polish mathematician of the 13th century, as he flourished about 1254. We have of his a large *Treatise on Optics*, the best edition of which is that of 1572. Vitello was the first optical writer of any consequence among the modern Europeans. He collected all that was given by Euclid, Archimedes, Ptolomy, and Alhazen; though his work is of but little use now.

VITREOUS *Humour*, or *Vitreus Humor*, denotes the third or glassy humour of the eye; thus called from its resemblance to melted glass. It lies under the crystalline; by the impression of which, its fore-part is rendered concave. It greatly exceeds in quantity both the aqueous and crystalline humours taken together, and consequently occupies much the greatest part of the cavity of the globe of the eye. Scheiner says, that the refractive power of this humour is a medium between those of the aqueous, which does not differ much from water, and of the crystalline, which is nearly the same with glass. Hawksbee makes its refractive power the same with that of water; and, according to Robertson, its specific gravity agrees nearly with that of water.

VITRUVIUS (MARCUS VITRUVIUS POLLIO), a celebrated Roman architect, of whom however nothing is known, but what is to be collected from his ten books *De Architectura*, still extant. In the preface to the sixth book he writes, that he was carefully educated by his parents; and instructed in the whole circle of arts and sciences; a circumstance which he speaks of with much gratitude, laying it down as certain, that no man can be a complete architect, without some knowledge and skill in every one of them. And in the preface to the first book he informs us, that he was known to Julius Cæsar; that he was afterwards recommended by Octavia to her brother Augustus Cæsar; and that he was so favoured and provided for by this emperor, as to be out of all fear of poverty as long as he might live.

It is supposed that Vitruvius was born either at Rome or Verona; but it is not known which. His books of architecture are addressed to Augustus Cæsar, and not only shew consummate skill in that particular science, but also very uncommon genius and natural abilities. Cardan, in his 16th book *De Subtilitate*, ranks Vitruvius as one of the 12 persons, whom he supposes to have excelled all men in the force of genius and invention; and would not have scrupled to have given him the first place, if it could be imagined that he had delivered nothing but his own discoveries. Those 12 persons were, Euclid, Archimedes, Apollonius Pergæus, Aristotle, Archytas of Tarentum, Vitruvius, Achindus, Mahomet Ibn Moses the inventor or improver of Algebra, Duns Scotus, John Suisset surnamed the Calculator, Galen, and Heber of Spain.

The architecture of Vitruvius has been often printed; but the best edition is that of Amsterdam in 1649. Perrault also, the noted French architect, gave an excellent French translation of the same, and added notes and figures: the first edition of which was published at Paris in 1673, and the second much improved, in 1684. —Mr. William Newton too, an ingenious architect, and late Surveyor to the works at Greenwich Hospital, published in 1780 &c, curious commentaries on Vitruvius, illustrated with figures; to which is added a description, with figures, of the Military Machines used by the Ancients.

VIVIANI (VINCENTIO), a celebrated Italian mathematician, was born at Florence in 1621, some say 1622. He was a disciple of the illustrious Galileo, and lived with him from the 17th to the 20th year of his age. After the death of his great master, he passed two or three years more in prosecuting geometrical studies without interruption, and in this time it was that he formed the design of his Restoration of Aristeus. This ancient geometrician, who was contemporary with Euclid, had composed five books of problems *De Locis Solidis*, the bare propositions of which were collected by Pappus, but the books are entirely lost; which Viviani undertook to restore by the force of his genius.

He broke this work off before it was finished, in order to apply himself to another of the same kind, and that

that was, to restore the 5th book of Apollonius's Conic Sections. While he was engaged in this, the famous Borelli found, in the library of the Grand Duke of Tuscany, an Arabic manuscript, with a Latin inscription, which imported, that it contained the eight books of Apollonius's Conic Sections: of which the 8th however was not found to be there. He carried this manuscript to Rome, in order to translate it, with the assistance of a professor of the Oriental languages. Viviani, very unwilling to lose the fruits of his labours, procured a certificate that he did not understand the Arabic language, and knew nothing of that manuscript: he was so jealous on this head, that he would not even suffer Borelli to send him an account of any thing relating to it. At length he finished his book, and published it, 1659, in folio, with this title, *De Maximis & Minimis Geometrica Divinatio in quintum Conicorum Apollonii Pergæi.* It was found that he had more than divined; as he seemed superior to Apollonius himself.

After this he was obliged to interrupt his studies for the service of his prince, in an affair of great importance, which was, to prevent the inundations of the Tiber, in which Cassini and he were employed for some time, though nothing was entirely executed.

In 1664 he had the honour of a pension from Louis the 14th, a prince to whom he was not subject, nor could be useful. In consequence he resolved to finish his Divination upon Aristeus, with a view to dedicate it to that prince; but he was interrupted in this task again by public works, and some negotiations which his master entrusted to him.—In 1666 he was honoured by the Grand Duke with the title of his first mathematician.—He resolved three problems, which had been proposed to all the mathematicians of Europe, and dedicated the work to the memory of Mr. Chapelain, under the title of *Enodatio Problematum* &c.—He proposed the problem of the quadrable arc, of which Leibnitz and l'Hospital gave solutions by the Calculus Differentialis.—In 1669, he was chosen to fill, in the Royal Academy of Sciences, a place among the eight foreign associates. This new favour reanimated his zeal; and he published three books of his Divination upon Aristeus, at Florence in 1701, which he dedicated to the King of France. It is a thin folio, intitled, *De Locis Solidis secunda Divinatio Geometrica*, &c. This was a second edition enlarged; the first having been printed at Florence in 1673.—Viviani laid out the fortune, which he had raised by the bounties of his prince, in building a magnificent house at Florence; in which he placed a bust of Galileo, with several inscriptions in honour of that great man; and died in 1703, at 81 years of age.

Viviani had, says Fontenelle, that innocence and simplicity of manners which persons commonly preserve, who have less commerce with men than with books; without that roughness and a certain savage fierceness which those often acquire who have only to deal with books, not with men. He was affable, modest, a fast and faithful friend, and, what includes many virtues in one, he was grateful in the highest degree for favours.

ULLAGE, *of a Cask*, in Gauging, is so much as it wants of being full.

ULTERIOR, in Geography, is applied to some part of a country or province, which, with regard to the rest of that country, is situate on the farther side of a river, or mountain, or other boundary, which divides the country into two parts.

ULTRAMUNDANE, beyond the world, is that part of the universe supposed to be without or beyond the limits of our world or system.

UMBILICUS, and Umbilical *Point*, in Geometry, the same with focus.

UMBRA, a Shadow. See Light, Shadow, Penumbra, &c.

UNCIA, a term generally used for the 12th part of a thing In which sense it occurs in Latin writers, both for a weight, called by us an *ounce*, and a measure called an *inch*.

UNCIÆ, in Algebra, first used by Vieta, are the numbers prefixed to the letters in the terms of any power of a binomial; now more usually, and generally, called *coefficients*. Thus, in the 4th power of $a + b$, viz,

$$a^4 + 4a^3b + 6a^2b^2 + 4ab^3 + b^4,$$

the Unciæ are 1, 4, 6, 4, 1.

Briggs first shewed how to find these Unciæ, one from another, in any power, independent of the foregoing powers. They are now usually found by what is called Newton's binomial theorem, which is the same rule as Briggs's in another form. See Binomial.

UNDECAGON, is a polygon of eleven sides.

If the side of a regular Undecagon be 1, its area will be $9{\cdot}3656399 = \frac{11}{4} \times$ tang. of $73\frac{7}{11}$ degrees; and therefore if this number be multiplied by the square of the side of any other regular Undecagon, the product will be the area of that Undecagon. See my Mensuration, pa. 114 &c, 2d edit.

UNDETERMINED, is sometimes used for Indeterminate.

UNDULATORY *Motion*, is applied to a motion in the air, by which its parts are agitated like the waves of the sea; as is supposed to be the case when the string of a musical instrument is struck. This Undulatory motion of the air is supposed the matter or cause of sound.—Instead of the Undulatory, some authors choose to call this a *vibratory* motion.

UNEVEN *Number*, the same as odd number, or such as cannot be divided by 2 without leaving 1 remaining. The series of Uneven Numbers are 1, 3, 5, 7, 9, &c. See Number, and Odd *Number*.

UNGULA, in Geometry, is a part cut off a cylinder, cone, &c, by a plane passing obliquely through the base, and part of the curve surface; so called from its resemblance to the (ungula) hoof of a horse &c. For the contents &c of such Ungulas, see my Mensuration, pa. 218—246, 2d edition.

UNICORN, in Astronomy. See Monoceros.

UNIFORM, or *Equable Motion*, is that by which a body passes always with the same celerity, or over equal spaces in equal times. See Motion.

In Uniform motions, the spaces described or passed over, are in the compound ratio of the times and velocities; but the spaces are simply as the times, when the velocity is given; and as the velocities, when the time is given.

UNIFORM *Matter*, in Natural Philosophy, is that which is all of the same kind and texture.

UNISON, in Music, is when two sounds are exactly alike, or the same note, or tone.

What constitutes a Unison, is the equality of the number of vibrations, made in the same time, by the two sonorous bodies.

It is a noted phenomenon in music, that an intense sound being raised, either with the voice, or a sonorous body, another sonorous body near it, whose tone is either Unison, or octave to that tone, will sound its proper note Unison, or octave, to the given note. The experiment is easily tried with the strings of two instruments; or with a voice and harpsichord; or a bell, or even a drinking glass.

This phenomenon is thus accounted for: one string being struck, and the air put into a vibratory motion by it; every other string, within the reach of that motion, will receive some impression from it: but each string can only move with a determinate velocity of recourses or vibrations; and all Unisons proceed from equal vibrations; and other concords from other proportions of vibration. The Unison string then, keeping equal pace with the sounding string, as having the same measure of vibrations, must have its motion continued, and still improved, till at length its motion become sensible, and it give a distinct sound. Other concording strings have their motions propagated in different degrees, according to the frequency of the coincidence of their vibrations with those of the sounded string: the octave therefore most sensibly; then the 5th; after which, the crossing of the motions prevents any effect.

This is illustrated, as Galileo first suggested, by the pendulum, which being set a-moving, the motion may be continued and augmented, by making frequent, light, coincident impulses; as blowing on it when the vibration is just finished: but if it be touched by any cross or opposite motion, and that frequently too, the motion will be interrupted, and cease altogether. So, of two Unison strings, if the one be forcibly struck, it communicates motion, by the air, to the other; and both performing their vibrations together, the motion of that other will be improved and heightened by the frequent impulses received from the vibrations of the first, because given precisely when the other has finished its vibration, and is ready to return: but if the vibrations of the chords be unequal in duration, there will be a crossing of motions, more or less, according to the proportion of the inequality; by which the motion of the untouched string will be so checked, as never to be sensible. And this we find to be the case in all consonances, except Unison, octave, and the fifth.

UNIT, UNITE, or UNITY, in Arithmetic, the number one, or one single individual part of discrete quantity. See NUMBER.—The place of units, is the first place on the right hand in integer numbers.

According to Euclid, Unity is not a number, for he defines number to be a multitude of Units.

UNITY, the abstract or quality which constitutes or denominates a thing *one*.

UNIVERSE, a collective name, signifying the assemblage of heaven and earth, with all things in them.

The Ancients, and after them the Cartesians, imagine the Universe to be infinite; and the reason they give is, that it implies a contradiction to suppose it finite or bounded; since it is impossible not to conceive space beyond any limits that can be assigned it; which space, according to the Cartesians, is body, and consequently part of the Universe.

UNLIKE *Quantities*, in Algebra, are such as are expressed by different letters, or by different powers of the same letter. Thus, a, and b, and a^2, and ab are all Unlike quantities.

UNLIKE *Signs*, are the different signs + and −.

UNLIMITED or *Indeterminate Problem*, is such a one as admits of many, or even of infinite answers. As, to divide a given triangle into two equal parts; or to describe a circle through two given points. See DIOPHANTINE, and INDETERMINATE.

VOID *Space*, in Physics. See VACUUM.

VOLUTE, in Architecture, a kind of spiral scroll, and used in the Ionic and Composite capitals; of which it makes the principal characteristic and ornament.

VORTEX, or *Whirlwind*, in Meteorology, a sudden, rapid, violent motion of the air, in circular whirling directions.

VORTEX is also used for an eddy or whirlpool, or a body of water, in certain seas and rivers, which runs rapidly round, forming a sort of cavity in the middle.

VORTEX, in the Cartesian Philosophy, is a system or collection of particles of matter moving the same way, and round the same axis.

Such Vortices are the grand machines by which these philosophers solve most of the motions and other phenomena of the heavenly bodies. And accordingly, the doctrine of these Vortices makes a great part of the Cartesian philosophy.

The matter of the world they hold to have been divided at the beginning into innumerable little equal particles, each endowed with an equal degree of motion, both about its own centre, and separately, so as to constitute a fluid.

Several systems, or collections of this matter, they farther hold to have been endowed with a common motion about certain points, as common centres, placed at equal distances, and that the matters, moving round these, composed so many Vortices.

Then, the primitive particles of the matter they suppose, by these intestine motions, to become, as it were, ground into spherical figures, and so to compose globules of divers magnitudes; which they call the matter of the second element: and the particles rubbed, or ground off them, to bring them to that form, they call the matter of the first element.

And since there would be more of the first element than would suffice to fill all the vacuities between the globules of the second, they suppose the remaining part to be driven towards the centre of the Vortex, by the circular motion of the globules; and that being there amassed into a sphere, it would produce a body like the sun.

This sun being thus formed, and moving about its own axis with the common matter of the Vortex, would necessarily throw out some parts of its matter, through the vacuities of the globules of the second element constituting the Vortex; and this especially at such places as are farthest from its poles; receiving, at the same time, in,

in, by these poles, as much as it loses in its equatorial parts. And, by this means, it would be able to carry round with it those globules that are nearest, with the greater velocity; and the remoter, with less. And by this means, those globules, which are nearest the centre of the sun, must be smallest; because, were they greater, or equal, they would, by reason of their velocity, have a greater centrifugal force, and recede from the centre. If it should happen, that any of these sun-like bodies, in the centres of the several Vortices, should be so incrustated, and weakened, as to be carried about in the Vortex of the true sun; if it were of less solidity, or had less motion, than the globules towards the extremity of the solar Vortex, it would descend towards the sun, till it met with globules of the same solidity, and susceptible of the same degree of motion with itself; and thus, being fixed there, it would be for ever after carried about by the motion of the Vortex, without either approaching any nearer to the sun, or receding from it; and so would become a planet.

Supposing then all this; we are next to imagine, that our system was at first divided into several Vortices, in the centre of each of which was a lucid spherical body; and that some of these, being gradually incrustated, were swallowed up by others which were larger, and more powerful, till at length they were all destroyed, and swallowed up by the largest solar Vortex; except some few which were thrown off in right lines from one Vortex to another, and so become comets.

But this doctrine of Vortices is, at best, merely hypothetical. It does not pretend to shew by what laws and means the celestial motions are effected, so much as by what means they possibly might, in case it should have so pleased the Creator. But we have another principle which accounts for the same phenomena as well, nay, better than that of Vortices; and which we plainly find has an actual existence in the nature of things: and this is gravity, or the weight of bodies.

The Vortices, then, should be thrown out of philosophy, were it only that two different adequate causes of the same phenomena are inconsistent.

But there are other objections against them. For, 1°, if the bodies of the planets and comets be carried round the sun in Vortices, the bodies with the parts of the Vortex immediately investing them, must move with the same velocity, and in the same direction; and besides, they must have the same density, or the same vis inertiæ. But it is evident, that the planets and comets move in the very same parts of the heavens with different velocity, and in different directions. It follows, therefore, that those parts of the Vortex must revolve at the same time, in different directions, and with different velocities; since one velocity, and direction, will be required for the passage of the planets, and another for that of the comets.

2°, If it were granted, that several Vortices are contained in the same space, and do penetrate each other, and revolve with divers motions; since these motions must be conformable to those of the bodies, which are perfectly regular, and performed in conic sections; it may be asked, How they should have been preserved entire so many ages, and not disturbed and confounded by the adverse actions and shocks of so much matter as they must meet withal?

3°, The number of comets is very great, and their motions are perfectly regular, observing the same laws with the planets, and moving in orbits, that are exceedingly eccentric. Accordingly, they move every way, and towards all parts of the heavens, freely pervading the planetary regions, and going frequently contrary to the order of the signs; which would be impossible unless these Vortices were away.

4°, If the planets move round the sun in Vortices, those parts of the Vortices next the planets, we have already observed, would be equally dense with the planets themselves; consequently the vortical matter, contiguous to the perimeter of the earth's orbit, would be as dense as the earth itself: and that between the orbits of the earth and Saturn, must be as dense, or denser. For a Vortex cannot maintain itself, unless the more dense parts be in the centre, and the less dense towards the circumference: and since the periodical times of the planets are in sesquialterate ratio of their distances from the sun, the parts of the Vortex must be in the same ratio. Whence it follows, that the centrifugal forces of the parts will be reciprocally as the squares of the distances. Such, therefore, as are at a greater distance from the centre, will endeavour to recede from it with the less force. Accordingly, if they be less dense, they must give way to the greater force, by which the parts nearer the centre endeavour to rise. Thus, the more dense will rise, and the less dense descend; and thus there will be a change of places, till the whole fluid matter of the Vortex be so adjusted as that it may rest in equilibrio.

Thus will the greatest part of the Vortex without the earth's orbit, have a degree of density and inactivity, not less than that of the earth itself. Whence the comets must meet with a very great resistance, which is contrary to all appearances. Cotes, Præf. ad Newt. Princip. The doctrine of Vortices, Newton observes, labours under many difficulties: for a planet to describe areas proportional to the times, the periodical times of a Vortex should be in a duplicate ratio of their distances from the sun; and for the periodical time of the planets, to be in a sesquiplicate proportion of their distances from the sun, the periodical times of the parts of the Vortex should be in the same proportion of their distances: and, lastly, for the less Vortices about Jupiter, Saturn, and the other planets, to be preserved, and swim securely in the sun's Vortex, the periodical times of the sun's Vortex should be equal. None of which proportions are found to obtain in the revolutions of the sun and planets round their axes. Phil. Nat. Princ. Math. apud Schol. Gen. in Calce.

Besides, the planets, according to this hypothesis, being carried about the sun in ellipses, and having the sun in the focus of each figure, by lines drawn from themselves to the sun, they always describe areas proportionable to the times of their revolutions, which that author shews the parts of no Vortex can do. Schol. prop. ult. lib. ii. Princip.

Again, Dr. Keill proves, in his Examination of Burnet's Theory, that if the earth were carried in a Vortex, it would move faster in the proportion of three to two,

two, when it is in Virgo, than when it is in Pisces; which all experience proves to be false.

There is, in the Philosophical Transactions, a Physico-mathematical demonstration of the impossibility and insufficiency of Vortices to account for the Celestial Phenomena; by Monf. de Sigorne. See Num. 457. Sect. vi. pa. 409 et seq.

This author endeavours to shew, that the mechanical generation of a Vortex is impossible; and that it has only an axifugal force, and not a centrifugal and centripetal one; that it is not sufficient for explaining gravity and its properties; that it destroys Kepler's astronomical laws; and therefore he concludes, with Newton, that the hypothesis of Vortices is fitter to disturb than explain the celestial motions. We must refer to the dissertation itself for the proof of these assertions. See Cartesian Philosophy.

VOSSIUS (Gerard John), one of the most learned and laborious writers of the 17th century, was of a considerable family in the Netherlands: and was born in 1577, in the Palatinate near Heidelberg, at a place where his father, John Vossius, was minister. He first learned Latin, Greek, and Philosophy at Dort, where his father had settled, and died. In 1595 he went to Leyden, where he farther pursued these studies, joining mathematics to them, in which science he made a considerable progress. He became Master of Arts and Doctor in Philosophy in 1598; and soon after, Director of the College at Dort; then, in 1614, Director of the Theological College just founded at Leyden; and, in 1618, Professor of Eloquence and Chronology in the Academy there, the same year in which appeared his History of the Pelagian Controversy. This history procured him much odium and disgrace on the continent, but an ample reward in England, where archbishop Laud obtained leave of king Charles the 1st for Vossius to hold a prebendary in the church of Canterbury, while he resided at Leyden: this was in 1629, when he came over to be installed, took a Doctor of Laws degree at Oxford, and then returned.—In 1633 he was called to Amsterdam to fill the chair of a Professor of History; where he died in 1649, at 72 years of age; after having written and published as many works as, when they came to be collected and printed at Amsterdam in 1695 &c, made 6 volumes folio, works which will long continue to be read with pleasure and profit. The principal of these are, —1. *Etymologicon Linguæ Latinæ*.—2. *De Origine & Progressu Idololatriæ*.—3. *De Historicis Græcis*.—4. *De Historicis Latinis*.—5. *De Arte Grammatica*.—6. *De Vitiis Sermonis & Glossematis Latino-Barbaris*.—7. *Institutiones Oratoriæ*.—8. *Institutiones Poeticæ*.—9. *Ars Historica*.—10. *De quatuor Artibus popularibus, Grammatice, Gymnastice, Musice, & Graphice*.—11. *De Philologia*.—12. *De Universa Matheseos Natura & Constitutione*.—13. *De Philosophia*.—14. *De Philosophorum Sectis*.—15. *De Veterum Poetarum Temporibus*.

Vossius (*Denis*), son of the foregoing Gerard John, died at 22 years of age, a prodigy of learning, whose incessant studies brought on him so immature a death. There are of his, among other smaller pieces, Notes upon Cæsar's Commentaries, and upon Maimonides on Idolatry.

Vossius (*Francis*), brother of Denis and son of Gerard John, died in 1645, after having published a Latin poem in 1640, on a naval victory gained by the celebrated Van Tromp.

Vossius (*Gerard*), brother of Denis and Francis, and son of Gerard John, wrote Notes upon Paterculus, which were printed in 1639. He was one of the most learned critics of the 17th century; but died in 1640, like his two brothers, at a very early age, and before their father.

Vossius (*Isaac*), was the youngest son of Gerard John, and the only one that survived him. He was born at Leyden in 1618, and was a man of great talents and learning. His father was his only preceptor, and his whole time was spent in studying. His merit recommended him to a correspondence with queen Christina of Sweden, who employed him in some literary commissions. At her request, he made several journeys into Sweden, where he had the honour to teach her the Greek language; though she afterwards discarded him on hearing that he intended to write against Salmasius, for whom she had a particular regard. In 1663 he received a handsome present of money from Louis the 14th of France, accompanied with a complimentary letter from the minister Colbert.—In 1670 he came over to England, when he was created Doctor of Laws at Oxford, and king Charles the 2d made him Canon of Windsor; though he knew his character well enough to say, there was nothing that Vossius refused to believe, excepting the Bible. He appears indeed, by his publications, which are neither so numerous nor so useful as his father's, to have been a most credulous man, while he afforded many circumstances to bring his religious faith in question. He died at his lodgings in Windsor Castle, in 1688; leaving behind him the best private library, as it was then supposed, in the world; which, to the shame and reproach of England, was suffered to be purchased and carried away by the university of Leyden. His publications chiefly were:—1. *Periplus Scylacis Caryandensis, &c*, 1639.—2. Justin, with Notes, 1640.—3. *Ignatii Epistolæ, & Barnabæ Epistola*, 1646.—4. *Pomponius Mela de Situ Orbis*, 1648.—5. *Dissertatio de vera Ætate Mundi, &c*, 1659.—6. *De Septuaginta Interpretibus, &c*, 1661.—7. *De Luce*, 1662.—8. *De Motu Marium & Ventorum*.—9. *De Nili & aliorum Fluminum Origine*.—10. *De Poematum Cantu & Viribus Rythmi*, 1673.—11. *De Sybillinis aliisque, quæ Christi natalem præcessere*, 1679.—12. *Catullus, & in eum Isaaci Vossii Observationes*, 1684.—13. *Variarum Observationum liber*, 1685, in which are contained the following pieces: viz, *De Antiquæ Romæ & aliarum quarundam Urbium Magnitudine; De Artibus & Scientiis Sinarum; De Origine & Progressu Pulveris Bellici apud Europæos; De Triremium & Liburnicarum Constructione; De Emendatione Longitudinum; De patefacienda per Septentrionem ad Japonenses & Indos Navigatione; De apparentibus in Luna circulis; Diurna Telluris conversione omnia gravia ad medium tendere.*

VOUSSOIRS, vault-stones, are the stones which immediately form the arch of a bridge, &c, being cut somewhat in the manner of a truncated pyramid, their under sides constituting the intrados, to which their joints

joints or ends should be every where in a perpendicular direction.

The length of the middle Vouſſoir, or key-ſtone, and which is the leaſt of all, ſhould be about $\frac{1}{15}$th or $\frac{1}{18}$th of the ſpan of the arch; from hence theſe ſtones ſhould be made larger and larger, all the way down to the impoſt; that they may the better ſuſtain the great weight which reſts upon them, without being cruſhed or broken, and that they may alſo bind the firmer together.

To find the juſt length of the Vouſſoirs, or the figure of the extrados, when that of the intrados is given; ſee my Principles of Bridges, or Emerſon's Conſtruction of Arches, in his volume of Miſcellanies.

URANIBURGH, or celeſtial town, the name of a celebrated obſervatory, in a caſtle in the little iſland Weenen, in the Sound; built by the celebrated Daniſh aſtronomer, Tycho Brahe, who furniſhed it with inſtruments for obſerving the courſe and motions of the heavenly bodies.

This obſervatory, which was finiſhed about the year 1580, had not ſubſiſted above 17 years when Tycho, who little thought to have erected an edifice of ſo ſhort a duration, and who had even publiſhed the figure and poſition of the heavens, which he had choſen for the moment to lay the firſt ſtone in, was obliged to abandon his country.

Soon after this, the perſons to whom the property of the iſland was given, demoliſhed the building: part of the ruins was diſperſed into divers places: the reſt ſerved to build Tycho a handſome ſeat upon his ancient eſtate, which to this day bears the name of Uraniburgh; and it was here that Tycho compoſed his catalogue of the ſtars. Its latitude is 55° 54′ north, and longitude 12° 47′ eaſt of Greenwich.

M. Picart, making a voyage to Uraniburgh, found that Tycho's meridian line, there drawn, deviated from the meridian of the world; which ſeems to confirm the conjecture of ſome perſons, that the poſition of the meridian line may vary.

URSA, in Aſtronomy, the Bear, a name common to two conſtellations of the northern hemiſphere, near the pole, diſtinguiſhed by *Major* and *Minor*.

Ursa *Major*, or the *Great Bear*, one of the 48 old conſtellations, and perhaps more ancient than many of the others; being familiarly known and alluded to by the oldeſt writers, and is mentioned by Homer as obſerved by navigators. It is ſuppoſed that this conſtellation is that mentioned in the book of Job, under the name of *Cheſil*, which our tranſlation has rendered Orion, where it is ſaid, "Canſt thou looſe the bands of Cheſil (Orion)?" It is farther ſaid that the Ancients repreſented each of theſe two conſtellations under the form of a waggon drawn by a team of horſes, and the Greeks originally called them waggons and two bears; they are to this day popularly called the wains, or waggons, and the greater of them Charles's Wain. Hence is remarked the propriety of the expreſſion, "looſe the bands &c," the binding and looſing being terms very applicable to a harneſs, &c.

Perhaps the Egyptians, or whoever elſe were the people that invented the conſtellations, placed thoſe ſtars, which are near the pole, in the figure of a bear, as being an animal inhabiting towards the north pole, and making neither long journeys, nor ſwift motions. But the Greeks, in their uſual way, have adapted ſome of their fables to it. They ſay this bear was Calliſto, daughter of Lycaon, king of Arcadia; that being debauched by Jupiter, he afterwards placed her in the heavens, as well as her ſon Arcturus.

The Greeks called this conſtellation Arctos and Helice, from its turning round the pole. The Latins from the name of the nymph, as variouſly written, Calliſto, Megiſto, and Flemiſto, and from the Arabians, ſometimes Feretrum Majus, the Great Bier. And the Urſa Minor, they called Feretrum Minus, the Little Bier. The Italians have followed the ſame cuſtom, and call them Cataletto. They ſpoke alſo of the Phenicians being guided by the Leſſer Bear, but the Greeks by the Greater.

There are two remarkable ſtars in this conſtellation, viz, thoſe in the middle of his body, conſidered as the two hindermoſt of the wain, and called the pointers, becauſe they always point nearly in a direction towards the north pole ſtar, and ſo are uſeful in finding this ſtar out.

The ſtars in Urſa Major, are, according to Ptolomy's catalogue, 35; in Tycho's 56; in Hevelius's 73; but in the Britannic catalogue 87.

Ursa *Minor*, the *Little Bear*, called alſo *Arctos Minor*, *Phœnice*, and *Cynoſura*, one of the 48 old conſtellations, and near the north pole, the large ſtar in the tip of its tail being very near to it, and thence called the pole-ſtar.

The Phenicians guided their navigations by this conſtellation, for which reaſon it was called Phenice, or the Phenician conſtellation. It was alſo called Cynoſura by the Greeks, becauſe, according to ſome, that was one of the dogs of the huntreſs Calliſto, or the Great Bear; but according to others Cynoſura was one of the Idæan nymphs that nurſed the infant Jupiter; and ſome ſay that Calliſto was another of them, and that, for their care, they were taken up together to the ſkies.

Ptolomy places in this conſtellation 8 ſtars, Tycho 7, Hevelius 12, and Flamſteed 24.

URSUS (Nicholas Raimarus), a very extraordinary perſon, and diſtinguiſhed in the ſcience of aſtronomy, was born at Henſtedt in Dithmarſen, in the duchy of Holſtein, about the year 1550. He was a ſwineherd in his youth, and did not begin to read till he was 18 years of age; but then he employed all the hours he could ſpare from his daily labour, in learning to read and write. He afterwards applied himſelf to learn the languages; and, having a ſtrong genius, made a rapid progreſs in Greek and Latin. He quickly learned alſo the French language, the mathematics, aſtronomy, and philoſophy; and moſt of them without the aſſiſtance of a maſter.

Having left his native country, he gained a maintenance by teaching; which he did in Denmark in 1584, and on the frontiers of Pomerania and Poland in 1585. It was in this place that he invented a new ſyſtem of aſtronomy, very little different from that of Tycho Brahe. This he communicated, in 1586, to the landgrave of Heſſe, which gave riſe to a terrible diſpute between him and Tycho. This celebrated aſtronomer charged him with being a plagiary: who, as he related, happening to come with his maſter into his ſtudy, ſaw there, drawn on a piece of paper, the figure of his

his system; and afterwards insolently boasted that he himself was the inventor of it. Ursus, upon this accusation, wrote furiously against Tycho, called the honour of his invention in question, ascribing the system to Apollonius Pergæus; and in short abused him in so brutal a manner, that he was going to be prosecuted for it.

Ursus was afterwards invited by the emperor to teach the mathematics in Prague; from which city, to avoid the presence of Tycho, he withdrew silently in 1589, and died soon after.

He made some improvements in trigonometry, and wrote several books, which discover the marks of his hasty studies; his erudition being indigested, and his style incorrect, as is almost always to be observed of persons that are late-learned.

VULPECULA *et* ANSER, the *Fox and Goose*, in Astronomy, one of the new constellations of the northern hemisphere, made out of the unformed stars by Hevelius, in which he reckons 27 stars; but Flamsteed counts 35.

W.

WAD, or WADDING, in Gunnery, a stopple of paper, hay, straw, old rope-yarn, or tow, rolled firmly up like a ball, or a short cylinder, and forced into a gun upon the powder, to keep it close in the chamber; or put up close to the shot, to keep it from rolling out, as well as, according to some, to prevent the inflamed powder from dilating round the sides of the ball, by its windage, as it passes along the chace, which it was thought would much diminish the effort of the powder. But, from the accurate experiments lately made at Woolwich, it has not been found to have any such effect.

WADHOOK, or WORM, a long pole with a screw at the end, to draw out the wad, or the charge, or paper &c from a gun.

WAGGONER, in Astronomy, is the constellation Ursa Major, or the Great Bear, called also vulgarly Charles's Wain.

WAGGONER is also used for a routier, or book of charts, describing the seas, their coasts, &c.

WALLIS (Dr. JOHN), an eminent English mathematician, was the son of a clergyman, and born at Ashford in Kent, Nov. 23. 1616. After being instructed, at different schools, in grammar learning, in Latin, Greek, and Hebrew, with the rudiments of logic, music, and the French language, he was placed in Emanuel college, Cambridge. About 1640 he entered into orders, and was chosen fellow of Queen's college. He kept his fellowship till it was vacated by his marriage, but quitted his college to be chaplain to Sir Richard Darley; after a year spent in this situation, he spent two more as chaplain to lady Vere. While he lived in this family, he cultivated the art of deciphering, which proved very useful to him on several occasions: he met with rewards and preferment from the government at home for deciphering letters for them; and it is said, that the elector of Brandenburg sent him a gold chain and medal, for explaining for him some letters written in ciphers.

In 1643 he published *Truth Tryed*, or Animadversions on lord Brooke's treatise, called The Nature of Truth &c; styling himself "a minister in London," probably of St. Gabriel Fenchurch, the sequestration of which had been granted to him.—In 1644 he was chosen one of the scribes or secretaries to the assembly of divines at Westminster.

Academical studies being much interrupted by the civil wars in both the universities, many learned men from them resorted to London, and formed assemblies there. Wallis belonged to one of these, the members of which met once a week, to discourse on philosophical matters; and this society was the rise and beginning of that which was afterwards incorporated by the name of the Royal Society, of which Wallis was one of the most early members.

The Savilian professor of geometry at Oxford being ejected by the parliamentary visitors, in 1649, Wallis was appointed to succeed him, and he opened his lectures there the same year. In 1650 he published some Animadversions on a book of Mr. Baxter's, intitled, "Aphorisms of Justification and the Covenant." And in 1653, in Latin, a Grammar of the English tongue, for the use of foreigners; to which was added, a tract *De Loquela seu Sonorum formatione, &c*, in which he considers philosophically the formation of all sounds used in articulate speech, and shews how the organs being put into certain positions, and the breath pushed out from the lungs, the person will thus be made to speak, whether he hear himself or not. Pursuing these reflections, he was led to think it possible, that a deaf person might be taught to speak, by being directed so to apply the organs of speech, as the sound of each letter required, which children learn by imitation and frequent attempts, rather than by art. He made a trial or two with success; and particularly upon one Popham, which involved him in a dispute with Dr. Holder, of which some account has already been given in the life of that gentleman.

In 1654 he took the degree of Doctor in Divinity; and the year after became engaged in a long controversy with Mr. Hobbes. This philosopher having, in 1655, printed his treatise *De Corpore Philosophico*, Dr. Wallis the same year wrote a confutation of it in Latin, under the title of *Elenchus Geometriæ Hobbianæ*; which so provoked Hobbes, that in 1656 he published it in English, with the addition of what he called, "Six Lessons to the Professors of Mathematics in Oxford." Upon this Dr. Wallis wrote an answer in English, intitled, "Due Correction for Mr. Hobbes; or School discipline for not saying his Lessons right," 1656: to which Mr. Hobbes replied in a pamphlet called "ΣΤΙΓΜΑΙ, &c, or Marks of the absurd Geometry, Rural Language, Scottish Church-politics, and Barbarisms, of John Wallis, 1657." This was immediately rejoined to by Dr. Wallis, in *Hobbiani Puncti Dispunctio*, 1657. And here this controversy seems to have ended, at this time: but in 1661 Mr. Hobbes printed *Examinatio & Emendatio Mathematicorum Hodiernorum in sex Dialogis*; which occasioned Dr. Wallis to publish the next year, *Hobbius Heautontimorumenos*, addressed to Mr. Boyle.

In 1657 he collected and published his mathematical works, in two parts, entitled, *Mathesis Universalis*, in 4to; and in 1658, *Commercium Epistolicum de Quæstionibus quibusdam Mathematicis nuper habitum*, in 4to; which was a collection of letters written by many learned men, as Lord Brounker, Sir Kenelm Digby, Fermat, Schooten, Wallis, and others.

He was this year chosen *Custos Archivorum* of the university. Upon this occasion Mr. Stubbe, who, on account of his friend Mr. Hobbes, had before waged war against Wallis, published a pamphlet, intitled, "The Savilian Professor's Case Stated," 1658. Dr. Wallis replied to this; and Mr. Stubbe republished his case, with enlargements, and a vindication against the exceptions of Dr. Wallis.

Upon the Restoration he met with great respect; the king thinking favourably of him on account of some services he had done both to himself and his father Charles the first. He was therefore confirmed in his places, also admitted one of the king's chaplains in ordinary, and appointed one of the divines empowered to revise the book of Common Prayer. He complied with the terms of the act of uniformity, and continued a steady conformist till his death. He was a very useful member of the Royal Society; and kept up a literary correspondence with many learned men. In 1670 he published his *Mechanica; sive de Motu*, 4to. In 1676 he gave an edition of *Archimedis Syracusani Arenarius & Dimensio Circuli*; and in 1682 he published from the manuscripts, *Claudii Ptolomæi Opus Harmonicum*, in Greek, with a Latin version and notes; to which he afterwards added, *Appendix de veterum Harmonica ad hodiernam comparata, &c.* In 1685 he published some theological pieces; and, about 1690, was engaged in a dispute with the Unitarians; also, in 1692, in another dispute about the Sabbath. Indeed his books upon subjects of divinity are very numerous, but nothing near so important as his mathematical works.

In 1685 he published his History and Practice of Algebra, in folio; a work that is full of learned and useful matter. Besides the works above mentioned, he published many others, particularly his *Arithmetic of Infinites*, a book of genius and good invention, and perhaps almost his only work that is so, for he was much more distinguished for his industry and judgment, than for his genius. Also a multitude of papers in the Philos. Trans. in almost every volume, from the 1st to the 25th volume. In 1697, the curators of the University press at Oxford thought it for the honour of the university to collect the doctor's mathematical works, which had been printed separately, some in Latin, some in English, and published them all together in the Latin tongue, in 3 vols folio, 1699.

Dr. Wallis died at Oxford the 28th of October 1703, in the 88th year of his age, leaving behind him one son and two daughters. We are told that he was of a vigorous constitution, and of a mind which was strong, calm, serene, and not easily ruffled or discomposed. He speaks of himself, in his letter to Mr. Smith, in a strain which shews him to have been a very cautious and prudent man, whatever his secret opinions and attachments might be: he concludes, "It hath been my endeavour all along to act by moderate principles, being willing, whatever side was uppermost, to promote any good design, for the true interest of religion, of learning, and of the public good."

WARD (Dr. Seth), an English prelate, chiefly famous for his knowledge in mathematics and astronomy, was the son of an attorney, and born at Buntingford, Hertfordshire, in 1617 or 1618. From hence he was removed and placed a student in Sidney college, Cambridge, in 1632. Here he applied with great vigour to his studies, particularly to the mathematics, and was chosen fellow of his college. In 1640 he was pitched upon by the Vice-chancellor to be Prævaricator, which at Oxford is called Terræ-filius; whose office it was to make a witty speech, and to laugh at any thing or any body: a privilege which he exercised so freely, that the Vice-chancellor actually suspended him from his degree; though he reversed the censure the day following.

The civil war breaking out, Ward was involved not a little in the consequences of it. He was ejected from his fellowship for refusing the Covenant; against which he soon after joined with several others, in drawing up that noted treatise, which was afterwards printed. Being now obliged to leave Cambridge, he resided for some time with certain friends about London, and at other times at Aldbury in Surry, with the noted mathematician Oughtred, where he prosecuted his mathematical studies. He afterwards lived for the most part, till 1649, with Mr. Ralph Freeman at Aspenden in Hertfordshire, whose sons he instructed as their preceptor; after which he resided some months with lord Wenman, of Thame Park, in Oxfordshire.

He had not been long in this family before the visitation of the university of Oxford began; the effect of which was, that many learned and eminent persons were turned out, and among them Mr. Greaves, the Savilian professor of Astronomy: this gentleman laboured to procure Ward for his successor, whose abilities in his way were universally known and acknowledged; and effected it; Dr. Wallis succeeding to the Geometry professorship at the same time. Mr. Ward then entered himself of Wadham college, for the sake of Dr.

Dr. Wilkins, who was the warden; and he presently applied himself to bring the astronomy lectures, which had long been neglected and disused, into repute again; and for this purpose he read them very constantly, never missing one reading day, all the while he held the lecture.

In 1654, both the Savilian professors did their exercises, in order to proceed doctors in divinity; and when they were to be presented, Wallis claimed precedency. This occasioned a dispute; which being decided in favour of Ward, who was really the senior, Wallis went out grand compounder, and so obtained the precedency. In 1659, Ward was chosen president of Trinity college; but was obliged at the Restoration to resign that place. He had amends made him, however, by being presented in 1660 to the rectory of St. Laurence Jewry. The same year he was also installed precentor of the church of Exeter. In 1661 he became fellow of the Royal Society, and dean of Exeter; and the year following he was advanced to the bishopric of the same church. In 1667 he was translated to the see of Salisbury; and in 1671 was made chancellor of the order of the garter; an honour which he procured to be permanently annexed to the see of Salisbury, after it had been held by laymen for above 150 years.

Dr. Ward was one of those unhappy persons who have the misfortune to survive their senses, which happened in consequence of a fever ill cured: he lived till the Revolution, but without knowing any thing of the matter; and died in January 1689, about 71 years of age. He was the author of several Latin works in astronomy and different parts of the mathematics, which were thought excellent in their day; but their use has been superseded by later improvements and the Newtonian philosophy. Some of these were,

1. A Philosophical Essay towards an Eviction of the Being and Attributes of God, &c. 1652.

2. De Cometis, &c; 4to, 1653.

3. In Ismaelis Bullialdi Astronomia Inquisitio; 4to, 1653.

4. Idea Trigonometriæ demonstratæ; 4to, 1654.

5. Astronomia Geometrica; 8vo, 1656. In this work, a method is proposed, by which the astronomy of the planets is geometrically resolved, either upon the Elliptical or Circular motion; it being in the third or last part of this work that he proposes and explains what is called Ward's Circular *Hypothesis*.

6. Exercitatio epistolica in Thomæ Hobbii Philosophiam, ad D. Joannem Wilkins; 1656, 8vo.

But that by which he hath chiefly signalized himself, as to astronomical invention, is his celebrated approximation to the true place of a planet, from a given mean anomaly, founded upon an hypothesis, that the motion of a planet, though it be really performed in an elliptic orbit, may yet be considered as equable as to angular velocity, or with an uniform circular motion round the upper focus of the ellipse, or that next the aphelion, as a centre. By this means he rendered the praxis of calculation much easier than any that could be used in resolving what has been commonly called Kepler's problem, in which the coequate anomaly was to be immediately investigated from the mean elliptic one. His hypothesis agrees very well with those orbits which are elliptical but in a very small degree, as that of the Earth and Venus: but in others, that are more elliptical, as those of Mercury, Mars, &c, this approximation stood in need of a correction, which was made by Bulliald. Both the method, and the correction, are very well explained and demonstrated, by Keill, in his Astronomy, lecture 24.

WARGENTIN (Peter), an ingenious Swedish mathematician and astronomer, was born Sept. 22, 1717, and died Dec. 13, 1783. He became secretary to the Academy at Stockholm in 1749, when he was only 32 years of age; and he became successively a member of most of the literary academies in Europe, as London, Paris, Petersburg, Gottingen, Upsal, Copenhagen, Drontheim, &c. In this country he is probably most known on account of his tables for computing the eclipses of Jupiter's satellites, which are annexed to the Nautical Almanac of 1779 I know not that he has published any separate work; but his communications were very numerous to several of those Academies of which he was a member; as the Academy of Stockholm, in which are 52 of his memoirs; in the Philosophical Transactions, the Upsal Acts, the Paris Memoirs, &c.

WATCH, a small portable machine, or movement, for measuring time; having its motion commonly regulated by a spiral spring. Perhaps, strictly speaking, watches are all such movements as *shew* the parts of time; as clocks are such as *publish* them, by striking on a bell, &c. But commonly, the term Watch is appropriated to such as are carried in the pocket; and clock to the large movements, whether they strike the hour or not.

Spring or *Pendulum* WATCHES stand pretty much on the same principle with pendulum clocks. For if a pendulum, describing small circular arcs, make vibrations of unequal lengths, in equal times, it is because it describes the greater arc with a greater velocity; so a spring put in motion, and making greater and less vibrations, as it is more or less stiff, and as it has a greater or less degree of motion given it, performs them nearly in equal times. Hence, as the vibrations of the pendulum had been applied to large clocks, to rectify the inequality of their motions; so, to correct the unequal motions of the balance in Watches, a spring is added, by the isochronism of whose vibrations the correction is to be affected. The spring is usually wound into a spiral; that, in the little compass allotted it, it may be as long as possible; and may have strength enough not to be mastered, and dragged about, by the inequalities of the balance it is to regulate. The vibrations of the two parts, viz, the spring and the balance, should be of the same length; but so adjusted, as that the spring, being more regular in the length of its vibrations than the balance, may occasionally communicate its regularity to the latter.

The Invention of Spring or Pocket Watches, is due to the last age. It is true, it is said, in the history of Charles the 5th, that a Watch was presented to that prince: but this was probably no more than a kind of clock to be set on a table: some resemblance of which we have still remaining in the ancient pieces made before the year 1670. Some accounts also say, the first Watches were made at Nuremberg in 1500, by Peter Hell,

Hell, and were called Nuremberg eggs, on account of their oval form. And, farther, that the same year George Purbach, a mathematician of Vienna, employed a watch that pointed to seconds, for astronomical observations, which was probably a kind of clock. In effect, it is between Hook and Huygens that the glory of this excellent invention lies; but to which of them it properly belongs, has been greatly disputed; the English ascribing it to the former, and the French, Dutch, &c, to the latter. Derham, in his Artificial Clockmaker, says roundly, that Dr. Hook was the inventor; and adds, that he contrived various ways of regulation: one way was with a loadstone: another with a tender straight spring, one end of which played backward and forward with the balance; so that the balance was to the spring as the ball of a pendulum, and the spring as the rod of the same: a third method was with two balances, of which there were divers sorts; some having a spiral spring to the balance for a regulator, and others without. But the way that prevailed, and which still continues in mode, was with one balance, and one spring running round the upper part of the verge of it: though this has a disadvantage, which those with two springs &c were free from; in that, a sudden jerk, or confused shake will alter its vibrations, and flurry it very much.

The time of these inventions was about the year 1658; as appears, among other evidences, from an inscription on one of the double-balance Watches presented to king Charles the second, viz, Rob. Hook inven. 1658. T. Tompion fecit, 1675. The invention soon came into repute both at home and abroad; and two of the machines were sent for by the Dauphin of France. Soon after this, M. Huygens's Watch with a spiral spring got abroad, and made a great noise in England, as if the longitude could be found by it. It is certain however, that this invention was later than the year 1673, when his book De Horol. Oscillat. was published; in which there is no mention of this, though he speaks of several other contrivances in the same way.

One of these the lord Brounker sent for out of France, where M. Huygens had got a patent for them. This Watch agreed with Dr. Hook's, in the application of the spring to the balance; only that of Huygens had a longer spiral spring, and its pulses and beats were much slower; also the balance, instead of turning quite round, as Dr. Hook's, turned several times every vibration. Huygens also invented divers other kinds of Watches, some of them without any string or chain at all, which he called pendulum Watches.

Mr. Derham suggests that he suspects Huygens's fancy was first set to work by some intelligence he might have of Hook's invention from Mr. Oldenburg, or some other of his correspondents in England; though Mr. Oldenburg vindicates himself against that charge, in the Philos. Trans. numbers 118 and 129.

Watches, since their first invention, have gone on in a continued course of improvement, and they have lately been brought to great perfection, both in England and in France, but more especially the former, particularly owing to the great encouragement that has been given to them by the Board of Longitude. Some of the chief writers and improvers of Watches, are, Le Roy, Cummins, Harrison, Mudge, Emery, and Arnold, whose Watches are now in very high repute, and in frequent use in the navy and India ships, for keeping the longitude. See Derham's Artificial Clockmaker; Cummins's Principles of Clock and Watch work; Mudge's Thoughts on the Means of improving Watches, &c.

Striking WATCHES, are such as, besides the proper Watch part, for measuring time, have a clock part, for striking the hours, &c. These are real clocks; only moved by a spring instead of a weight; and are properly called pocket-clocks.

Repeating WATCHES, are such as, by pulling a string, &c, repeat the hour, quarter, or minute, at any time of the day or night.—This repetition was the invention of Mr. Barlow, being first put in practice by him in larger movements or clocks, about the year 1676. The contrivance immediately set the other artists to work, who soon contrived divers ways of effecting the same. But its application to pocket Watches was not known before K. James the second's reign; when the ingenious inventor above mentioned was soliciting a patent for it. The talk of a patent engaged Mr. Quare to resume the thoughts of a like contrivance, which he had in view some years before: he now effected it; and being pressed to endeavour to prevent Mr. Barlow's patent, a Watch of each kind was produced before the king and council; upon trial of which, the preference was given to Mr. Quare's. The difference between them was, that Barlow's was made to repeat by pushing in two pieces on each side the Watch-box; one of which repeated the hour, and the other the quarter: whereas Quare's was made to repeat by a pin that stuck out near the pendant, which being thrust in (as now is done by thrusting in the pendant itself) repeated both the hour and quarter with the same thrust.

Of the Mechanism of a WATCH.

Watches, as well as clocks, are composed of wheels and pinions, with a regulator to direct the quickness or slowness of the wheels, and of a spring which communicates motion to the whole machine. But the regulator and spring of a Watch are vastly inferior to the weight and pendulum of a clock, neither of which can be employed in Watches. Instead of a pendulum, therefore, they are obliged to use a balance (Pl. 34, fig. 4) to regulate the motion of a Watch; and of a spring (fig. 6), which serves instead of a weight, to give motion to the wheels and balance.

The wheels of a Watch, like those of a clock, are placed in a frame, formed of two plates and four pillars. Fig. 3 represents the inside of a Watch, after the plate (Fig. 5) is taken off. A is the barrel which contains the spring (fig. 6); the chain is rolled about the barrel, with one end of it fixed to the barrel A, and the other to the fusee B.

When a Watch is wound up, the chain which was upon the barrel winds about the fusee, and by this means the spring is stretched; for the interior end of the spring is fixed by a spring to the immoveable axis, about which the barrel revolves; the exterior end of the spring is fixed to the inside of the barrel, which turns upon an axis. It is there easy to perceive how the spring extends itself, and how its elasticity forces

the

the barrel to turn round, and consequently obliges the chain which is upon the fusee to unfold and turn the fusee; the motion of the fusee is communicated to the wheel CC; then by means of the teeth, to the pinion *c*, which carries the wheel D; then to the pinion *d*, which carries the wheel E; then to the pinion *e*, which carries the wheel F; then to the pinion *f*, upon which is the balance-wheel G, whose pivot runs in the piece A, called the potance, and B called a follower, which are fixed on the plate fig. 5. This plate, of which only a part is represented, is applied to that of fig. 3, in such a manner, that the pivots of the wheels enter into holes made in the plate fig. 3. Thus the impressed force of the spring is communicated to the wheels: and the pinion *f* being then connected to the wheel F, obliges it to turn (fig. 7). This wheel acts upon the pallats of the verge 1, 2, (fig. 4) the axis of which carries the balance HH (fig. 4). The pivot I, in the end of the verge, enters into the hole G in the potance A (fig. 5). In this figure the pallats are represented; but the balance is on the other side of the plate, as may be seen in fig. 11. The pivot 3 of the balance enters into a hole of the cock BC (fig. 10), a perspective view of which is represented in fig. 12. Thus the balance, turns between the cock and the potance *c* (fig. 5), as in a kind of cage. The action of the balance-wheel upon the pallats 1, 2, (fig. 4) is the same with that of the same wheel in the clock; i. e. in a Watch the balance-wheel obliges the balance to vibrate backwards and forwards like a pendulum.

At each vibration of the balance a pallat allows a tooth of the balance-wheel to escape; so that the quickness of the motion of the wheels is entirely determined by the quickness of the vibrations of the balance, and these vibrations of the balance and motion of the wheels are produced by the action of the spring.

But the quickness or slowness of the vibrations of the balance depends not solely upon the action of the great spring, but chiefly upon the action of the spring *abc*, called the spiral spring (fig. 13) situated under the balance H, and represented in perspective (fig. 11); the exterior end of the spiral is fixed to the pin *a* (fig. 13). This pin is applied near the plate in *a* (fig. 11); the interior end of the spiral is fixed by a peg to the centre of the balance. Hence if the balance be turned upon itself, the plates remaining immoveable, the spring will extend itself, and make the balance perform one revolution. Now, after the spiral is thus extended, if the balance be left to itself, the elasticity of the spiral will bring back the balance, and in this manner the alternate vibrations of the balance are produced.

In fig. 7 all the wheels above described are represented in such a manner, that we may easily perceive at first sight how the motion is communicated from the barrel to the balance.

In fig. 8 are represented the wheels under the dial-plate, by which the hands are moved. The pinion *a* is adjusted to the force of the prolonged pivot of the wheel D (fig. 7), and is called a cannon pinion. This wheel revolves in an hour. The end of the axis of the pinion *a*, upon which the minute hand is fixed, is square; the pinion (fig. 8) is indented into the wheel *b*, which is carried by the pinion *a*. Fig. 9 is a wheel fixed upon a barrel, into the cavity of which the pinion *a* enters, and upon which it turns freely. This wheel *d* revolves in 12 hours, and carries along with it the hour-hand.

WATER, in Physiology, a clear, insipid, and colourless fluid, coagulable into a transparent solid substance, called ice, when placed in a temperature of 32° of Fahrenheit's thermometer, or lower, but volatile and fluid in every degree of heat above that; and when pure, or freed from heterogeneous particles, is reckoned one of the four elements.

By some late experiments of Messrs. Lavoisier, Watt, Cavendish, Priestley, Kirwan, &c. it appears, that Water consists of dephlogisticated air, and inflammable air or phlogiston intimately united; or, as Mr. Watt conceives, of those two principles deprived of part of their latent heat. And in some instances it appears that air and Water are mutually convertible into each other. Thus, Mr. Cavendish (Philos. Trans. vol. 74, p. 128) recites several experiments, in which he changed common air into pure Water, by decomposing it in conjunction with inflammable air. Dr. Priestley likewise, having decomposed dephlogisticated and inflammable air, by firing them together by the electric explosion, found a manifest decomposition of Water, which, as nearly as he could judge, was equal in weight to that of the decomposed air. He also made a number of other curious experiments, which seemed to favour the idea of a conversion of Water into air, without absolutely proving it. The difficulty which M. De Luc and others have found in expelling all air from Water, is best accounted for on the supposition of the generation of air from Water; and admitting that the conversion of Water into air is effected by the intimate union of what is called the principle of heat with the Water, it appears sufficiently analogous to other changes, or rather combinations, of substances. Is not, says Dr. Priestley, the acid of nitre, and also that of vitriol, a thing as unlike to air as Water is, their properties being as remarkably different? And yet it is demonstrable that the acid of nitre is convertible into the purest respirable air, and probably by the union of the same principle of heat. Philos. Trans. vol. 73, p. 414 &c.

Indeed there seems to be Water in all bodies, and particles of almost all kinds of matter in Water; so that it is hardly ever sufficiently pure to be considered as an element. Water, if it could be had alone, and pure, Boerhaave argues, would have all the requisites of an element, and be as simple as fire; but there is no expedient hitherto discovered for procuring it so pure. Rain Water, which seems the purest of all those we know of, is replete with infinite exhalations of all kinds, which it imbibes from the air: so that if filtered and distilled a thousand times, there still remain fæces. Besides this, and the numberless impurities it acquires after it is raised, by mixing with all sorts of effluvia in the atmosphere, and by falling upon and running over the earth, houses, and other places. There is also fire contained in all Water; as appears from its fluidity, which is owing to fire alone. Nor can any kinds of filtering through sand, stone, &c, free it entirely from salts &c. Nor have all the experiments that have been invented by the philosophers, ever been able to derive Water perfectly pure. Hence Boerhaave says, that he is convinced nobody ever saw a drop of pure Water; that

that the utmost of its purity known, only amounts to its being free from this or that sort of matter; and that it can never, for instance, be quite deprived of salt; since air will always accompany Water, and air always contains salt.

Water seems to be diffused everywhere, and to be present in all space wherever there is matter. There are hardly any bodies in nature but what will yield Water: it is even asserted that fire itself is not without it. A single grain of the fiery salt, which in a moment's time will penetrate through a man's hand, readily imbibes half its weight of Water, and melts even in the driest air imaginable. Among innumerable instances, hartshorn, kept 40 years, and turned as hard and dry as any metal, so that it will yield sparks of fire when struck against a flint, yet being put into a glass vessel, and distilled, will afford $\frac{1}{8}$th part of its quantity of Water. Bones dead and dried 25 years, and thus become almost as hard as iron, yet by distillation have yielded half their weight of Water. And the hardest stones, ground and distilled, always discover a portion of it. But hitherto no experiment shews, that Water enters as a principle into the combination of metallic matters, or even into that of vitrescible stones.

From such considerations, philosophers have been led to hold the opinion, that all things were made of Water. Basil Valentine, Paracelsus, Van Helmont, and others have maintained, that Water is the elemental matter or stamen of all things, and suffices alone for the production of all the visible creation. Thus too Newton: "All birds, beasts, and fishes, insects, trees, and vegetables, with their several parts, do grow out of Water, and watery tinctures, and salts; and by putrefaction they all return again to watery substances." And the same doctrine is held, and confirmed by experiments, by Van Helmont, Boyle, and others.

But Dr. Woodward endeavours to shew that the whole is a mistake.—Water containing extraneous corpuscles, some of which, according to him, are the proper matter of nutrition; the Water being still found to afford so much the less nourishment, the more it is purified by distillation. So that Water, as such, does not seem to be the proper nutriment of vegetables; but only the vehicle which contains the nutritious particles, and carries them along with it, through all the parts of the plant.

Helmont however carries his system still farther, and imagines that all bodies may be reconverted into Water. His alkahest, he affirms, adequately resolves plants, animals, and minerals, into one liquor, or more, according to their several internal differences of parts; and the alkahest, being abstracted again from these liquors, in the same weight, and with the same virtues, as when it dissolved them, the liquors may, by frequent cohobations from chalk, or some other proper matter, be totally deprived of their seminal endowments, and at last return to their first matter; which is insipid Water.

Spirit of wine, of all other spirits, seems freest from Water: yet Helmont affirms, it may be so united with Water, as to become Water itself. He adds, that it is material Water, only under a sulphureous disguise. And the same thing he observes of all salts, and of oils, which may be almost wholly changed into Water.

No standard for the Weight and Purity of WATER.—Water scarce ever continues two moments exactly of the same weight; by reason of the air and fire contained in it. The expansion of Water in boiling shews what effect the different degrees of fire have on the gravity of Water. This makes it difficult to fix the specific gravity of Water, in order to settle its degree of purity. However, the purest Water we can obtain, according to the experiments of Mr. Hawskbee, is 850 times heavier than air: or according to the experiments of Mr. Cavendish, the thermometer being at 50° and the barometer at 29¼, about 800 times as heavy as air: and according to the experiments of Sir Geo. Shuckburgh, when the barometer is at 29·27 and the thermometer at 53°, Water is 836 times heavier than air; whence also may be deduced this general proportion, which may be accounted a standard, viz, that, when the barometer is at 30° and the thermometer at 55°, then Water is 820 times heavier than air; also that in such a state the cubic foot of Water weighs 1000 ounces avoirdupois, and that of air 1·222, or $1\frac{2}{9}$ nearly, also that of mercury 13600 ounces; and for other states of the thermometer and barometer, the allowance is after this rate, viz, that the column of mercury in the barometer varies its length by the 10 thousandth part of itself for a change of each single degree of temperature, and Water changes by $\frac{1}{20000}$ part of its height or magnitude by each degree of the same. However, we have not any very exact standard in air; for Water being so much heavier than air, the more Water there is contained in the air, the heavier of course must the air be; as indeed a considerable part of the weight of the atmosphere seems to arise from the Water that is in it.

Properties and Effects of WATER.——Water is a very volatile body. It is entirely reduced into vapours and dissipated, when exposed to the fire and unconfined.

Water heated in an open vessel, acquires no more than a certain determinate degree of heat, whatever be the intensity of the fire to which it is exposed; which greatest degree of heat is when it boils violently.

It has been found that the degree of heat necessary to make Water boil, is variable, according to the purity of the Water and the weight of the atmosphere. The following table shews the degree of heat at which Water boils, at various heights of the barometer, being a medium between those resulting from the experiments of Sir Geo. Shuckburgh and Mr. De Luc:

Height of the Barometer.	Heat of Boiling Water.
Inches.	°
26	205
26½	206
27	206·9
27½	207·7
28	208·5
28½	209·4
29	210·3
29½	211·2
30	212·0
30½	212·8
31	213·6

Water

Water is found the most penetrative of all bodies, after fire; and the most difficult to confine; passing through leather, bladders, &c, which will confine air; making its way gradually through woods; and is only retainable in glass and metals; nay it was found by experiment at Florence, that when shut up in a spherical vessel of gold, which was pressed with a great force, it made its way through the pores even of the gold itself.

Water, by this penetrative quality alone, may be inferred to enter the composition of all bodies, both vegetable, animal, fossil, and even mineral; with this particular circumstance, that it is easily, and with a gentle heat, separable again from bodies it had united with.

And yet the same Water, as little cohesive as it is, and as easily separated from most bodies, will cohere firmly with some others, and bind them together in the most solid masses; as in the tempering of earth, or ashes, clay, or powdered bones, &c, with Water, and then dried and burnt, when the masses become hard as stones, though without the Water they would be mere dust or powder. Indeed it appears wonderful that Water, which is otherwise an almost universal dissolvent, should nevertheless be a great coagulator.

Some have imagined that Water is incompressible, and therefore nonelastic; founding their opinion on the celebrated Florentine experiment above mentioned, with the globe of gold; when the Water being, as they say, incapable of condensation, rather than yield, transuded through the pores of the metal, so that the ball was found wet all over the outside; till at length making a cleft in the gold, it spun out with great vehemence. But the truth of the conclusions drawn from this Florentine experiment has been very justly questioned; Mr. Canton having proved by accurate experiments, that Water is actually compressed even by the weight of the atmosphere. See COMPRESSION.

Besides, the diminution of size which Water suffers when it passes to a less degree of heat, sufficiently shews that the particles of this fluid are, like those of all other known substances, capable of approaching nearer together.

Ditch WATER, is often used as an object for the microscope, and seldom fails to afford a great variety of animalcules; often appearing of a greenish, reddish, or yellowish colour, from the great multitudes of them. And to the same cause is to be ascribed the green skim on the surface of such Water. Dunghill Water is also full of an immense crowd of animalcules.

Fresh WATER, is said of that which is insipid, or without salt, and inodorous; being the natural and pure state of the element.

Hard WATER, or *Crude* WATER, is that in which soap does not dissolve completely or uniformly, but is curdled. The dissolving power of hard Water is less than that of soft; and hence its unfitness for washing, bleaching, dyeing, boiling kitchen vegetables, &c.

The hardness of Water may arise either from salts, or from gas. That which arises from salts, may be discovered and remedied by adding some drops of a solution of fixed alkali; but the latter by boiling, or exposure to the open air.

Spring Waters are often hard, but river Water soft. Hard Waters are remarkably indisposed to corrupt; they even preserve putrescible substances for a considerable length of time: hence they seem to be best fitted for keeping at sea, especially as they are so easily softened by a little alkaline salt.

Putrid WATER, is that which has acquired an offensive smell and taste by the putrescence of animal or vegetable substances contained in it. This kind of Water is in the highest degree pernicious to the human frame, and capable of bringing on mortal diseases even by its smell. Quicklime put into water is useful to preserve it longer sweet; or even exposure to the air in broad shallow vessels. And putrid Water may be in a great measure sweetened, by passing a current of fresh air through it, from bottom to top.

Rain WATER may be considered as the purest distilled Water, but impregnated during its passage through the air with a considerable quantity of phlogistic and putrescent matter; whence it is superior to any other in fertilizing the earth. Hence also it is inferior for domestic purposes to spring or river Water, even if it could be readily procured: but such as is gotten from spouts placed below the roofs of houses, the common way of procuring it in this country, is evidently very impure, and becomes putrid in a short time.

River or *Running* WATER, is next in purity to snow or distilled water; and for domestic purposes superior to both, in having less putrescent matter, and more fixed air. That however is much the purest that runs over a clean rocky or stony bottom.

River Waters generally putrefy sooner than those of springs. During the putrefaction, they throw off a part of their heterogeneous matter, and at length become sweet again, and purer than at first; after which they commonly preserve a long time: this is remarkably the case with the Thames Water, taken up about London; which is commonly used by seamen, in their voyages.

Salt WATER, such as has much salt in it, so as to be sensible to the taste.

Sea WATER, or Water of the sea, is an assemblage of bodies, in which Water can scarce be said to have the principal part: it is an universal colluvies of all the bodies in nature, sustained and kept swimming in Water as a vehicle: being a solution of common salt, sal catharticus amarus, a selenitic substance, and a compound of muriatic acid with magnesia, mixed together in various proportions. It may be freshened by simple distillation without any addition, and thus it has sometimes been useful in long voyages at sea. Sea Water by itself has a purgative quality, owing to the salts it contains; and has been greatly recommended in scrophulous disorders.

Sea Water is about 3 parts in 100 heavier than common Water; and its temperature at great depths is from 34 to 40 degrees; but near the surface it follows more nearly the temperature of the air.

Snow WATER, is the purest of all the common Waters, when the snow has been collected pure. Kept in a warm place, in clean glass vessels, not closely stopped, but covered from dust, &c, snow-water becomes in time putrid; though in well stopped bottles it remains unaltered for several years. But distilled Water suffers no alteration in either circumstance.

Spring WATER is commonly impregnated with a

small

small portion of imperfect neutral salt, extracted from the different strata through which it percolates. Some contain a vast quantity of stony matter, which they deposit as they run along, and thus form masses of stone; sometimes incrustating various animal and vegetable matters, which they are therefore said to petrify. Spring-Water is much used for domestic purposes, and on account of its coolness is an agreeable drink; but on account of its being usually somewhat hard, is inferior to that which has run for a considerable way in a channel.

Spring-water arises from the rain, and from the mists and moisture in the atmosphere. These falling upon hills and other parts of the earth, soak into the ground, and pass along till they find a vent out again, in the form of a spring.

WATER-*Bellows*, in Mechanics, are bellows, for blowing air into furnaces, that are worked by the force of water.

WATER-*Clock*. See CLEPSYDRA.

WATER-*Engine*, an engine for extinguishing fires; or any engine to raise water; or any engine moved by the force of Water. See ENGINE, and STEAM *Engine*.

WATER-*Gage*, an instrument for measuring the depth or quantity of any water. See GAGE.

WATER-*Level*, is the true level which the surface of still Water takes, and is the truest of any.

WATER-*Logged*, in Sea-Language, denotes the state of a ship when, by receiving a great quantity of Water into her hold, by leaking, &c, she has become heavy and inactive upon the sea, so as to yield without resistance to the effort of every wave rushing over her deck.

WATER-*Machine*. See MACHINE.

WATER-*Measure*. Salt, sea-coal, &c, while on board vessels in the pool, or river, are measured with the corn-bushel heaped up; or else 5 striked pecks are allowed to the bushel. This is called Water-measure; and it exceeds Winchester-measure by about 3 gallons in the bushel.

WATER-*Microscope*. See MICROSCOPE.

WATER-*Mill*. See MILL.

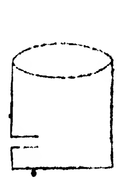
Motion of WATER, in Hydraulics. The theory of the motion of running Water is one of the principal objects of hydraulics, and to which many eminent mathematicians have paid their attention. But it were to be wished that their theories were more consistent with each other, and with experience. The inquisitive reader may consult Newton's Principia, lib. 2, pr. 36, with the comment. Dan. Bernoulli's Hydrodynamica. J. Bernoulli, Hydraulica, Oper. tom. 4, pa. 389. Dr. Jurin, in the Philos. Trans. num. 452, or Abridg. vol. 8, pa. 282. Gravesande, Physic. Elem. Mathem. lib. 3, par. 2. Maclaurin's Flux. art. 537. Poleni de Castellis, Ximenes, D'Alembert, Bossu, Buat, and many others.

But notwithstanding the labours of all these eminent authors, this intricate subject still remains in a great measure obscure and uncertain. Even the simple case of the motion of running water, when it issues from a hole in the bottom of a vessel, has never yet been determined, so as to give universal satisfaction to the learned. On this head, it is now pretty generally allowed, that the velocity of the issuing stream, is equal to that which a heavy body acquires by falling through the height of the fluid above the hole, as may be demonstrated by theory: but in practice, the quantity of the effluent Water is much less than what is given by this theory; owing to the obstruction to the motion in the hole, partly from the sides of it, and partly from the different directions of the parts of the Water in entering it, which thence obstruct each other's motion. And this obstruction, and the diminution in the quantity of Water run out, is still the more in proportion as the hole is the smaller; in such sort, that when the hole is very small, the quantity is diminished in the ratio of $\sqrt{2}$ to 1 very nearly, which is the ratio of the greatest diminution; and for larger holes, the diminution is always less and less. This fact is ascertained, or admitted by Newton, and all the other philosophers abovementioned, with some small variations.

That the velocity of the Water in the hole, or at least some part of it, as that for example in the middle of the stream, is equal to that abovementioned, is even evinced by experiment, by directing the stream either sideways, or upwards: for in the former case, it is found to range upon an horizontal plane, a distance that just answers to that velocity, by the nature of projectiles; and in the latter case, the jet rises nearly to the height of the Water in the vessel; which it could not do, if its velocity were not equal to that acquired by the free descent of a body through that height. Hence it is evident then, that the particles of the Water, which are in the hole at the same moment of time, do not all burst out with the same velocity; and, in fact, the velocity is found to decrease all the way from the middle of the hole, where it is greatest, towards the side or edge, where it is the least.

At a small distance from the hole, the diameter of the vein of Water is much less than that of the hole. Thus, if the diameter of the hole be 1, the diameter of the vein of Water just without it, will be $\frac{21}{25}$, or 0·84, according to Newton's measure, who first observed this phenomenon; and according to Poleni's measure 0·78 nearly.

By the experiments of Buat (Principes d'Hydraulique), the quantity by theory is to that by experiment, for a small hole made in the thin side of a reservoir, as 8 to 5. When a short pipe is added to the hole outwards, of the length of two or three times its diameter, that ratio is as 16 to 13. And when the short pipe is all within side the vessel, as in the margin, the same ratio becomes that of 3 to 2. Poleni also found that the quantity of Water flowing through a pipe or tube, was much greater than that through a hole of the same diameter in the thin side or bottom of the vessel, the height of the head of Water above each being the same. See also many other curious circumstances in Buat's Principes above mentioned.



Some authors give this rule for finding the height due to the velocity in a flat orifice, or a medium among all the parts of it, such that this medium velocity being drawn into the area of the hole, shall give the quantity per second that runs through: viz, let *A* denote the area

area of the surface of the Water in the vessel, a the area of the orifice by which the Water issues, and H the height of the Water above the orifice; then, as $2A - a : A :: H : h$, the height due to the medium velocity, or the height from which a body must freely descend, by the force of gravity, to acquire that mean velocity.

Authors are not yet agreed as to the force with which a vein of Water, spouting from a round hole in the side of a vessel, presses upon a plane directly opposed to the motion of the vein. Most authors agree, that the pressure of this vein, flowing uniformly, ought to be equal to the weight of a cylinder of Water, whose base is equal to the hole through which the Water flows, and its height equal to the height of the Water in the vessel above the hole. The experiments made by Mariotte, and others, seem to countenance this opinion. But Dan. Bernoulli rejects it, and estimates this pressure by the weight of a column of the fluid, whose diameter is equal to the contracted vein (according to Newton's observation abovementioned), and the height of which is equal to double the altitude due to the real velocity of the spouting Water; and this pressure is also equal to the force of repulsion, arising from the reaction of the spouting Water upon the vessel. The ingenious author remarks that he speaks only of single veins of Water, the whole of which are received by the planes upon which they press; for as to the pressures exerted by fluids surrounding the bodies they press upon, as the wind, or a river, the case is different, though confounded with the former by writers on this subject. Hydrodynamica, pa. 289.

Another rule however had been adopted by the Academicians of Paris, who made a number of experiments to confirm or establish it. Hist. Acad. Paris, ann. 1679, sect. 3, cap. 5.

D. Bernoulli, on the other hand, thinks his own theory sufficiently established by the experiments he relates; for the particulars of which see the Acta Petropolitana, vol. 8, pa. 122.

This ingenious author is of opinion that his theory of the quantity of the force of repulsion, exerted by a vein of spouting Water, might be usefully applied to move ships by pumping; and he thinks the motion produced by this repulsive force would fall little, if at all, short of that produced by rowing. He has given his reasons and computations at length in his Hydrodynamica, pa. 293 &c.

This science of the pressures exerted by Water or other fluids in motion, is what Bernoulli calls *Hydraulico-statica*. This science differs from hydrostatics, which considers only the pressure of Water, and other fluids at rest; whereas hydraulico-statics considers the pressure of Water in motion. Thus the pressure exerted by Water moving through pipes, upon the sides of those pipes, is an hydraulico-statical consideration, and has been erroneously determined by many, who have given no other rules in these cases, but such as are applicable only to the pressure of fluids at rest. See Hydrodynam. pa. 256 &c.

WATER-*Poise*. See HYDROMETER, and AREOMETER.

Dr. Hook contrived a Water-poise, which may be of good service in examining the purity &c of Water. It consists of a round glass ball, like a bolt head, about 3 inches diameter, with a narrow stem or neck, the 24th of an inch in diameter; which being poised with red lead, so as to make it but little heavier than pure sweet Water, and thus fitted to one end of a fine balance, with a counterpoise at the other end; upon the least addition of even the 2000th part of salt to a quantity of Water, half an inch of the neck will emerge above the water. Philos. Trans. num. 197.

Raising of WATER, in Hydraulics. The great use of raising Water by engines for the various purposes of life, is well known. Machines have in all ages been contrived with this view; a detail of the best of which, with the theory of their construction, would be very curious and instructive. M. Belidor has executed this in part in his Architecture Hydraulique. Dr. Desaguliers has also given a description of several engines to raise Water, in his Course of Experimental Philosophy, vol. 2; and there are several other smaller works of the same kind.

Engines for raising Water are either such as throw it up with a great velocity, as in jets; or such as raise it from one place to another by a gentle motion. For the general theory of these engines, see Bernoulli's Hydrodynamica.

Desaguliers has settled the maximum of engines for raising water, thus: a man with the best Water engine cannot raise above one hogshead of Water in a minute, 10 feet high, to hold it all day; but he can do almost twice as much for a minute or two.

WATER-*Spout*. See SPOUT.

WATER-*Wheel*; an engine for raising Water in great quantity out of a deep well, &c. See PERSIAN-*Wheel*.

WATER-*Works*. See *Raising of* WATER.

WAVE, in Physics, a volume of water elevated by the action of the wind &c, upon its surface, into a state of fluctuation, and accompanied by a cavity. The extent from the bottom or lowest point of one cavity, and across the elevation, to the bottom of the next cavity, is the breadth of the Wave.

Waves are considered as of two kinds, which may be distinguished from one another by the names of natural and accidental Waves. The natural Waves are those which are regularly proportioned in size to the strength of the wind which produces them. The accidental Waves are those occasioned by the wind's reacting upon itself by repercussion from hills or high shores, and by the dashing of the Waves themselves, otherwise of the natural kind, against rocks and shoals; by which means these Waves acquire an elevation much above what they can have in their natural state.

Mr. Boyle proved, by numerous experiments, that the most violent wind never penetrates deeper than 6 feet into the water; and it seems a natural consequence of this, that the water moved by it can only be elevated to the same height of 6 feet from the level of the surface in a calm; and these 6 feet of elevation being added to the 6 of excavation, in the part from whence that water so elevated was raised, should give 12 feet for the utmost elevation of a Wave. This is a calculation that does great honour to its author; as many experiments and observations

observations have proved that it is very nearly true in deep seas, where the Waves are purely natural, and have no accidental causes to render them larger than their just proportion.

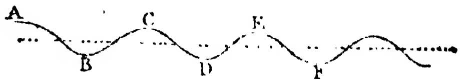
It is not to be understood however, that no Wave of the sea can rise more than 6 feet above its natural level in open and deep water; for Waves vastly higher than these are formed in violent tempests in the great seas. These however are not to be accounted Waves in their natural state, but as compound Waves formed by the union of many others; for in these wide plains of water, when one Wave is raised by the wind, and would elevate itself up to the exact height of 6 feet, and no more, the motion of the water is so great, and the succession of Waves so quick, that while this is rising, it receives into it several other Waves, each of which would have been at the same height with itself; these run into the first Wave one after another, as it is rising; by which means its rise is continued much longer than it naturally would have been, and it becomes accumulated to an enormous size. A number of these complicated Waves rising together, and being continued in a long succession by the continuation of the storm, make the Waves so dangerous to ships, which the sailors in their phrase call mountains high.

Different Waves do not disturb one another when they move in different directions. The reason is, that whatever figure the surface of the water has acquired by the motion of the Waves, there may in that be an elevation and depression; as also such a motion as is required in the motion of a Wave.

Waves are often produced by the motion of a tremulous body, which also expand themselves circularly, though the body goes and returns in a right line; for the water which is raised by the agitation, descending, forms a cavity, which is every where surrounded with a rising.

The Motion of the WAVES, makes an article in the Newtonian philosophy; that author having explained their motions, and calculated their velocity from mathematical principles, similar to the motion of a pendulum, and to the reciprocation of water in the two legs of a bent and inverted syphon or tube.

His proposition concerning such canal or tube is the 44th of the 2d book of his Principia, and is this: "If water ascend and descend alternately in the erected legs of a canal or pipe; and a pendulum be constructed, whose length between the point of suspension and the centre of oscillation, is equal to half the length of the water in the canal; then the water will ascend and descend in the same times in which the pendulum oscillates." The author hence infers, in prop. 45, that the velocity of Waves is in the subduplicate ratio of their breadths; and in prop. 46, he proceeds "To find the velocity of Waves," as follows: "Let a pendulum be constructed, whose length between the point of suspension and the centre of oscillation is equal to the breadth of the Waves; and in the time that the pendulum will perform one single oscillation, the Waves will advance forward nearly a space equal to their breadth. That which I call the breadth of the Waves, is the transverse measure lying between the deepest part of the hollows, or between the tops of the ridges. Let ABCDEF represent the surface of stagnant water ascending and descending in successive Waves; also let



A, C, E, &c, be the tops of the Waves; and B, D, F, &c, the intermediate hollows. Because the motion of the Waves is carried on by the successive ascent and descent of the water, so that the parts of it, as A, C, E, &c, which are highest at one time, become lowest immediately after; and because the motive force, by which the highest parts descend and the lowest ascend, is the weight of the elevated water, that alternate ascent and descent will be analogous to the reciprocal motion of the water in the canal, and observe the same laws as to the times of its ascent and descent; and therefore (by prop. 44, above mentioned) if the distances between the highest places of the Waves A, C, E, and the lowest B, D, F, be equal to twice the length of any pendulum, the highest parts A, C, E, will become the lowest in the time of one oscillation, and in the time of another oscillation will ascend again. Therefore between the passage of each Wave, the time of two oscillations will intervene; that is, the Wave will describe its breadth in the time that the pendulum will oscillate twice; but a pendulum of 4 times that length, and which therefore is equal to the breadth of the Waves, will just oscillate once in that time. *Q. E. I.*

"*Corol.* 1. Therefore Waves, whose breadth is equal to 39⅛ inches, or 3$\frac{7}{24}$ feet, will advance through a space equal to their breadth in one second of time; and therefore in one minute they will go over a space of 195⅚ feet; and in an hour a space of 11737 feet, nearly, or 2 miles and almost a quarter.

"*Corol.* 2. And the velocity of greater or less Waves, will be augmented or diminished in the subduplicate ratio of their breadth.

"These things (Newton adds) are true upon the supposition, that the parts of water ascend or descend in a right line; but in fact, that ascent and descent is rather performed in a circle; and therefore I propose the time defined by this proposition as only near the truth."

Stilling WAVES *by means of Oil.* This wonderful property, though well known to the Ancients, as appears from the writings of Pliny, was for many ages either quite unnoticed, or treated as fabulous by succeeding philosophers. Of late it has, by means of Dr. Franklin, again attracted the attention of the learned, though it appears, from some anecdotes, that seafaring people have always been acquainted with it. In Martin's description of the Western Islands of Scotland, we have the following passage: "The steward of Kilda, who lives in Pabbay, is accustomed, in time of a storm, to tie a bundle of puddings, made of the fat of sea-fowl, to the end of his cable, and lets it fall into the sea behind his rudder. This, he says, hinders the Waves from breaking, and calms the sea." Mr. Pennant, in his British Zoology, vol. iv, under the article

Seal,

Seal, takes notice, that when these animals are devouring a very oily fish, which they always do under water, the Waves above are remarkably smooth; and by this mark the fishermen know where to find them. Sir Gilbert Lawson, who served long in the army at Gibraltar, assured Dr. Franklin, that the fishermen in that place are accustomed to pour a little oil on the sea, in order to still its motion, that they may be enabled to see the oysters lying at its bottom, which are there very large, and which they take up with a proper instrument. A similar practice obtains among fishermen in various other parts, and Dr. Franklin was informed by an old sea-captain, that the fishermen of Lisbon, when about to return into the river, if they saw too great a surf upon the bar, would empty a bottle or two of oil into the sea, which would suppress the breakers, and allow them to pass freely.

The Doctor having revolved in his mind all these pieces of information, became impatient to try the experiment himself. At last having an opportunity of observing a large pond very rough with the wind, he dropped a small quantity of oil upon it. But having at first applied it on the lee-side, the oil was driven back again upon the shore. He then went to the windward side, and poured on about a tea-spoon full of oil; this produced an instant calm over a space several yards square, which spread amazingly, and extended itself gradually till it came to the lee-side; making all that quarter of the pond, perhaps half an acre, as smooth as glass. This experiment was often repeated in different places, and always with success. Our author accounts for it in the following manner:

"There seems to be no natural repulsion between water and air, to keep them from coming into contact with each other. Hence we find a quantity of air in water; and if we extract it by means of the air pump, the same water again exposed to the air will soon imbibe an equal quantity.—Therefore air in motion, which is wind, in passing over the smooth surface of water, may rub as it were upon that surface, and raise it into wrinkles; which, if the wind continues, are the elements of future Waves. The smallest Wave once raised does not immediately subside and leave the neighbouring water quiet; but in subsiding raises nearly as much of the water next to it, the friction of the parts making little difference. Thus a stone dropped into a pool raises first a single Wave round itself, and leaves it, by sinking to the bottom; but that first Wave subsiding raises a second, the second a third, and so on in circles to a great extent.

"A small power continually operating, will produce a great action. A finger applied to a weighty suspended bell, can at first move it but little; if repeatedly applied, though with no greater strength, the motion increases till the bell swings to its utmost height, and with a force that cannot be resisted by the whole strength of the arm and body. Thus the small first raised Waves being continually acted upon by the wind, are, though the wind does not increase in strength, continually increased in magnitude, rising higher and extending their bases, so as to include a vast mass of water in each Wave, which in its motion acts with great violence. But if there be a mutual repulsion between the particles of oil, and no attraction between oil and water, oil dropped on water will not be held together by adhesion to the spot whereon it falls; it will not be imbibed by the water; it will be at liberty to expand itself; and it will spread on a surface that, besides being smooth to the most perfect degree of polish, prevents, perhaps by repelling the oil, all immediate contact, keeping it at a minute distance from itself; and the expansion will continue, till the mutual repulsion between the particles of the oil is weakened and reduced to nothing by their distance.

"Now I imagine that the wind blowing over water thus covered with a film of oil cannot easily catch upon it, so as to raise the first wrinkles, but slides over it, and leaves it smooth as it finds it. It moves the oil a little indeed, which being between it and the water, serves it to slide with, and prevents friction, as oil does between those parts of a machine that would otherwise rub hard together. Hence the oil dropped on the windward side of a pond proceeds gradually to leeward, as may be seen by the smoothness it carries with it quite to the opposite side. For the wind being thus prevented from raising the first wrinkles that I call the elements of Waves, cannot produce Waves, which are to be made by continually acting upon and enlarging those elements; and thus the whole pond is calmed.

"Totally therefore we might suppress the Waves in any required place, if we could come at the windward place where they take their rise. This in the ocean can seldom if ever be done. But perhaps something may be done on particular occasions to moderate the violence of the Waves when we are in the midst of them, and prevent their breaking when that would be inconvenient. For when the wind blows fresh, there are continually rising on the back of every great Wave a number of small ones, which roughen its surface, and give the wind hold, as it were, to push it with greater force. This hold is diminished by preventing the generation of those small ones. And possibly too, when a Wave's surface is oiled, the wind, in passing over it, may rather in some degree press it down, and contribute to prevent its rising again, instead of promoting it.

"This, as mere conjecture, would have little weight, if the apparent effects of pouring oil into the midst of Waves were not considerable, and as yet not otherwise accounted for.

"When the wind blows so fresh, as that the Waves are not sufficiently quick in obeying its impulse, their tops being thinner and lighter, are pushed forward, broken, and turned over in a white foam. Common Waves lift a vessel without entering it; but these, when large, sometimes break above and pour over it, doing great damage.

"That this effect might in any degree be prevented, or the height and violence of Waves in the sea moderated, we had no certain account; Pliny's authority for the practice of seamen in his time being slighted. But discoursing lately on this subject with his excellency Count Bentinck of Holland, his son the honourable Captain Bentinck, and the learned professor Allemand (to all whom I showed the experiment of smoothing in a windy day the large piece of water at the head of the green

green park), a letter was mentioned which had been received by the Count from Batavia, relative to the ſaving of a Dutch ſhip in a ſtorm by pouring oil into the ſea."

WAY *of a Ship*, is ſometimes uſed for her wake or track. But more commonly the term is underſtood of the courſe or progreſs which ſhe makes on the water under ſail: thus, when ſhe begins her motion, ſhe is ſaid to be *under Way*; when that motion increaſes, ſhe is ſaid to have *freſh Way* through the water; when ſhe goes apace, they ſay *ſhe has a good Way*; and the account of her rate of ſailing by the log, they call, *keeping an account of her Way*. And becauſe moſt ſhips are apt to fall a little to the leeward of their true courſe; it is cuſtomary, in caſting up the log-board, to allow ſomething for her *leeward Way*, or *leeway*. Hence alſo a ſhip is ſaid to have *head-Way*, and *ſtern-Way*.

WAYWISER, an inſtrument for meaſuring the road, or diſtance travelled; called alſo PERAMBULATOR, and PEDOMETER. See theſe two articles.

Mr. Lovell Edgworth communicated to the Society of Arts, &c, an account of a Way-wiſer of his invention; for which he obtained a ſilver medal. This machine conſiſts of a nave, formed of two round flat pieces of wood, 1 inch thick and 9 inches in diameter. In each of the pieces there are cut eleven grooves, ⅛ of an inch wide, and ⅜ deep; and when the two pieces are ſcrewed together, they encloſe eleven ſpokes, forming a wheel of ſpokes, without a rim: the circumference of the wheel is exactly one pole; and the inſtrument may be eaſily taken to pieces, and put up in a ſmall compaſs. On each of the ſpokes there is driven a ferril, to prevent them from wearing out; and in the centre of the nave, there is a ſquare hole to receive an axle. Into this hole is inſerted an iron or braſs rod, which has the thread of a very fine ſcrew worked upon it from one end to the other; upon this ſcrew hangs a nut which, as the rod turns round with the wheel, advances towards the nave of the wheel or recedes from it. The nut does this, becauſe it is prevented from turning round with the axle, by having its centre of gravity placed at ſome diſtance below the rod, ſo as always to hang perpendicularly like a plummet. Two ſides of this ſcrew are filed away flat, and have figures engraved upon them, to ſhew by the progreſſive motion of the nut, how many circumvolutions of the wheel and its axle have been made: on one ſide the diviſions of miles, furlongs, and poles are in a direct order, and on the other ſide the ſame diviſions are placed in a retrograde order.

If the perſon who uſes this machine places it at his right hand ſide, holding the axle looſely in his hands, and walks forward, the wheel will revolve, and the nut advance from the extremity of the rod towards the nave of the wheel. When two miles have been meaſured, it will have come cloſe to the wheel. But to continue this meaſurement, nothing more is neceſſary than to place the wheel at the left hand of the operator; and the nut will, as he continues the courſe, recede from the axletree, till another ſpace of two miles is meaſured.

It appears from the conſtruction of this machine, that it operates like circular compaſſes; and does not, like the common wheel Way-wiſer, meaſure the ſurface of every ſtone and molehill, &c, but paſſes over moſt of the obſtacles it meets with, and meaſures the chords only, inſtead of the arcs of any curved ſurfaces upon which it rolls.

WEATHER, denotes the ſtate or diſpoſition of the atmoſphere, with regard to heat and cold, drought and moiſture, fair or foul, wind, rain, hail, froſt, ſnow, fog, &c. See ATMOSPHERE, HAIL, HEAT, FROST, RAIN, &c.

There does not ſeem in all philoſophy any thing of more immediate concernment to us, than the ſtate of the Weather; as it is in, and by means of the atmoſphere, that all plants are nouriſhed, and all animals live and breathe; and as any alterations in the denſity, heat, purity, &c, of that, muſt neceſſarily be attended with proportionable ones in the ſtate of theſe.

The great, but regular alterations, a little change of Weather makes in many parts of inanimate matter, every perſon knows, in the common inſtance of barometers, thermometers, hygrometers, &c; and it is owing partly to our inattention, and partly to our unequal and intemperate courſe of life, that we alſo, like many other animals, do not feel as great and as regular ones in the tubes, chords, and fibres of our own bodies.

To eſtabliſh a proper theory of the Weather, it would be neceſſary to have regiſters carefully kept in divers parts of the globe, for a long ſeries of years; from whence we might be enabled to determine the directions, breadth, and bounds of the winds, and of the weather they bring with them; with the correſpondence between the Weather of divers places, and the difference between one ſort and another at the ſame place. We might thus in time learn to foretell many great emergencies; as, extraordinary heats, rains, froſts, droughts, dearths, and even plagues, and other epidemical diſeaſes, &c.

It is however but very few, and partial regiſters or accounts of the Weather, that have been kept. The Royal Society, the French Academy, and a few particular philoſophers, have at times kept ſuch regiſters as their fancies have dictated, but at no time a regular and correſpondent ſeries in many different places, at the ſame time, followed with particular compariſons and deductions from the whole, &c. The moſt of what has been done in this way, is as follows: The volumes of the Philoſophical Tranſactions from year to year; the ſame, for inſtructions and examples pertaining to the ſubject, vol. 65, part 2, art. 16; Eraſ. Bartholin has obſervations of the Weather for every day in the year 1671: Mr. W. Merle made the like at Oxford, for 7 years: Dr. Plot did the ſame at the ſame place, for the year 1684: Mr. Hillier, at Cape Corſe, for the years 1686 and 1687: Mr. Hunt and others at Greſham College, for the years 1695 and 1696: Dr. Derham at Upminſter in Eſſex, for the years 1691, 1692, 1697, 1698, 1699, 1703, 1704, 1705: Mr. Townley, in Lancaſhire, in 1697, 1698: Mr. Cunningham, at Emin in China, for the years 1698, 1699, 1700, 1701: Mr. Locke, at Oats in Eſſex, 1692: Dr. Schenchzer, at Zurich, 1708; and Dr. Tilly, at Piſa, the ſame year: Profeſſor Toaldo, at Padua, for many years: Mr. T. Barker, at Lyndon, in Rutland, for many years in the Philoſ. Tranſ.: Mr. Dalton for Kendal, and Mr. Croſthwaite for Keſwick, in the years 1788,

1788, 1789, 1790, 1791, 1792, &c; and several others. The register now kept, for many years, in the Philos. Trans. contains an account, two times every day, of the thermometer, barometer, hygrometer, quantity of rain, direction and strength of the wind, and appearance of the atmosphere, as to fair, cloudy, foggy, rainy, &c. And if similar registers were kept in many other parts of the globe, and printed in such-like public Transactions, they might readily be consulted, and a proper use made of them, for establishing this science on the true basis of experiment.

From many experiments, some general observations have been made, as follow: That barometers generally rise and fall together, even at very distant places, and a consequent conformity and similarity of Weather; but this is the more uniformly so, as the places are nearer together, as might be expected. That the variations of the barometer are greater, as the places are nearer the pole; thus, for instance, the mercury at London has a greater range by 2 or 3 lines than at Paris; and at Paris, a greater than at Zurich; and at some places near the equator, there is scarce any variation at all. That the rain in Switzerland and Italy is much greater in quantity, for the whole year, than in Essex; and yet the rains are more frequent, or there are more rainy days, in Essex, than at either of those places. That cold contributes greatly to rain; and this apparently by condensing the suspended vapours, and so making them descend: thus, very cold months, or seasons, are commonly followed immediately by very rainy ones; and cold summers are always wet ones. That high ridges of mountains, as the Alps, and the snows with which they are covered, not only affect the neighbouring places by the colds, rains, vapours, &c, which they produce; but even distant countries, as England, often partake of their effects. See a collection of ingenious and meteorological observations and conjectures, by Dr. Franklin, in his Experiments, &c, pa. 182, &c. Also a Meteorological Register kept at Mansfield Woodhouse, from 1784 to 1794, Nottingham 1795, 8vo; and Kirwin's ingenious papers on this subject in the Transactions of the Irish Academy, vol. 5. See also the articles EVAPORATION, RAIN, and WIND.

Other Prognostics and Observations, are as follow:

That a thick dark sky, lasting for some time, without either sun or rain, always becomes first fair, and then foul, i. e. it changes to a fair clear sky, before it turns to rain. And the reason is obvious: the atmosphere is replete with vapours which, though sufficient to reflect and intercept the sun's rays from us, yet want density to descend; and while the vapours continue in the same state, the Weather will do so too: accordingly, such Weather is commonly attended with moderate warmth, and with little or no wind to disturb the vapours, and a heavy atmosphere to sustain them; the barometer being commonly high: but when the cold approaches, and by condensing the vapours drives them into clouds or drops, then way is made for the sun beams; till the same vapours, by farther condensation, be formed into rain, and fall down in drops.

That a change in the warmth of the Weather is followed by a change in the wind. Thus, the northerly and southerly winds, though commonly accounted the *causes* of cold and warm Weather, are really the *effects* of the cold or warmth of the atmosphere; of which Dr. Derham assures us he had so many confirmations, that he makes no doubt of it. Thus, it is common to see a warm southerly wind suddenly changed to the north, by the fall of snow or hail; or to see the wind, in a cold frosty morning, north, when the sun has well warmed the air, wheel towards the south; and again turn northerly or easterly in the cold evening.

That most vegetables expand their flowers and down in sunshiny Weather: and towards the evening, and against rain, close them again; especially at the beginning of their flowering, when their seeds are tender and sensible. This is visible enough in the down of Dandelion, and other downs: and eminently so in the flowers of pimpernel; the opening and shutting of which make what is called the countryman's *Weather-wiser*, by which he foretels the Weather of the following day. The rule is, when the flowers are close shut up, it betokens rain, and foul Weather; but when they are spread abroad, fair Weather.

The stalk of trefoil, lord Bacon observes, swells against rain, and grows more upright: and the like may be observed, though less sensibly, in the stalks of most other plants. He adds, that in the stubble fields there is found a small red flower, called by the country people pimpernel, which opening in a morning, is a sure indication of a fine day.

It is very conceivable that vegetables should be affected by the same causes as the Weather, as they may be considered as so many hygrometers and thermometers, consisting of an infinite number of tracheæ, or air-vessels; by which they have an immediate communication with the air, and partake of its moisture, heat, &c.

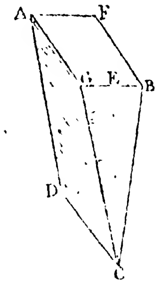
Hence it is, that all wood, even the hardest and most solid, swells in moist Weather; the vapours easily insinuating into the pores, especially of the lighter and drier kinds. And hence is derived a very extraordinary use of wood, viz, for breaking rocks or millstones. The method at the quarries is this: Having cut a rock into the form of a cylinder, the workmen divide it into several thinner cylinders, of horizontal courses, by making holes at proper distances round the great one; into these holes they drive pieces of sallow wood, dried in an oven; these in moist Weather, imbibing the humidity from the air, swell, and acting like wedges they break or cleave the rock into several flat stones. And, in like manner, to separate large blocks of stone in the quarry, they wedge such pieces of wood into holes, forming the block into the intended shape, and then pour water upon the wedges, to produce the effect more immediately.

WEATHER-*Glasses*, are instruments contrived to shew the state of the atmosphere, as to heat, cold, moisture, weight, &c; and so to measure the changes that take place in those respects; by which means we are enabled to predict the alteration of Weather, as to rain, wind, frost, &c.

Under the class of Weather glasses, are comprehended barometers, thermometers, hygrometers, manometers, and anemometers.

WEDGE,

WEDGE, in Geometry, is a solid having a rectangular base, and two of its opposite sides ending in an acies or edge. Thus, AB is the rectangular base; and DC the edge; a perpendicular CE, from the edge to the base, is the height of the Wedge. When the length of the edge DC is equal to the length of the base BF, which is the most common form of it, the Wedge is equal to half a rectangular prism of the same base AB and height EC; or it is then a whole triangular prism, having the triangle BCG for its base, and AG or DC for its height. If the edge be more or less than AG, its solid content will be more or less. But, in all cases of the Wedge, the following is a general rule for finding the content of it, viz,



To twice the length of the base add the length of the edge, multiply the sum by the breadth of the base, and the product by the height of the Wedge; then $\frac{1}{6}$ of the last product will be the solid content.

That is, $\overline{2AG + DC} \times AF \times \frac{1}{6} EC =$ the content. See this rule demonstrated, and illustrated with examples, in my Mensuration. p. 191, 2d edition.

Wedge, in Mechanics, one of the five mechanical powers, or simple engines; being a geometrical Wedge, or very acute triangular prism, applied to the splitting of wood, or rocks, or raising great weights.

The Wedge is made of iron, or some other hard matter, and applied to the raising of vast weights, or separating large or very firm blocks of wood or stone, by introducing the thin edge of the Wedge, and driving it in by blows struck upon the back by hammers or mallets.

The Wedge is the most powerful of all the simple machines, having an almost unlimited and double advantage over all the other simple mechanical powers; both as it may be made vastly thin, in proportion to its height; in which consists its own natural power; and as it is urged by the force of percussion, or of smart blows, which is a force incomparably greater than any mere dead weight or pressure, such as is employed upon other machines. And accordingly we find it produces effects vastly superior to those of any other power whatever; such as the splitting and raising the largest and hardest rocks; or even the raising and lifting the largest ship, by driving a Wedge below it; which a man can do by the blow of a mallet: and thus the small blow of a hammer, on the back of a Wedge, appears to be incomparably greater than any mere pressure, and will overcome it.

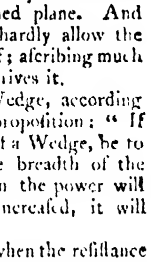
To the Wedge may be referred all edge-tools, and tools that have a sharp point, in order to cut, cleave, slit, split, chop, pierce, bore, or the like; as knives, hatchets, swords, bodkins, &c.

In the Wedge, the friction against the sides is very great, at least equal to the force to be overcome; because the Wedge retains any position to which it is driven; and therefore the resistance is at least doubled by the friction.

Authors have been of various opinions concerning the principle from whence the Wedge derives its power. Aristotle considers it as two levers of the first kind, inclined towards each other, and acting opposite ways. Guido Ubaldi, Mersenne, &c, will have them to be levers of the second kind. But De Lanis shews, that the Wedge cannot be reduced to any lever at all. Others refer the Wedge to the inclined plane. And others again, with De Stair, will hardly allow the Wedge to have any force at all in itself; ascribing much the greatest part to the mallet which drives it.

The doctrine of the force of the Wedge, according to some writers, is contained in this proposition: "If a power directly applied to the head of a Wedge, be to the resistance to be overcome, as the breadth of the back GB, is to the height EC; then the power will be equal to the resistance; and if increased, it will overcome it."

But Desaguliers has proved that, when the resistance acts perpendicularly against the sides of the Wedge, the power is to the whole resistance, as the thickness of the back is to the length of both the sides taken together. And the same proportion is adopted by Wallis (Op. Math. vol. 1, p. 1016), Keill (Intr. ad Ver. Phys.), Gravesande (Elem. Math. Lib. 1, cap. 14), and by almost all the modern mathematicians. Gravesande indeed distinguishes the mode in which the Wedge acts, into two cases, one in which the parts of a block of wood, &c, are separated farther than the edge has penetrated to, and the other in which they have not separated farther: In his Scholium de Ligno findendo (ubi supra), he observes, that when the parts of the wood are separated before the Wedge, the equilibrium will be when the force by which it is pushed in, is to the resistance of the wood, as the line DE drawn from the middle of the base to the side of the Wedge but perpendicular to the separated side of the wood continued FG, is to the height of the Wedge DC; but when the parts of the wood are separated no farther than the Wedge is driven in, the equilibrium will be, when the power is to the resistance, as the half base AD, is to its side AC.



Mr. Ferguson, in estimating the proportion of equilibrium in the two cases last mentioned by Gravesande, agrees with this author, and other modern philosophers, in the latter case; but in the former he contends, that when the wood cleaves to any distance before the Wedge, as it generally does, then the power impelling the Wedge, will be to the resistance of the wood, as half its thickness, is to the length of either side of the cleft, estimated from the top or acting part of the Wedge: for, supposing the Wedge to be lengthened down to the bottom of the cleft, the power will be to the resistance, as half the thickness of the Wedge is to the length of either of its sides. See Ferguson's Lect. p. 40, &c, 4to. See also Desagu. Exp. Phil. vol. 1, p. 107; and Ludlam's Essay on the Power of the Wedge, printed in 1770; &c.

The generally acknowledged property of the Wedge, and the simplest way of demonstrating it, seem to be the following: When a Wedge is kept in equilibrio, the power acting against the back, is to the force acting

Perpendicularly againſt either ſide, as the breadth of the back AB, is to the length of the ſide AC or BC. —*Demonſtra.* For any three forces which ſuſtain one another in equilibrio, are as the correſponding ſides of a triangle that are drawn perpendicular to the directions in which the forces act. But AB is perpendicular to the force acting on the back, to drive the Wedge forward; and the ſides AC and BC are perpendicular to the forces acting upon them; therefore the three forces are as the ſaid lines AB, AC, BC.

Hence, the thinner a Wedge is, the greater is its effect, in ſplitting any body, or in overcoming any reſiſtance againſt the ſide of the Wedge.

WEDNESDAY, the 4th day of the week, formerly conſecrated by the inhabitants of the northern nations to Woden or Oden; who, being reputed the author of magic and inventor of all the arts, was thought to anſwer to the Mercury of the Greeks and Romans, in honour of whom the ſame day was by them called *dies Mercurii*; and hence it is denoted by aſtronomers by the character of Mercury ☿.

WEEK, a diviſion of time that compriſes ſeven days.

The origin of this diviſion of Weeks, or of computing time by ſevenths, is much controverted. It has often been thought to have taken its riſe from the four quarters or intervals of the moon, between her changes of phaſes, which, being about 7 days diſtant, gave occaſion to the diviſion: but others more probably from the ſeven planets.

Be this however as it may, the diviſion is certainly very ancient. The Syrians, Egyptians, and moſt of the oriental nations, appear to have uſed it from the earlieſt ages: though it did not get footing in the weſt till brought in by chriſtianity. The Romans reckoned their days not by ſevenths, but by ninths; and the ancient Greeks by decads, or tenths; in imitation of which the new French calendar ſeems to have been framed.

The Jews divided their time by Weeks, of 7 days each, as preſcribed by the law of Moſes; in which they were appointed to work 6 days, and to reſt the 7th, in commemoration of the creation, which being effected in 6 days, God reſted on the 7th.

Some authors will even have the uſe of Weeks, among the other eaſtern nations, to have proceeded from the Jews; but with little appearance of probability. It is with better reaſon that others ſuppoſe the uſe of Weeks, among the eaſtern nations, to be a remnant of the tradition of the creation, which they had ſtill retained with divers others; or elſe from the number of the planets.

The Jews denominated the days of the Week, the firſt, ſecond, third, fourth, and fifth; and the ſixth day they named the preparation of the ſabbath, or 7th day, which anſwered to our Saturday. And the like method is ſtill kept up by the chriſtian Arabs, Perſians, Ethiopians, &c.

The ancient heathens denominated the days of the Week from the ſeven planets; which names are ſtill moſtly retained among the chriſtians of the weſt: thus, the firſt day was called *dies ſolis*, *ſun-day*; the 2d *dies lunæ*, *moon day*; &c; a practice the more natural on Dion's principle, that the Egyptians took the diviſion of the Week itſelf from the ſeven planets.

In fact, the true reaſon for theſe denominations ſeems to be founded in aſtrology. For the aſtrologers diſtributing the government and direction of all the hours in the Week among the ſeven planets, ♄ ♃ ♂ ☉ ♀ ☿ ☽, ſo as that the government of the firſt hour of the firſt day fell to Saturn, that of the ſecond day to Jupiter, &c, they gave each day the name of the planet which, according to their doctrine, preſided over the firſt hour of it, and that according to the order above ſtated. So that the order of the planets in the Week, bears little relation to that in which they follow in the heavens; the former being founded on an imaginary power each planet has, in its turn, on the firſt hour of each day.

Dion Caſſius gives another reaſon for the denomination, drawn from the celeſtial harmony. For it being obſerved, that the harmony of the diateſſaron, which conſiſts in the ratio of 4 to 3, is of great force and effect in muſic; it was judged meet to proceed directly from Saturn to the Sun; becauſe, according to the old ſyſtem, there are three planets between Saturn and the Sun, and 4 from the Sun to the Moon.

Our Saxon anceſtors, before their converſion to Chriſtianity, named the ſeven days of the Week from the Sun and Moon and ſome of their deified heroes, to whom they were peculiarly conſecrated, and repreſenting the ancient gods or planets; which names we received and ſtill retain: Thus, Sunday was devoted to the Sun; Monday to the Moon; Tueſday to Tuiſco; Wedneſday to Woden; Thurſday to Thor, the thunderer; Friday to Friga or Friya or Fræa, the wife of Thor; and Saturday to Seater. And nearly according to this order, the modern aſtronomers expreſs the days of the Week by the ſeven planets as below:

☉ Sunday
☾ Monday
♂ Tueſday
☿ Wedneſday
♃ Thurſday
♀ Friday
♄ Saturday.

In the ſame order and number alſo do theſe obtain in the Hindoo days of the Week. See Kinderſley's Specimens of Hindoo Literature, juſt publiſhed, 8vo.

WEIGH, Way, or Wey, a weight of cheeſe, wool, &c, containing 256 pounds avoirdupois. Of corn, the Weigh contains 40 buſhels; of barley or malt, 6 quarters.

WEIGHT, or *Gravity*, in Phyſics, a quality in natural bodies, by which they tend downwards toward the centre of the earth. See Gravity.

Weight, like gravity, may be diſtinguiſhed into *abſolute*, *ſpecific*, and *relative*.

Newton demonſtrates, 1. That the Weights of all bodies, at equal diſtances from the centre of the earth, are directly proportional to the quantities of matter that each contains: Whence it follows, that the Weights of bodies have no dependence on their ſhapes or textures; and that all ſpaces are not equally full of matter.

2. On different parts of the earth's ſurface, the Weight of the ſame body is different; owing to the ſpheroidal figure of the earth, which cauſes the body on the ſurface to be nearer the centre in going from the equator toward the poles: and the increaſe in the Weight is nearly

nearly in proportion to the versed sine of double the latitude; or, which is the same thing, to the square of the right sine of the latitude: the Weight at the equator to that at the pole, being as 229 to 230; or the whole increase of Weight from the equator to the pole, is the 229th part of the former.

3. That the Weights of the same body, at different distances above the earth, are inversely as the squares of the distances from the centre. So that, a body at the distance of the moon, which is 60 semidiameters from the earth's centre, would weigh only the 3600th part of what it weighs at the earth's surface.

4. That at different distances within the earth, or below the surface, the weights of the same body are directly as the distances from the earth's centre: so that, at half way toward the centre, a body would weigh but half as much, and at the very centre it would be no Weight at all.

5. A body immersed in a fluid, which is specifically lighter than itself, loses so much of its Weight, as is equal to the Weight of a quantity of the fluid of the same bulk with itself. Hence, a body loses more of its weight in a heavier fluid than in a lighter one; and therefore it weighs more in a lighter fluid than in a heavier one.

The Weight of a cubic foot of pure water, is 1000 ounces, or $62\frac{1}{2}$ pounds, avoirdupois. And the Weights of the cubic foot of other bodies, are as set down under the article *Specific* GRAVITY.

In the Philos. Trans. (number 458, p. 457 &c) is contained some account of the analogy between English Weights and measures, by Mr. Barlow. He states, that anciently the cubic foot of water was assumed as a general standard for liquids. This cubic foot, of $62\frac{1}{2}$ lb, multiplied by 32, gives 2000, the weight of a ton: and hence 8 cubic feet of water made a hogshead, and 4 hogsheads a tun, or ton, in capacity and denomination, as well as Weight.

Dry measures were raised on the same model. A bushel of wheat, assumed as a general standard for all sorts of grain, also weighed $62\frac{1}{2}$lb. Eight of these bushels make a quarter, and 4 quarters, or 32 bushels, a ton Weight. Coals were sold by the chaldron, supposed to weigh a ton, or 2000 pounds; though in reality it weighs perhaps upwards of 3000 pounds.

Hence a ton in Weight is the common standard for liquids, wheat, and coals. Had this analogy been adhered to, the confusion now complained of would have been avoided.—It may reasonably be supposed that corn and other commodities, both dry and liquid, were first sold by Weight; and that measures, for convenience, were afterwards introduced, as bearing some analogy to the Weights before used.

WEIGHT, *Pondus*, in Mechanics, denotes any thing to be raised, sustained, or moved by a machine; or any thing that in any manner resists the motion to be produced.

In all machines, there is a natural and fixed ratio between the Weight and the moving power; and if they be such as to balance each other in equilibrio, and then the machine be put in motion by any other force; the Weight and power will always be reciprocally as the velocities of them, or of their centres of gravity; or their momentums will be equal, that is, the product of the Weight multiplied by its velocity, will be equal to the product of the power multiplied by its velocity.

WEIGHT, in Commerce, denotes a body of a known Weight, appointed to be put into a balance against other bodies, whose Weight is required to be known. These Weights are usually of lead, iron, or brass; though in several parts of the East Indies common flints are used; and in some places a sort of little beans.

The diversity of Weights, in all nations, and at all times, makes one of the most perplexing circumstances in commerce, &c. And it would be a very great convenience if all nations could agree upon a universal standard, and system, both of Weights and measures.

Weights may be distinguished into *ancient* and *modern*, *foreign* and *domestic*.

Modern WEIGHTS, *used in the several parts of Europe, and the Levant.*

English WEIGHTS. By the 27th chapter of Magna Charta, the Weights are to be the same all over England: but for different commodities there are two different sorts, viz, *troy Weight*, and *averdupois Weight*.

The origin from which both of these are raised, is the grain of wheat, gathered in the middle of the ear:

32 of these, well dried, made one pennyweight,
20 pennyweights - - - - - one ounce, and
12 ounces - - - - - - - - - one pound troy;

by Stat. 51 Hen. III; 31 Edw. I; 12 Henry VII.

A learned writer has shewn that, by the laws of assize, from William the Conqueror to the reign of Henry VII, the legal pound Weight contained a pound of 12 ounces, raised from 32 grains of wheat; and the legal gallon measure contained 8 of those pounds of wheat, 8 gallons making the bushel, and 8 bushels the quarter.

Henry VII. altered the old English Weight, and introduced the troy pound in its stead, being 3 quarters of an ounce only heavier than the old Saxon pound, or 1-16th heavier. The first statute that directs the use of the averdupois Weight, is that of 24 Henry VIII; and the particular use to which this Weight is thus directed, is simply for weighing butcher's meat in the market; though it is now used for weighing all sorts of coarse and large articles. This pound contains 7000 troy grains; while the troy pound itself contains only 5760 grains, and the old Saxon pound Weight but 5400 grains. Philos. Trans. vol. 65, art. 3.

Hence there are now in common use in England, two different Weights, viz, troy Weight, and averdupois Weight, the former being employed in weighing such fine articles as jewels, gold, silver, silk, liquors, &c; and the latter for coarse and heavy articles, as bread, corn, flesh, butter, cheese, tallow, pitch, tar, iron, copper, tin, &c. and all grocery wares. And Mr. Ward supposes that it was brought into use from this circumstance, viz, as it was customary to allow larger Weight, of such coarse articles, than the law had expressly enjoined, and this he observes happened to be a 6th part more. Apothecaries buy their drugs by averdupois Weight, but they compound them by troy Weight, though under some little variation of name and divisions.

The troy or trone pound Weight in Scotland, which by statute is to be the same as the French pound, is commonly supposed equal to 15¾ English troy ounces, or 7560 grains; but by a mean of the standards kept by the dean of gild of Edinburgh, it weighs $7599\frac{1}{16}$ or 7600 grains nearly.

The following tables shew the divisions of the troy and averdupois Weights.

Table of Troy Weight, as used,

1. By the Goldsmiths, &c.

Grains	Pennywt.	Ounce	Pound
24 =	1 dwt.		
480 =	20 =	1 oz.	
5760 =	240 =	12 =	1 lb.

2. By the Apothecaries.

Grains	Scruples	Drams	Ounces	Pound
20 =	1 ℈			
60 =	3 =	1 ʒ		
480 =	24 =	8 =	1 ℥	
5760 =	288 =	96 =	12 =	1 lb.

Table of Averdupois Weight.

Drams	Ounces	Pounds	Quarters	Hund. wt.	Ton
16 =	1				
256 =	16 =	1			
7168 =	448 =	28 =	1		
28672 =	1792 =	112 =	4 =	1	
573440 =	35840 =	2240 =	80 =	20 =	1

Mr. Ferguson (Lect. on Mech. p. 100, 4to) gives the following comparison between troy and averdupois Weight.

175 troy pounds are equal to 144 averdup. pounds.
175 troy ounces are equal to 192 averdup. ounces.
1 troy pound contains 5760 grains.
1 averdupois pound contains 7000 grains.
1 averdupois ounce contains 437½ grains.
1 averdupois dram contains 27·34375 grains.
1 troy pound contains 13 oz. 2·651428576 drams averdupois
1 averdup. lb. contains 1 lb 2 oz 11 dwts 16 gr troy

The moneyers, jewellers, &c. have a particular class of Weights, for gold and precious stones, viz. *carat* and *grain*; and for silver, the *pennyweight* and *grain*. The moneyers have also a peculiar subdivision of the troy grain: thus, dividing

the grain into 20 mites
the mite into 24 droits
the droit into 20 periots
the periot into 24 blanks.

The dealers in wool have likewise a particular set of Weights; viz. the *sack*, *weigh*, *tod*, *stone*, and *clove*, the proportions of which are as below: viz.

the sack containing	2	weighs
the weigh - - - -	6½	tods
the tod - - - - - -	2	stones
the stone - - - - -	2	cloves
the clove - - - - -	7	pounds.

Also 12 sacks make a last or 4368 pounds.

Farther,
56 lb of old hay, or 60 lb new hay, make a truss.
40 lb of straw make a truss.
36 trusses make a load, of hay or straw.
14 lb make a stone.
5 lb of glass a stone.

French WEIGHTS. The common or Paris pound Weight, is to the English troy pound, as 21 to 16, and to the averdupois pound as 27 to 25: it therefore contains 7560 troy grains; and it is divided into 16 ounces like the pound averdupois, but more particularly thus: the pound into 2 *marcs*; the marc into 8 *ounces*; the ounce into 8 *gros*, or *drams*; the gross or dram into 3 deniers, Paris scruples or pennyweights; and the pennyweight into 24 *grains*; the grain being an equivalent to a grain of wheat. So that the Paris ounce contains 472½ troy grains, and therefore it is to the English troy ounce as 63 to 64. But in several of the French provinces, the pound is of other different Weights. A *quintal* is equal to 100 pounds.

The Weights above enumerated under the two articles of English and French Weights, are the same as are used throughout the greatest part of Europe; only under somewhat different names, divisions, and proportions. And besides, particular nations have also certain Weights peculiar to themselves, of too little consequence here to be enumerated. But to shew the proportion of these several Weights to one another, there may be here added a reduction of the divers pounds in use throughout Europe, by which the other Weights are estimated, to one standard pound, viz, the pound of Amsterdam, Paris, and Bourdeaux; as they were accurately calculated by M. Ricard, and published in the new edition of his Traité de Commerce, in 1781.

Proportion of the WEIGHTS *of the chief Cities in Europe to that of Amsterdam.*

100 pounds of Amsterdam are equal to

108 lbs	of Alicant	100 lbs	of Bilboa
105	Antwerp	105	Bois le Duc
120	Archangel, or 3 poedes	151	Bologna
		100	Bourdeaux
105	Arschot	104	Bourg en Bresse
120	Avignon	103	Bremen
98	Basil	125	Breslaw
100	Bayonne	105	Bruges
166	Bergamo	105	Brussels
97	Berg. op Zoom	105	Cadiz
95¼	Bergen, Norw.	105	Cologne
111	Bern	107½	Copenhagen
100	Besançon	87	Constantinople

WEIGHTS *continued.*

100 pounds of Amsterdam are equal to

113½	lbs of Dantzic	154	lbs of Messina
100	Dort	168	Milan
97	Dublin	120	Montpelier
97	Edinburgh	125	Muscovy
143	Florence	100	Nantes
98	Franckfort, sur Maine	100	Nancy
		169	Naples
105	Gaunt	98	Nuremberg
89	Geneva	100	Paris
163	Genoa	112½	Revel
102	Hamburgh	109	Riga
125	Koningsberg	100	Rochel
105	Leipsic	146	Rome
106	Leyden	100	Rotterdam
143	Leghorn	96	Rouen
105½	Liege	100	S. Malo
106	Lisbon	100	S. Sebastian
114	Lisle	$158\frac{1}{7}$	Saragosa
109	London, averdupois	100	Seville
		114	Smyrna
105	Louvain	110	Stetin
105	Lubeck	81	Stockholm
141½	Lucca	118	Tholouse
116	Lyons	151	Turin
114	Madrid	158½	Valencia
105	Malines	182	Venice.
123½	Marseilles		

Ancient WEIGHTS.

1. The Weights of the ancient Jews, reduced to the English troy Weights, will stand as below:

	lb	oz	dwt	gr
Shekel - - - -	0	0	9	$2\frac{4}{7}$
Manch - - - -	2	3	6	$10\frac{2}{7}$
Talent - - - -	113	10	1	$10\frac{2}{7}$

2. Grecian and Roman Weights, reduced to English troy Weight, are as in the following table:

	lb	oz	dwt	gr
Lentes - - - -	0	0	0	$0\frac{85}{112}$
Siliquæ - - - -	0	0	0	$3\frac{1}{28}$
Obolus - - - -	0	0	0	$9\frac{3}{28}$
Scriptulum - -	0	0	0	$18\frac{3}{14}$
Drachma - - -	0	0	2	$6\frac{9}{14}$
Sextula - - - -	0	0	3	$0\frac{6}{7}$
Sicilicus - - - -	0	0	4	$13\frac{2}{7}$
Duella - - - - -	0	0	6	$1\frac{5}{7}$
Uncia - - - - -	0	0	18	$5\frac{1}{7}$
Libra - - - - -	0	10	18	$13\frac{5}{7}$

The Roman ounce is the English averdupois ounce, which they divide into 7 denarii, as well as 8 drachms: and as they reckoned their denarius equal to the Attic drachm, this will make the Attic Weights one-eighth heavier than the correspondent Roman Weights. Arbuth.

Regulation of WEIGHTS *and Measures*. This is a branch of the king's prerogative. For the public convenience, these ought to be universally the same throughout the nation, the better to reduce the prices of articles to equivalent values. But as Weight and measure are things in their nature arbitrary and uncertain, it is necessary that they be reduced to some fixed rule or standard. It is however impossible to fix such a standard by any written law or oral proclamation; as no person can, by words only, give to another an adequate idea of a pound Weight, or foot-rule. It is therefore expedient to have recourse to some visible, palpable, material standard; by forming a comparison with which, all Weights and measures may be reduced to one uniform size. Such a standard was anciently kept at Winchester: and we find in the laws of king Edgar, near a century before the conquest, an injunction that that measure should be observed throughout the realm.

Most nations have regulated the standard of measures of length from some parts of the human body; as the palm, the hand, the span, the foot, the cubit, the ell (*ulna* or arm), the pace, and the fathom. But as these are of different dimensions in men of different proportions, ancient historians inform us, that a new standard of length was fixed by our king Henry the first; who commanded that the *ulna* or ancient ell, which answers to the modern yard, should be made of the exact length of his own arm.

A standard of long measure being once gained, all others are easily derived from it; those of greater length by multiplying that original standard, those of less by dividing it. Thus, by the statute called *compositio ulnarum et perticarum*, 5½ yards make a perch; and the yard is subdivided into 3 feet, and each foot into 12 inches; which inches will be each of the length of 3 barley corns. But some, on the contrary, derive all measures, by composition, from the barley corn.

Superficial measures are derived by squaring those of length; and measures of capacity by cubing them.

The standard of Weights was originally taken from grains or corns of wheat, whence our lowest denomination of Weights is still called a *grain*; 32 of which are directed, by the statute called *compositio mensurarum*, to compose a pennyweight, 20 of which make an ounce, and 12 ounces a pound, &c.

Under king Richard the first it was ordained, that there should be only one Weight and one measure throughout the nation, and that the custody of the assize or standard of Weights and measures, should be committed to certain persons in every city and borough; from whence the ancient office of the king's ulnager seems to have been derived. These original standards were called *pondus regis*, and *mensura domini regis*, and are directed by a variety of subsequent statutes to be kept in the exchequer chamber, by an officer called the *clerk of the market*, except the wine gallon, which is committed to the city of London, and kept in Guildhall.

The Scottish standards are distributed among the oldest boroughs. The elwand is kept at Edinburgh, the pint at Stirling, the pound at Lanark, and the firlot at Linlithgow.

The two principal Weights established in Great Britain, are troy Weight, and avoirdupois Weight, as

as before mentioned. Under the head of the former it may farther be added, that

A carat is a Weight of 4 grains; but when the term is applied to gold, it denotes the degree of fineness. Any quantity of gold is supposed divided into 24 parts. If the whole mass be pure gold, it is said to be 24 carats fine; if there be 23 parts of pure gold, and one part of alloy or base metal, it is said to be 23 carats fine, and so on.

Pure gold is too soft to be used for coin. The standard coin of this kingdom is 22 carats fine. A pound of standard gold is coined into $44\frac{1}{2}$ guineas, and therefore every guinea should weigh 5 dwts $9\frac{1}{8}\frac{9}{9}$ grains.

A pound of silver for coin contains 11 oz 2 dwts pure silver, and 18 dwts alloy: and standard silver-plate, 11 ounces pure silver, with 1 ounce alloy. A pound of standard silver is coined into 62 shillings; and therefore the Weight of a shilling should be 3 dwts $20\frac{8}{31}$ grains.

Universal Standard for WEIGHTS *and Measures.*

Philosophers, from their habits of generalizing, have often made speculations for forming a general standard for Weights and measures through the whole world. These have been devised chiefly of a philosophical nature, as best adapted to universality. After the invention of pendulum clocks, it first occurred that the length of a pendulum which should vibrate seconds, would be proper to be made a universal standard for lengths; whether it should be called a yard, or any thing else. But it was found, that it would be difficult in practice, to measure and determine the true length of such a pendulum, that is the distance between the point of suspension and the point of oscillation. Another cause of inaccuracy was afterwards discovered, when it was found that the seconds pendulum was of different lengths in all the different latitudes, owing to the spheroidal figure of the earth, which causes that all places in different latitudes are at different distances from the centre, and consequently the pendulums are acted upon by different forces of gravity, and therefore require to be of different lengths. In the latitude of London this is found to be $39\frac{1}{8}$ inches.

The Society of Arts in London, among their many laudable and patriotic endeavours, offered a handsome premium for the discovery of a proper standard for Weights and measures. This brought them many frivolous expedients, as well as one which was an improvement on the method of the pendulum, by one Hatton. This consisted in measuring the difference of the lengths of two pendulums of different times of vibration; which could be performed more easily and accurately than that of the length of one single pendulum. This method was put in practice, and fully explained and illustrated, by the late Mr. Whitehurst, in his attempt to ascertain an Universal Standard of Weights and Measures. But still the same kind of inaccuracy of measurement &c, obtains in this way, as in the single pendulum, though in a smaller degree.

Another method that has been proposed for this purpose, is the space that a heavy body falls freely through in 1 second of time. But this is an experiment more difficult than the former to be made with accuracy; on which account, different persons will all make the space fallen to be of different quantities, which would give as many different standards of length. Add to this, that the spheroidal form of the earth here again introduces a diversity in the space, owing to the different distances from the centre, and the consequent diversity in the force of gravity by which the body falls. This space has been found to be 193 inches, or $16\frac{1}{12}$ feet, in the latitude of London; but it will be a different quantity in other latitudes.

Many other inferior expedients have also been proposed for the purpose of universal measures, and Weights; but there is another which now has the best prospect of success, and is at present under particular experiments, by the philosophers both of this and the French nation. This method is by the measure of the degrees of latitude; which would give a large quantity, and admit of more accurate measures, by subdivision, than what could be obtained by beginning from a small quantity, or measure, and thence to proceed increasing by multiples. This measure might be taken either from the extent of the whole compass of the earth, or of all the 360 degrees, or a medium degree among them all, or from the measure of a degree in the medium latitude of 45 degrees. It will also be most convenient to make the subdivisions of this measure, when found, to proceed decimally, or continually by 10ths.

The universal standard for lengths being once established, those of Weights, &c, would easily follow. For instance, a vessel, of certain dimensions, being filled with distilled water, or some other homogeneous matter, the Weight of that may be considered as a standard for Weights.

WEIGHT of the Air, Water, &c. See those articles severally. See also SPECIFIC GRAVITY.

WERST, a Russian measure of length, equal to 3500 English feet.

WEST, one of the cardinal points of the horizon, or of the compass, diametrically opposite to the east, or lying on the left hand when we face the north. Or West is strictly the intersection of the prime vertical with the horizon, on that side where the sun sets.

WEST *Wind*, is also called *Zephyrus*, and *Favonius*.

WEST *Dial*. See DIAL.

WESTERN *Amplitude*, *Horizon*, *Ocean*. See the several articles.

WESTING, in Navigation, is the quantity of departure made good to the westward from the meridian.

WEY. See WEIGH.

WHALE, in Astronomy, one of the constellations. See CETUS.

WHEEL, in Mechanics, a simple machine, consisting of a circular piece of wood, metal, or other matter, that revolves on an axis. This is otherwise called *Wheel and Axle*, or AXIS *in Peritrochio*, as a mechanical power, being one of the most frequent and useful of any. In this capacity of it, the Wheel is a kind of perpetual lever, and the axis another lesser one; or the radius of the Wheel and that of its axis may be considered as the longer and shorter arms of a lever, the centre of the Wheel being the fulcrum or point of suspen-

ſuſpenſion. Whence it is, that the power of this machine is eſtimated by this rule, as the radius of the axis is to the radius of the Wheel or of the circumference, ſo is any given power, to the weight it will ſuſtain.

Wheels, as well as their axes, are frequently dented, or cut into teeth, and are then of uſe upon innumerable occaſions; as in jacks, clocks, mill-work, &c; by which means they are capable of moving and acting on one another, and of being combined together to any extent; the teeth either of the axis or circumference working in thoſe of other Wheels or axles; and thus, by multiplying the power to any extent, an amazing great effect is produced.

To compute the power of a combination of Wheels; the teeth of the axis of every Wheel acting on thoſe in the circumference of the next following. Multiply continually together the radii of all the axes, as alſo the radii of all the Wheels; then it will be, as the former product is to the latter product, ſo is a given power applied to the circumference, to the weight it can ſuſtain. Thus, for example, in a combination of five Wheels and axles, to find the weight a man can ſuſtain, or raiſe, whoſe force is equal to 150 pounds, the radii of the Wheels being 30 inches, and thoſe of the axes 3 inches. Here $3 \times 3 \times 3 \times 3 \times 3 = 243$,

and $30 \times 30 \times 30 \times 30 \times 30 = 24300000$,

therefore as $243 : 24300000 :: 150 : 15000000$ lb, the weight he can ſuſtain, which is more than 6696 tons weight. So prodigious is the increaſe of power in a combination of Wheels!

But it is to be obſerved, that in this, as well as every other mechanical engine, whatever is gained in power, is loſt in time; that is, the weight will move as much ſlower than the power, as the force is increaſed or multiplied, which in the example above is 100000 times ſlower.

Hence, having given any power, and the weight to be raiſed, with the proportion between the Wheels and axles neceſſary to that effect; to find the number of the Wheels and axles. Or, having the number of the Wheels and axles given, to find the ratio of the radii of the Wheels and axles. Here, putting

$p =$ the power acting on the laſt wheel,
$w =$ the weight to be raiſed,
$r =$ the radius of the axles,
$R =$ the radius of the wheels,
$n =$ the number of the wheels and axles;

then, by the general proportion, as $r^n : R^n :: p : w$; therefore $pR^n = wr^n$ is a general theorem, from whence may be found any one of theſe five letters or quantities, when the other four are given. Thus, to find n the number of Wheels: we have firſt

$$\frac{R^n}{r^n} = \frac{w}{p}, \text{ then } n = \frac{\log. w - \log. p}{\log. R - \log. r}.$$

And to find $\frac{R}{r}$, the ratio of the Wheel to the axle; it is

$$\frac{R}{r} = \sqrt[n]{\frac{w}{p}}.$$

Wheels *of a Clock, &c*, are, the crown wheel, contrat wheel, great wheel, ſecond wheel, third wheel, ſtriking wheel, detent wheel, &c.

Wheels *of Coaches, Carts, Waggons, &c*. With reſpect to Wheels of carriages, the following particulars are collected from the experiments and obſervations of Deſaguliers, Beighton, Camus, Ferguſon, Jacob, &c.

1. The uſe of Wheels, in carriages, is twofold; viz, that of diminiſhing or more eaſily overcoming the reſiſtance or friction from the carriage; and that of more eaſily overcoming obſtacles in the road. In the firſt caſe the friction on the ground is transferred in ſome degree from the outer ſurface of the Wheel to its nave and axle; and in the latter, they ſerve eaſily to raiſe the carriage over obſtacles and aſperities met with on the roads. In both theſe caſes, the height of the Wheel is of material conſideration, as the ſpokes act as levers, the top of an obſtacle being the fulcrum, their length enables the carriage more eaſily to ſurmount them; and the greater proportion of the Wheel to the axle ſerves more eaſily to diminiſh or to overcome the friction of the axle. See Jacob's Obſervations on Wheel Carriages, p. 23 &c.

2. The Wheels ſhould be exactly round; and the fellies at right angles to the naves, according to the inclination of the ſpokes.

3. It is the moſt general opinion, that the ſpokes be ſomewhat inclined to the naves, ſo that the Wheels may be diſhing or concave. Indeed if the Wheels were always to roll upon ſmooth and level ground, it would be beſt to make the ſpokes perpendicular to the naves, or to the axles; becauſe they would then bear the weight of the load perpendicularly. But becauſe the ground is commonly uneven, one Wheel often falls into a cavity or rut, when the other does not, and then it bears much more of the weight than the other does; in which caſe it is beſt for the Wheels to be diſhed, becauſe the ſpokes become perpendicular in the rut, and therefore have the greateſt ſtrength when the obliquity of the road throws moſt of the weight upon them; whilſt thoſe on the high ground have leſs weight to bear, and therefore need not be at their full ſtrength.

4. The axles of the Wheels ſhould be quite ſtraight, and perpendicular to the ſhafts, or to the pole. When the axles are ſtraight, the rims of the Wheels will be parallel to each other, in which caſe they will move the eaſieſt, becauſe they will be at liberty to proceed ſtraight forwards. But in the uſual way of practice, the ends of the axles are bent downwards; which always keeps the ſides of the Wheels that are next the ground nearer to one another than their upper ſides are; and this not only makes the Wheels drag ſideways as they go along, and gives the load a much greater power of cruſhing them than when they are parallel to each other, but alſo endangers the overturning the carriage when a Wheel falls into a hole or rut, or when the carriage goes on a road that has one ſide lower than the other, as along the ſide of a hill. Mr. Beighton however has offered ſeveral reaſons to prove that the axles of Wheels ought not to be ſtraight; for which ſee Deſaguliers's Exp. Phil. vol. 2, Appendix.

5. Large Wheels are found more advantageous for rolling than ſmall ones, both with regard to their power as a longer lever, and to the degree of friction, and to the advantage in getting over holes, rubs, and

stones, &c. If we consider Wheels with regard to the friction upon their axles, it is evident that small Wheels, by turning oftener round, and swifter about the axles, than large ones, must have much more friction. Again, if we consider Wheels as they sink into holes or soft earth, the large Wheels, by sinking less, must be much easier drawn out of them, as well as more easily over stones and obstacles, from their greater length of lever or spokes. Desaguliers has brought this matter to a mathematical calculation, in his Experim. Philos. vol. 1, p. 171, &c. See also Jacob's Observ. p. 63.

From hence it appears then, that Wheels are the more advantageous as they are larger, provided they are not more than 5 or 6 feet diameter; for when they exceed these dimensions, they become too heavy; or if they are made light, their strength is proportionably diminished, and the length of the spokes renders them more liable to break: besides, horses applied to such Wheels would not be capable of exerting their utmost strength, by having the axles higher than their breasts, so that they would draw downwards; which is even a greater disadvantage than small Wheels have in occasioning the horses to draw upwards.

6. Carriages with 4 Wheels, as waggons or coaches, are much more advantageous than carriages with 2 Wheels, as carts and chaises; for with 2 wheels it is plain the tiller horse carries part of the weight, in one way or other: in going down hill, the weight bears upon the horse; and in going up hill, the weight falls the other way, and lifts the horse, which is still worse. Besides, as the Wheels sink into the holes in the roads, sometimes on one side, sometimes on the other, the shafts strike against the tiller's sides, which destroys many horses: moreover, when one of the Wheels sinks into a hole or rut, half the weight falls that way, which endangers the overturning of the carriage.

7. It would be much more advantageous to make the 4 Wheels of a coach or waggon large, and nearly of a height, than to make the fore Wheels of only half the diameter of the hind Wheels, as is usual in many places. The fore Wheels have commonly been made of a less size than the hind ones, both on account of turning short, and to avoid cutting the braces. Crane-necks have also been invented for turning yet shorter, and the fore Wheels have been lowered, so as to go quite under the bend of the crane-neck.

It is held, that it is a great disadvantage in small Wheels, that as their axle is below the bow of the horses breasts, the horses not only have the loaded carriage to draw along, but also part of its weight to bear, which tires them soon, and makes them grow much stiffer in their hams, than they would be if they drew on a level with the fore axle.

But Mr. Beighton disputes the propriety of fixing the line of traction on a level with the breast of a horse, and says it is contrary to reason and experience. Horses, he says, have little or no power to draw but what they derive from their weight; without which they could not take hold of the ground, and then they must slip, and draw nothing. Common experience also teaches, that a horse must have a certain weight on his back or shoulders, that he may draw the better. And when a horse draws hard, it is observed that he bends forward, and brings his breast near the ground; and then if the Wheels are high, he is pulling the carriage against the ground. A horse tackled in a waggon will draw two or three ton, because the point or line of traction is below his breast, by the lowness of the Wheels. It is also common to see, when one horse is drawing a heavy load, especially up hill, his fore feet will rise from the ground; in which case it is usual to add a weight on his back, to keep his fore part down, by a person mounting on his back or shoulders, which will enable him to draw that load, which he could not move before. The greatest stress, or main business of drawing, says this ingenious writer, is to overcome obstacles; for on level plains the drawing is but little, and then the horse's back need be pressed but with a small weight.

8. The utility of broad Wheels, in amending and preserving the roads, has been so long and generally acknowledged, as to have occasioned the legislature to enforce their use. At the same time, the proprietors and drivers of carriages seem to be convinced by experience, that a narrow-wheeled carriage is more easily and speedily drawn by the same number of horses, than a broad-wheeled one of the same burthen: probably because they are much lighter, and have less friction on the axle.

On the subject of this article, see Jacob's Observ. &c. on Wheel-Carriages, 1773, p. 81. Desagul. Exper. Phil. vol. 1, p. 201. Ferguson's Lect. 4to, p. 56. Martin's Phil. Brit. vol. 1, p. 229.

Blowing Wheel, is a machine contrived by Desaguliers, for drawing the foul air out of any place, or for forcing in fresh, or doing both successively, without opening doors or windows. See Philos. Trans. number 437. The intention of this machine is the same as that of Hales's ventilator, but not so effectual, nor so convenient. See Desag. Exper. Philos. vol. 2, p. 563, 568.—This Wheel is also called a *centrifugal Wheel*, because it drives the air with a centrifugal force.

Water Wheel, of a Mill, that which receives the impulse of the stream by means of ladle-boards or float-boards. M. Parent, of the Academy of Sciences, has determined that the greatest effect of an undershot Wheel, is when its velocity is equal to the 3d part of the velocity of the water that drives it; but it ought to be the half of that velocity, as is fully shewn in the article Mill, pa. 111. In fixing an undershot Wheel, it ought to be considered whether the water can run clear off, so as to cause no back-water to stop its motion. Concerning this article, see Desagul. Exp. Philos. vol. 2, p. 422. Also a variety of experiments and observations relating to undershot and overshot Wheels, by Mr. Smeaton, in the Philos. Trans. vol. 51, p. 100.

WHIRL-POOL, an eddy, vortex, or gulph, where the water is continually turning round.

WHIRLING-TABLE, a machine contrived for repre-

representing several phenomena in philosophy, and nature; as, the principal laws of gravitation, and of the planetary motions in curvilinear orbits.

The figure of this instrument is exhibited fig. 1, pl. 35: where AA is a strong frame of wood; B a winch fixed on the axis C of the wheel D, round which is the catgut string F, which also goes round the small wheels G and K, crossing between them and the great wheel D. On the upper end of the axis of the wheel G, above the frame, is fixed the round board *d*, to which may be occasionally fixed the bearer MSX. On the axis of the wheel H is fixed the bearer NTZ, and when the winch B is turned, the wheels and bearers are put into a Whirling motion. Each bearer has two wires W, X, and Y, Z, fixed and screwed tight into them at the ends by nuts on the outside; and when the nuts are unscrewed, the wires may be drawn out in order to change the balls U, V, which slide upon the wires by means of brass loops fixed into the balls, and preventing their touching the wood below them. Through each ball there passes a silk line, which is fixed to it at any length from the centre of the bearer to its end, by a nut-screw at the top of the ball; the shank of the screw going into the centre of the ball, and pressing the line against the under side of the whole which it goes through. The line goes from the ball, and under a small pulley fixed in the middle of the bearer; then up through a socket in the round plate (S and T) in the middle of each bearer; then through a slit in the middle of the square top (O and P) of each tower, and going over a small pulley on the top comes down again the same way, and is at last fastened to the upper end of the socket fixed in the middle of the round plate above mentioned. Each of these plates S and T has four round holes near their edges, by which they slide up and down upon the wires which make the corner of each tower. The balls and plates being thus connected, each by its particular line, it is plain that if the balls be drawn outward, or towards the end M and N of their respective bearers, the round plates S and T will be drawn up to the top of their respective towers O and P.

There are several brass weights, some of two, some of three, and others of four ounces, to be occasionally put within the towers O and P, upon the round plates S and T: each weight having a round hole in the middle of it, for going upon the sockets or axes of the plates, and being slit from the edge to the hole, that it may slip over the line which comes from each ball to its respective plate.

For a specimen of the experiments which may be made with this machine, may be subjoined the following.

1. Removing the bearer MX, put the loop of the line *b* to which the ivory ball *a* is fastened over a pin in the centre of the board *d*, and turn the winch B; and the ball will not immediately begin to move with the board, but, on account of its inactivity, endeavour to remain in its state of rest. But when the ball has acquired the same velocity with the board, it will remain upon the same part of the board, having no relative motion upon it. However, if the board be suddenly stopped, the ball will continue to revolve upon it, until the friction thereof stops its motion: so that matter resists every change of state, from that of rest to that of motion, and *vice versa*.

2. Put a longer cord to this ball; let it down through the hollow axis of the bearer MX and wheel G, and fix a weight to the end of the cord below the machine; and this weight, if left at liberty, will draw the ball from the edge of the Whirling board to its centre. Draw off the ball a little from the centre, and turn the winch; then the ball will go round and round with the board, and gradually fly farther from the centre, raising up the weight below the machine. And thus it appears that all bodies, revolving in circles, have a tendency to fly off from those circles, and must be retained in them by some power proceeding from or tending to the centre of motion. Stop the machine, and the ball will continue to revolve for some time upon the board; but as the friction gradually stops its motion, the weight acting upon it will bring it nearer and nearer to the centre in every revolution, till it brings it quite thither. Hence it appears, that if the planets met with any resistance in going round the sun, its attractive power would bring them nearer and nearer to it in every revolution, till they would fall into it.

3. Take hold of the cord below the machine with one hand, and with the other throw the ball upon the round board as it were at right angles to the cord, and it will revolve upon the board. Then, observing the velocity of its motion, pull the cord below the machine, and thus bring the ball nearer the centre of the board, and the ball will be seen to revolve with an increasing velocity, as it approaches the centre: and thus the planets which are nearest the sun perform quicker revolutions than those which are more remote, and move with greater velocity in every part of their respective circles.

4. Remove the ball *a*, and apply the bearer MX, whose centre of motion is in its middle at *w*, directly over the centre of the Whirling board *d*. Then put two balls (V and U) of equal weight upon their bearing wires, and having fixed them at equal distances from their respective centres of motion *w* and *x* upon their silk cords, by the screw nuts, put equal weights in the towers O and P. Lastly, put the catgut strings E and F upon the grooves G and H of the small wheels, which, being of equal diameters, will give equal velocities to the bearers above, when the winch B is turned; and the balls U and V will fly off toward M and N, and raise the weights in the towers at the same instant. This shews, that when bodies of equal quantities of matter revolve in equal circles with equal velocities, their centrifugal forces are equal.

5. Take away these equal balls, and put a ball of 6 ounces into the bearer MX, at a 6th part of the distance *wz* from the centre, and put a ball of one ounce into the opposite bearer, at the whole distance $xy = wz$; and fix the balls at these distances on their cords, by the screw nuts at the top: then the ball U, which is 6 times as heavy as the ball V, will be at only a 6th part of the distance from its centre of motion; and consequently will revolve in a circle of only a 6th part of the circumference of the circle in which V revolves. Let equal weights be put into the towers, and the winch be turned; which (as the catgut string is

is on equal wheels below, will cauſe the balls to revolve in equal times: but V will move 6 times as faſt as U, becauſe it revolves in a circle of 6 times its radius, and both the weights in the towers will riſe at once. Hence it appears, that the centrifugal forces of revolving bodies are in direct proportion to their quantities of matter multiplied into their reſpective velocities, or into their diſtance from the centres of their reſpective circles.

If theſe two balls be fixed at equal diſtances from their reſpective centres of motion, they will move with equal velocities; and if the tower O has 6 times as much weight put into it as the tower P has, the balls will raiſe their weights exactly at the ſame moment: i. e. the ball U, being 6 times as heavy as the ball V, has 6 times as much centrifugal force in deſcribing an equal circle with an equal velocity.

6. Let two balls, U and V, of equal weights, be fixed on their cords at equal diſtances from their reſpective centres of motion *w* and *x*; and let the catgut ſtring E be put round the wheel K (whoſe circumference is only half that of the wheel H or G) and over the pulley *s* to keep it tight, and let 4 times as much weight be put into the tower P as in the tower O. Then turn the winch B, and the ball V will revolve twice as faſt as the ball U in a circle of the ſame diameter, becauſe they are equidiſtant from the centres of the circles in which they revolve; and the weights in the towers will both riſe at the ſame inſtant; which ſhews that a double velocity in the ſame circle will exactly balance a quadruple power of attraction in the centre of the circle: for the weights in the towers may be conſidered as the attractive forces in the centres, acting upon the revolving balls; which moving in equal circles, are as if they both moved in the ſame circle. Whence it appears that, if bodies of equal weights revolve in equal circles with unequal velocities, their centrifugal forces are as the ſquares of the velocities.

7. The catgut ſtring remaining as before, let the diſtance of the ball V from the centre *x* be equal to 2 of the diviſions on its bearer; and the diſtance of the ball U from the centre *w* be 3 and a 6th part; the balls themſelves being equally heavy, and V making two revolutions by turning the winch, whilſt U makes one; ſo that if we ſuppoſe the ball V to revolve in one moment, the ball U will revolve in 2 moments, the ſquares of which are 1 and 4: therefore, the ſquare of the period of V is contained 4 times in the ſquare of the period of U. But the diſtance of V is 2, the cube of which is 8, and the diſtance of U is $3\frac{1}{6}$, the cube of which is 32 very nearly, in which 8 is contained 4 times: and therefore, the ſquares of the periods V and U are to one another as the cubes of their diſtances from *x* and *w*, the centres of their reſpective circles. And if the weight in the tower O be 4 ounces, or equal to the ſquare of 2, which is the diſtance of V from the centre *x*; and the weight in the tower P be 10 ounces, nearly equal to the ſquare of $3\frac{1}{6}$, the diſtance of U from *w*; it will be found upon turning the machine by the winch, that the balls U and V will raiſe their reſpective weights at very nearly the ſame inſtant of time. This experiment confirms the famous propoſition of Kepler, viz. that the ſquares of the periodical times of the planets round the ſun are in proportion as the cubes of their diſtances from him; and that the ſun's attraction is inverſely as the ſquare of the diſtance from his centre.

8. Take off the ſtring E from the wheels D and H, and let the ſtring F remain upon the wheels D and G; take away alſo the bearer MX from the Whirling-board *d*, and inſtead of it put on the machine AB (fig. 2), fixing it to the centre of the board by the pins *c* and *d*, ſo that the end *ef* may riſe above the board to an angle of 30 or 40 degrees. On the upper part of this machine, there are two glaſs tubes *a* and *b*, cloſe ſtopped at both ends, each tube being about three quarters full of water. In the tube *a* is a little quickſilver, which naturally falls down to the end *a* in the water; and in the tube *b* is a ſmall cork, floating on the top of the water, and ſmall enough to riſe or fall in the tube. While the board *b* with this machine upon it continues at reſt, the quickſilver lies at the bottom of the tube *a*, and the cork floats on the water near the top of the tube *b*. But, upon turning the winch and moving the machine, the contents of each tube fly off towards the uppermoſt ends, which are fartheſt from the centre of motion; the heavieſt with the greateſt force. Conſequently, the quickſilver in the tube *a* will fly off quite to the end *f*, occupying its bulk of ſpace, and excluding the water, which is lighter than itſelf: but the water in the tube *b*, flying off to its higher end *e*, will exclude the cork from that place, and cauſe it to deſcend toward the loweſt end of the tube; for the heavier body, having the greater centrifugal force, will poſſeſs the upper part of the tube, and the lighter body will keep between the heavier and the lower part.

This experiment demonſtrates the abſurdity of the Carteſian doctrine of vortices; for, if a planet be more denſe or heavy than its bulk of the vortex, it will fly off in it farther and farther from the ſun; if leſs denſe, it will come down to the loweſt part of the vortex, at the ſun: and the whole vortex itſelf, unleſs prevented by ſome obſtacle, would fly quite off, together with the planets.

9. If a body be ſo placed upon the Whirling-board of the machine (fig. 1.) that the centre of gravity of the body be directly over the centre of the board, and the board be moved ever ſo rapidly by the winch B, the body will turn round with the board, without removing from its middle; for, as all parts of the body are in equilibrio round its centre of gravity, and the centre of gravity is at reſt in the centre of motion, the centrifugal force of all parts of the body will be equal at equal diſtances from its centre of motion, and therefore the body will remain in its place. But if the centre of gravity be placed ever ſo little out of the centre of motion, and the machine be turned ſwiftly round, the body will fly off towards that ſide of the board on which its centre of gravity lies. Then if the wire C (fig. 3) with its little ball B be taken away from the ſemi-globe A, and the flat ſide *f* of the ſemiglobe be laid upon the Whirling-board, ſo that their centres may coincide; if then the board be turned ever ſo quickly by the winch, the ſemi-globe will remain where it was placed: but if the wire C be ſcrewed into the ſemi-globe at *d*, the whole becomes one body, whoſe centre of gravity is at or near *d*. Fix the pin *c* in

in the centre of the Whirling-board, and let the deep groove *b* cut in the flat side of the semi-globe be put upon the pin, so that the pin may be in the centre of A (see fig. 4) where the groove is to be represented at *b*, and let the board be turned by the winch, which will carry the little ball B (fig. 3) with its wire C, and the semi-globe A, round the centre-pin *c i*; and then, the centrifugal force of the little ball B, weighing one ounce, will be so great as to draw off the semi-globe A, weighing two pounds, until the end of the groove at *c* strikes against the pin *c*, and so prevents A from going any farther: otherwise, the centrifugal force of B would have been great enough to have carried A quite off the whirling-board. Hence we see that, if the sun were placed in the centre of the orbits of the planets, it could not possibly remain there; for the centrifugal forces of the planets would carry them quite off, and the sun with them; especially when several of them happened to be in one quarter of the heavens. For the sun and planets are as much connected by the mutual attraction subsisting between them, as the bodies A and B are by the wire C fixed into them both. And even if there were but one planet in the whole heavens to go round ever so large a sun in the centre of its orbit, its centrifugal force would soon carry off both itself and the sun: for the greatest body placed in any part of free space could be easily moved; because, if there were no other body to attract it, it would have no weight or gravity of itself, and consequently, though it could have no tendency of itself to remove from that part of space, yet it might be very easily moved by any other substance.

10. As the centrifugal force of the light body B will not allow the heavy body A to remain in the centre of motion, even though it be 24 times as heavy as B; let the ball A (fig. 5) weighing 6 ounces be connected by the wire C with the ball B, weighing one ounce, and let the fork E be fixed into the centre of the Whirling-board; then, hang the balls upon the fork by the wire C in such a manner that they may exactly balance each other, which will be when the centre of gravity between them, in the wire at *d*, is supported by the fork. And this centre of gravity is as much nearer to the centre of the ball A than to the centre B, as A is heavier than B; allowing for the weight of the wire on each side of the fork. Then, let the machine be moved, and the balls A and B will go round their common centre of gravity *d*, keeping their balance, because either will not allow the other to fly off with it. For, supposing the ball B to be only one ounce in weight, and the ball A to be six ounces; then, if the wire C were equally heavy on each side of the fork, the centre of gravity *d* would be 6 times as far from the centre of B as from the centre of A, and consequently B will revolve with a velocity 6 times as great as A does; which will give B 6 times as much centrifugal force as any single ounce of A has; but then as B is only one ounce, and A six ounces, the whole centrifugal force of A will exactly balance that of B; and therefore, each body will detain the other, so as to make it keep in its circle.

Hence it appears, that the sun and planets must all move round the common centre of gravity of the whole system, in order to preserve that just balance which takes place among them.

11. Take away the forks and balls from the Whirling-board, and place the trough AB (fig. 6) thereon, fixing its centre to that of the board by the pin H. In this trough are two balls D and E of unequal weights, connected by a wire *f*, and made to slide easily upon the wire stretched from end to end of the trough, and made fast by nut screws on the outside of the ends. Place these balls on the wire *c*, so that their common centre of gravity *g*, may be directly over the centre of the Whirling-board. Then turn the machine by the winch ever so swiftly, and the trough and balls will go round their centre of gravity, so as neither of them will fly off; because, on account of the equilibrium, each ball detains the other with an equal force acting against it. But if the ball E be drawn a little more towards the end of the trough at A, it will remove the centre of gravity towards that end from the centre of motion; and then, upon turning the machine, the little ball E will fly off, and strike with a considerable force against the end A, and draw the great ball B into the middle of the trough. Or, if the great ball D be drawn towards the end B of the trough, so that the centre of gravity may be a little towards that end from the centre of motion; and the machine be turned by the winch, the great ball D will fly off, and strike violently against the end B of the trough, and will bring the little ball E into the middle of it. If the trough be not made very strong, the ball D will break through it.

12. Mr. Ferguson has explained the reason why the tides rise at the same time on opposite sides of the earth, and consequently in opposite directions, by the following new experiment on the Whirling-table. For this purpose, let *a b c d* (fig. 7) represent the earth, with its side *c* turned toward the moon, which will then attract the water so as to raise them from *c* to *g*: and in order to shew that they will rise as high at the same time on the opposite side from *a* to *e*; let a plate AB (fig. 8) be fixed upon one end of the flat bar DC, with such a circle drawn upon it as *a b c d* (fig. 7) to represent the round figure of the earth and sea; and an ellipse as *e f g h* to represent the swelling of the tide at *e* and *g*, occasioned by the influence of the moon. Over this plate AB suspend the three ivory balls *e*, *f*, *g*, by the silk lines *h*, *i*, *k*, fastened to the tops of the wires H, I, K, so that the ball at *e* may hang freely over the side of the circle *e*, which is farthest from the moon M at the other end of the bar; the ball at *f* over the centre, and the ball at *g* over the side of the circle *g*, which is nearest the moon. The ball *f* may represent the centre of the earth, the ball *g* water on the side next the moon, and the ball *e* water on the opposite side. On the back of the moon M is fixed a short bar N parallel to the horizon, and there are three holes in it above the little weights *p*, *q*, *r*. A silken thread *o* is tied to the line *k* close above the ball *g*, and passing by one side of the moon M goes through a hole in the bar N, and has the weight *p* hung to it. Such another thread *m* is tied to the line *i*, close above the ball *f*, and, passing through the centre of the moon M and middle of the bar N, has the weight *q* hung to it which is lighter than the weight *p*. A third thread *m* is tied to the line *h*, close above

above the ball *e*, and, passing by the other side, of the moon M through the bar N, has the weight *r* hung to it, which is lighter than the weight *q*. The use of these three unequal weights is to represent the moon's unequal attraction at different distances from her; so that if they are left at liberty, they will draw all the three balls towards the moon with different degrees of force, and cause them to appear as in fig. 9, in which case they are evidently farther from each other than if they hung freely by the perpendicular lines *h*, *i*, *k*. Hence it appears, that as the moon attracts the side of the earth which is nearest her with a greater degree of force than she does the centre of the earth, she will draw the water on that side more than the centre, and cause it to rise on that side: and as she draws the centre more than the opposite side, the centre will recede farther from the surface of the water on that opposite side, and leave it as high there as she raised it on the side next her. For, as the centre will be in the middle between the tops of the opposite elevations, they must of course be equally high on both sides at the same time.

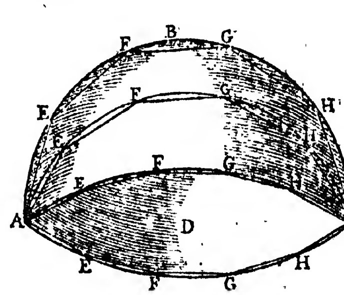
However, upon this supposition, the earth and moon would soon come together; and this would be the case if they had not a motion round their common centre of gravity, to produce a degree of centrifugal force, sufficient to balance their mutual attraction. Such motion they have; for as the moon revolves in her orbit every month, at the distance of 240000 miles from the earth's centre, and of 234000 miles from the centre of gravity of the earth and moon, the earth also goes round the same centre of gravity every month at the distance of 6000 miles from it, i. e. from it to the centre of the earth. But the diameter of the earth being, in round numbers, 8000 miles, its side next the moon is only 2000 miles from the common centre of gravity of the earth and moon, its centre 6000 miles from it, and its farthest side from the moon 10000 miles. Consequently the centrifugal forces of these parts are as 2000, 6000, and 10000; i. e. the centrifugal force of any side of the earth, when it is turned from the moon, is five times as great as when it is turned toward the moon. And as the moon's attraction, expressed by the number 6000 at the earth's centre, keeps the earth from flying out of this monthly circle, it must be greater than the centrifugal force of the waters on the side next her; and consequently, her greater degree of attraction on that side is sufficient to raise them; but as her attraction on the opposite side is less than the centrifugal force of the water there, the excess of this force is sufficient to raise the water just as high on the opposite side.

To prove this experimentally, let the bar DC with its furniture be fixed on the Whirling-board of the machine (fig. 1.) by pushing the pin P into the centre of the board; which pin is in the centre of gravity of the whole bar with its three balls, *e*, *f*, *g*, and moon M. Now if the Whirling-board and bar be turned slowly round by the winch, till the ball *f* hangs over the centre of the circle, as in fig. 10, the ball *g* will be kept towards the moon by the heaviest weight *p* (fig. 8), and the ball *e*, on account of its greater centrifugal force, and the less weight *r*, will fly off as far to the other side, as in fig. 10. And thus, whilst the machine is kept turning, the balls *e* and *g* will hang over the ends of the ellipse *l f k*. So that the centrifugal force of the ball *e* will exceed the moon's attraction just as much as her attraction exceeds the centrifugal force of the ball *g*, whilst her attraction just balances the centrifugal force of the ball *f*, and makes it keep in its circle. Hence it is evident, that the tides must rise to equal heights at the same time on opposite sides of the earth. See Ferguson's Lectures on Mechanics, lect. 2, and Desag. Ex. Phil. vol. 1, lect 5.

WHIRLWIND, a wind that rises suddenly, is exceedingly rapid and impetuous, in a Whirling direction, and often progressively also; but it is commonly soon spent.

Dr. Franklin, in his Physical and Meteorological Observations, read to the Royal Society in 1756, supposes a Whirlwind and a waterspout to proceed from the same cause: their only difference being, that the latter passes over the water, and the former over the land. This opinion is corroborated by the observations of M. de la Pryme, and many others, who have remarked the appearances and effects of both to be the same. They have both a progressive as well as a circular motion; they usually rise after calms and great heats, and mostly happen in the warmer latitudes: the wind blows every way from a large surrounding space, both to the waterspout and whirlwind; and a waterspout has, by its progressive motion, passed from the sea to the land, and produced all the phenomena and effects of a Whirlwind: so that there is no reason to doubt that they are meteors arising from the same general cause, and explicable upon the same principles, furnished by electrical experiments and discoveries. See HURRICANE, and WATERSPOUT. For Dr. Franklin's ingenious method of accounting for both these phenomena, see his Letters and Papers, &c, vol. 1, p. 191, 216, &c.

WHISPERING-*Places*, are places where a Whisper, or other small noise, may be heard from one part to another, to a great distance. They depend on a principle, that the voice, &c, being applied to one end of an arch, easily passes by repeated reflections to the other. Thus,



let ABC represent the segment of a sphere; and suppose a low voice uttered at A, the vibrations extending themselves every way, some of them will impinge upon the points B, E, &c; and thence be reflected to the points F, F, &c; thence to G, G, &c; till at last they meet in C; where by their union they cause a much stronger sound than in any part of the segment

whatever,

whatever, even louder than at the point from whence they set out. Accordingly, all the contrivance in a Whispering-place is, that near the person who Whispers, there be a smooth wall, arched either cylindrically, or elliptically, &c. A circular arch will do, but not so well.

Some of the most remarkable places for Whispering, are the following: viz, The prison of Dionysius at Syracuse, which increased a soft Whisper to a loud noise; or a clap of the hand to the report of a cannon, &c. The aqueducts of Claudius, which carried a voice 16 miles: beside divers others mentioned by Kircher in his Phonurgia. In England, the most considerable Whispering places are, the dome of St. Paul's church, London, where the ticking of a watch may be heard from side to side, and a very soft Whisper may be sent all round the dome: this Dr. Derham found to hold not only in the gallery below, but above upon the scaffold, where a Whisper would be carried over a person's head round the top of the arch, though there be a large opening in the middle of it into the upper part of the dome. And the celebrated Whispering-place in Gloucester cathedral, which is only a gallery above the east end of the choir, leading from one side of it to the other. See Birch's Hist. of the Royal Soc. vol. 1, pa. 120.

WHISTON (WILLIAM), an English divine, philosopher, and mathematician, of uncommon parts, learning, and extraordinary character, was born the 9th of December 1667, at Norton in the county of Leicester, where his father was rector. He was educated under his father till he was 17 years of age, when he was sent to Tamworth school, and two years after admitted of Clare-hall, Cambridge, where he pursued his studies, and particularly the mathematics, with great diligence. During this time he became afflicted with a great weakness of sight, owing to close study in a whitened room; which was in a good measure relieved by a little relaxation from study, and taking off the strong glare of light by hanging the place opposite his seat with green.

In 1693 he was made master of arts and fellow of the college, and soon after commenced one of the tutors; but his ill state of health soon after obliged him to relinquish this profession. Having entered into orders, in 1694 he became chaplain to Dr. More, bishop of Norwich; and while in this station he published his first work, intitled, *A New Theory of the Earth &c*; in which he undertook to prove that the Mosaic doctrine of the earth was perfectly agreeable to reason and philosophy: which work, having much ingenuity, though it was written against by Mr. John Keill, brought considerable reputation to the author.

In the year 1698, bishop More gave him the living of Lowestoff in Suffolk, where he immediately went to reside, and devoted himself with great diligence to the discharge of that trust.—In the beginning of this century he was made Sir Isaac Newton's deputy, and afterwards his successor in the Lucasian professorship of mathematics; when he resigned his living at Lowestoff, and went to reside at Cambridge. From this time his publications became very frequent, both in theology and mathematics. Thus, in 1702 he published, A Short View of the Chronology of the Old Testament, and of the Harmony of the four Evangelists.—In 1707, *Prælectiones Astronomicæ*; beside eight Sermons on the Accomplishment of the Scripture Prophecies, preached at Boyle's lecture; and Newton's Arithmetica Universalis.—In 1708, Tacquet's Euclid, with select Theorems of Archimedes; the former of which had accidentally been his first introduction to the study of the mathematics.—In the same year he drew up an Essay upon the Apostolical Constitutions, which the Vice chancellor refused his licence for printing. The author tells us, he had read over the two first centuries of the church, and found that the Eusebian or Arian doctrine was chiefly the doctrine of those ages, which, though deemed heterodox, he thought it his duty to discover.—In 1709, he published a volume of Sermons and Essays on various subjects.—In 1710, Prælectiones Physico-Mathematicæ, which with the Prælectiones Astronomicæ, were translated and published in English. And it may be said, with no small honour to the memory of Mr. Whiston, that he was one of the first who explained the Newtonian philosophy in a popular way, so as to be intelligible to the generality of readers.—Among other things also, he translated the Apostolical Constitutions into English, which favoured the doctrine of the supremacy of the father and subordination of the son, vulgarly called the Arian heresy: Upon which his friends began to be alarmed for him; and the consequence shewed it was not groundless; for, Oct. 30, 1710, he was deprived of his professorship, and expelled the university of Cambridge, after he had been formally convened and interrogated for some days together.—At the conclusion of this year, he wrote his Historical preface, afterwards prefixed to his Primitive Christianity Revived, containing the reasons for his dissent from the commonly received notions of the Trinity, which work he published the next year, in 4 volumes 8vo, for which the Convocation fell upon him most vehemently.

In 1713, he and Mr. Ditton composed their scheme for finding the longitude, which they published the year following, a method which consisted in measuring distances by means of the velocity of sound; some more particulars of which are related in the life of Mr. Ditton.—In 1719, he published an ironical Letter of Thanks to doctor Robinson, bishop of London, for his late Letter to his clergy against the use of New Forms of Doxology. And, the same year, a Letter to the earl of Nottingham, Concerning the Eternity of the Son of God, and his Holy Spirit.—In 1720, he was proposed by Sir Hans Sloane and Dr. Halley to the Royal Society as a member; but was refused admittance by Sir Isaac Newton the president.

On Mr. Whiston's expulsion from Cambridge, he went to London, where he conferred with Doctors Clarke, Hoadly, and other learned men, who endeavoured to moderate his zeal, which however he would not suffer to be tainted or corrupted, and many were not much satisfied with the authority of these constitutions, but approved his integrity. Mr. Whiston now settled in London with his family; where, without suffering his zeal to be intimidated, he continued to write, and to propagate his Primitive Christianity with as much ardour as if he had been in the most flourishing circumstances; which however were so bad, that, in 1721,

1721, a subscription was made for the support of his family, which amounted to 470l. For though he drew some profits from reading astronomical and philosophical lectures, and also from his publications, which were very numerous, yet these of themselves were very insufficient: nor, when joined with the benevolence and charity of those who loved and esteemed him for his learning, integrity, and piety, did they prevent his being frequently in great distress.—In 1722 he published an Essay towards restoring the true text of the Old Testament.—In 1724, The Literal Accomplishment of Scripture Prophecies.—Also, The Calculation of Solar Eclipses without Parallaxes.—In 1726, Of the Thundering Legion &c.—In 1727, A Collection of Authentic Records belonging to the Old and New Testament.—In 1730, Memoirs of the Life of Dr. Samuel Clarke.—In 1732, A Vindication of the Testimony of Phlegon, or an Account of the Great Darkness and Earthquake at our Saviour's Passion, described by Phlegon.—In 1736, Athanasian Forgeries, &c. And the Primitive Eucharist revived.—In 1737, The Astronomical Year, particularly of the Comet foretold by Sir Isaac Newton.—Also the Genuine Works of Flavius Josephus.—In 1739, Mr. Whiston put in his claim to the mathematical professorship at Cambridge, then vacant by the death of Dr. Saunderson, in a letter to Dr. Ashton, the master of Jesus-college; but no regard was paid to it.—In 1745, he published his Primitive New Testament in English.—In 1748, his Sacred History of the Old and New Testament. Also, Memoirs of his own Life and Writings, which are very curious.

Whiston continued many years a member of the established church; but at length forsook it, on account of the reading of the Athanasian Creed, and went over to the Baptists; which happened while he was at the house of Samuel Barker, Esq. at Lindon in Rutlandshire, who had married his daughter; where he died, after a week's illness, the 22d of August 1752, at upwards of 84 years of age.—We have mentioned the principal of his writings in the foregoing memoir; to which may be added, Chronological Tables, published in 1750.

The character of this conscientious and worthy man has been attempted by two very able personages, who were well acquainted with him, namely, bishop Hare and Mr. Collins, who unite in giving him the highest applauses, for his integrity, piety, &c.—Mr. Whiston left some children behind him; among them, Mr. John Whiston, who was for many years a very considerable bookseller in London.

WHITE, one of the colours of bodies. Though White cannot properly be said to be one colour, but rather a composition of all the colours together: for Newton has demonstrated that bodies only appear White by reflecting all the kinds of coloured rays alike; and that even the light of the sun is only White, because it consists of all colours mixed together.

This may be shewn mechanically in the following manner: Take seven parcels of coloured fine powders, the same as the primary colours of the rainbow, taking such quantities of these as shall be proportional to the respective breadths of these colours in the rainbow, which are of red 45 parts, orange 27, yellow 48, green 60, blue 60, indigo 40, and of violet 80; then mix intimately together these seven parcels of powders, and the mixture will be a pretty White colour: and this is only similar to the uniting the prismatic colours together again, to form a White ray or pencil of light of the whole of them. The same thing is done conveniently thus: Let the flat upper surface of a top be divided into 360 equal parts, all around its edge; then divide the same surface into seven sectors in the proportion of the numbers above, by seven radii or lines drawn from the centre; next let the respective colours be painted in a lively manner on these spaces, but so as the edge of each colour may be made nearly like the colour next adjoining, that the separation may not be well distinguished by the eye; then if the top be made to spin, the colours will thus seem to be mixed all together, and the whole surface will appear of a uniform whiteness: and if a large round black spot be painted in the middle, so as there may be only a broad flat ring of colours around it, the experiment will succeed the better. See Newton's Optics, prop. 6, book 1; and Ferguson's Tracts, pa. 296.

White bodies are found to take heat slower than black ones; because the latter absorb or imbibe rays of all kinds and colours, and the former reflect them. Hence it is that black paper is sooner put in flame, by a burning-glass, than White; and hence also black clothes, hung up in the sun by the dyers, dry sooner than white ones.

WHITEHURST (John), an ingenious English philosopher, was born at Congleton in the county of Cheshire, the 10th of April 1713, being the son of a clock and watch-maker there. Of the early part of his life but little is known; he who dies at an advanced age, leaving few behind him to communicate anecdotes of his youth. On his quitting school, where it seems the education he received was very defective, he was bred by his father to his own profession, in which he soon gave hopes of his future eminence.

It was very early in life that, from his vicinity to the many stupendous phenomena in Derbyshire, which were constantly presented to his observation, his attention was excited to enquire into the various causes of them.

At about the age of 21, his eagerness after new ideas carried him to Dublin, having heard of an ingenious piece of mechanism in that city, being a clock with certain curious appendages, which he was very desirous of seeing, and no less so of conversing with the maker. On his arrival however, he could neither procure a sight of the former, nor draw the least hint from the latter concerning it. Thus disappointed, he fell upon an expedient for accomplishing his design; and accordingly took up his residence in the house of the mechanic, paying the more liberally for his board, as he had hopes from thence of more readily obtaining the indulgence wished for. He was accommodated with a room directly over that in which the favourite piece was kept carefully locked up: and he had not long to wait for his gratification: for the artist, while one day employed in examining his machine, was suddenly called down stairs; which the young enquirer happening to overhear, softly slipped into the room, inspected the machine, and, presently satisfying himself as to the secret, escaped undiscovered

covered to his own apartment. His end thus compassed, he shortly after bid the artist farewell, and returned to his father in England.

About two or three years after his return from Ireland, he left Congleton, and entered into business for himself at Derby, where he soon got into great employment, and distinguished himself very much by several ingenious pieces of mechanism, both in his own regular line of business, and in various other respects, as in the construction of curious thermometers, barometers, and other philosophical instruments, as well as in ingenious contrivances for water-works, and the erection of various larger machines: being consulted in almost all the undertakings in Derbyshire, and in the neighbouring counties, where the aid of superior skill, in mechanics, pneumatics, and hydraulics, was requisite.

In this manner his time was fully and usefully employed in the country, till, in 1775, when the act passed for the better regulation of the gold coin, he was appointed stamper of the money-weights; an office conferred upon him, altogether unexpectedly, and without solicitation. Upon this occasion he removed to London, where he spent the remainder of his days, in the constant habits of cultivating some useful parts of philosophy and mechanism. And here too his house became the constant resort of the ingenious and scientific at large, of whatever nation or rank, and this to such a degree, as very often to impede him in the regular prosecution of his own speculations.

In 1778, Mr. Whitehurst published his Inquiry into the Original State and Formation of the Earth; of which a second edition appeared in 1786, considerably enlarged and improved; and a third in 1792. This was the labour of many years; and the numerous investigations necessary to its completion, were in themselves also of so untoward a nature, as at times, though he was naturally of a strong constitution, not a little to prejudice his health. When he first entered upon this species of research, it was not altogether with a view to investigate the formation of the earth, but in part to obtain such a competent knowledge of subterraneous geography as might become subservient to the purposes of human life, by leading mankind to the discovery of many valuable substances which lie concealed in the lower regions of the earth.

May the 13th, 1779, he was elected and admitted a Fellow of the Royal Society. He was also a member of some other philosophical societies, which admitted him of their respective bodies, without his previous knowledge; but so remote was he from any thing that might favour of ostentation, that this circumstance was known only to a very few of his most confidential friends. Before he was admitted a member of the Royal Society, three several papers of his had been inserted in the Philosophical Transactions, viz, Thermometrical Observations at Derby, in vol. 57; An Account of a Machine for raising Water, at Oulton, in Cheshire, in vol. 65; and Experiments on Ignited Substances, vol. 66: which three papers were printed afterwards in the collection of his works in 1792.

In 1783 he made a second visit to Ireland, with a view to examine the Giant's Causeway, and other northern parts of that island, which he found to be chiefly composed of volcanic matter: an account and representations of which are inserted in the latter editions of his Inquiry. During this excursion, he erected an engine, for raising water from a well, to the summit of a hill, in a bleaching ground, at Tullidoi, in the county of Tyrone: it is worked by a current of water, and for its utility is perhaps unequalled in any country.

In 1787 he published, An Attempt toward obtaining Invariable Measures of Length, Capacity, and Weight, from the Mensuration of Time. His plan is, to obtain a measure of the greatest length that conveniency will permit, from two pendulums whose vibrations are in the ratio of 2 to 1, and whose lengths coincide nearly with the English standard in whole numbers. The numbers which he has chosen shew much ingenuity. On a supposition that the length of a seconds pendulum, in the latitude of London, is 39^{1} inches, the length of one vibrating 42 times in a minute, must be 80 inches; and of another vibrating 84 times in a minute must be 20 inches; and their difference, 60 inches, or 5 feet, is his standard measure. By the experiments however, the difference between the lengths of the two pendulum rods, was found to be only 59·892 inches, instead of 60, owing to the error in the assumed length of the seconds pendulum, 39$\frac{1}{5}$ inches being greater than the truth, which ought to be 39$\frac{1}{8}$ very nearly. By this experiment, Mr. Whitehurst obtained a fact, as accurately as may be in a thing of this nature, viz, the difference between the lengths of two pendulum rods whose vibrations are known: a datum from whence may be obtained, by calculation, the true lengths of pendulums, the spaces through which heavy bodies fall in a given time, and many other particulars relating to the doctrine of gravitation, the figure of the earth, &c, &c.

Mr. Whitehurst had been at times subject to slight attacks of the gout, and he had for several years felt himself gradually declining. By an attack of that disease in his stomach, after a struggle of two or three months, it put an end to his laborious and useful life, on the 18th of February 1788, in the 75th year of his age, at his house in Bolt-court, Fleet-street, being the same house where another eminent self-taught philosopher, Mr. James Ferguson, had immediately before him lived and died.

For several years before his death, Mr. Whitehurst had been at times occupied in arranging and completing some papers, for a treatise on Chimneys, Ventilation, and Garden-stoves; which have since been collected and given to the public, by Dr. Willan, in 1794.

However respectable Mr. Whitehurst may have been in mechanics, and those parts of natural science which he more immediately cultivated, he was of still higher account with his acquaintance and friends on the score of his moral qualities. To say nothing of the uprightness and punctuality of his dealings in all transactions relative to business; few men have been known to possess more benevolent affections than he, or, being possessed of such, to direct them more judiciously to their proper ends. As to his person, he was above the middle stature, rather thin than otherwise, and of a countenance expressive at once of penetration and mildness. His fine gray locks, unpolluted by art, gave a venerable air to his whole appearance. In dress he was plain, in diet temperate, in his general intercourse with mankind

mankind easy and obliging. In company he was cheerful or grave alike, according to the dictate of the occasion; with now and then a peculiar species of humour about him, delivered with such gravity of manner and utterance, that those who knew him but slightly were apt to understand him as serious, when he was merely playful. But where any desire of information on subjects in which he was conversant was expressed, he omitted no opportunity of imparting it.

WHITSUNDAY, the 50th day or seventh sunday from Easter.—The season properly called Pentecost, is popularly called *Whitsuntide*; because, it is said, in the primitive church, the newly baptized persons came to church between Easter and Pentecost in *white* garments.

WILKINS (Dr. John), a very ingenious and learned English bishop and mathematician, was the son of a goldsmith at Oxford, and born in 1614. After being educated in Greek and Latin, in which he made a very quick progress, he was entered a student of New-Inn in that university, when he was but 13 years of age; but after a short stay there, he was removed to Magdalen Hall; where he took his degrees. Having entered into holy orders, he first became chaplain to William Lord Say, and afterwards to Charles Count Palatine of the Rhine, with whom he continued some time. Adhering to the Parliament during the civil wars, they made him warden of Wadham college about the year 1648. In 1656 he married the sister of Oliver Cromwell, then lord protector of England, who granted him a dispensation to hold his wardenship, notwithstanding his marriage. In 1659, he was by Richard Cromwell made master of Trinity college in Cambridge; but ejected the year following, upon the restoration. He was then chosen preacher to the society of Gray's Inn, and rector of St. Lawrence Jewry, London, upon the promotion of Dr. Seth Ward to the bishoprick of Exeter. About this time he became a member of the Royal Society, was chosen of their council, and proved one of their most eminent members. He was afterwards made dean of Rippon, and in 1668 bishop of Chester; but died of the stone in 1672, at 58 years of age.

Bishop Wilkins was a man who thought it prudent to submit to the powers in being; he therefore subscribed to the solemn league and covenant, while it was enforced; and was equally ready to swear allegiance to king Charles when he was restored: this, with his moderate spirit towards dissenters, rendered him not very agreeable to the churchmen; and yet several of them could not but give him one of the best of characters. Burnet writes, that "he was a man of as great a mind, as true a judgment, as eminent virtues, and of as good a soul, as any he ever knew: that though he married Cromwell's sister, yet he made no other use of that alliance, but to do good offices, and to cover the university of Oxford from the sourness of Owen and Goodwin. At Cambridge, he joined with those who studied to propagate better thoughts, to take men off from being in parties, or from narrow notions, from superstitious conceits, and fierceness about opinions. He was also a great observer and promoter of experimental philosophy, which was then a new thing, and much looked after. He was naturally ambitious, but was the wisest clergyman I ever knew. He was a lover of mankind, and had a delight in doing good." The same historian mentions afterwards another quality which Wilkins possessed in a supreme degree, and which it was well for him he did, since he had great occasion for the use of it; and that was, says he, "a courage, which could stand against a current, and against all the reproaches with which ill-natured clergymen studied to load him."

Of his publications, which are all of them very ingenious and learned, and many of them particularly curious and entertaining, the first was in 1638, when he was only 24 years of age, viz, The Discovery of a New World; or, A Discourse to prove, that it is probable there may be another Habitable World in the Moon; with a Discourse concerning the Possibility of a Passage thither.—In 1640, A Discourse concerning a New Planet, tending to prove that it is probable our earth is one of the Planets.—In 1641, Mercury; or, the Secret and Swift Messenger; shewing, how a man may with Privacy and Speed communicate his Thoughts to a Friend at any Distance, 8vo.—In 1648, Mathematical Magic; or, the Wonders that may be performed by Mathematical Geometry, 8vo. All these pieces were published entire in one volume 8vo, in 1708, under the title of, The Mathematical and Philosophical Works of the right rev. John Wilkins, &c; with a print of the author and general title page handsomely engraven, and an account of his life and writings. To this collection is also subjoined an abstract of a larger work, printed in 1668, folio, intitled, An Essay towards a Real Character and a Philosophical Language. These were all his mathematical and philosophical works; beside which, he wrote several tracts in theology, natural religion, and civil polity, which were much esteemed for their piety and moderation, and went through several editions.

WINCH, a popular term for a windlass. Also the bent handle for turning round wheels, grind-stones, &c.

WIND, a current, or stream of air, especially when it is moved by some natural cause.

Winds are denominated from the point of the compass or horizon they blow from; as the east Wind, north Wind, south Wind, &c.

Winds are also divided into several kinds; as *general, particular, perennial, stated, variable, &c.*

Constant or *Perennial* WINDS, are those that always blow the same way; such as the remarkable one between the two tropics, blowing constantly from east to west, called also the *general trade-Wind.*

Stated or *Periodical* WINDS, are those that constantly return at certain times. Such are the sea and land breezes, blowing from land to sea in the morning, and from sea to land in the evening. Such also are the shifting or particular trade Winds, which blow one way during certain months of the year, and the contrary way the rest of the year.

Variable or *Erratic* WINDS, are such as blow without any regularity either as to time, place, or direction. Such as the Winds that blow in the interior parts of England, &c: though some of these claim their certain times of the day; as, the north-Wind is most frequent in the morning, the west-Wind about noon, and the south-Wind in the night.

General

General WIND, is such as blows at the same time the same way, over a very large tract of ground, most part of the year; as the general trade-Wind.

Particular WINDS, include all others, excepting the general trade Winds.

Those peculiar to one little canton or province, are called *topical* or *provincial Winds*. The Winds are also divided, with respect to the points of the compass or of the horizon, into *cardinal* and *collateral*.

Cardinal WINDS, are those blowing from the four cardinal points, east, west, north, and south.

Collateral WINDS, are the intermediate Winds between any two cardinal Winds, and take their names from the point of the compass or horizon they blow from.

In Navigation, when the Wind blows gently, it is called a *breeze*; when it blows harder, it is called a *gale*, or a *stiff gale*; and when it blows very hard, a *storm*.

For a particular account of the trade-Winds, monsoons, &c, see Philos. Trans. number 183, or Abridg. vol. 2, p. 133. Also Robertson's Navigation book 5, sect. 6.

A Wind blowing from the sea, is always moist; as bringing with it the copious evaporation and exhalations from the waters: also, in summer, it is cool; and in winter warm. On the contrary, a Wind from the continent, is always dry; warm in summer, and cold in winter. Our northerly and southerly Winds however, which are usually accounted the causes of cold and warm weather, Dr. Derham observes, are really rather the effect of the cold or warmth of the atmosphere. Hence it is that we often find a warm southerly Wind suddenly change to the north, by the fall of snow or hail; and in a cold frosty morning, we find the Wind north, which afterward wheels about to the southerly quarter, when the sun has well warmed the air; and again in the cold evening, turns northerly, or easterly.

Physical Cause of WINDS. Some philosophers, as Descartes, Rohault, &c, account for the general Wind, from the diurnal rotation of the earth; and from this general Wind they derive all the particular ones. Thus, as the earth turns eastward, the particles of the air near the equator, being very light, are left behind; so that, in respect of the earth's surface, they move westwards, and become a constant easterly wind, as they are found between the tropics, in those parallels of latitude where the diurnal motion is swiftest. But yet, against this hypothesis, it is urged, that the air, being kept close to the earth by the principle of gravity, would in time acquire the same degree of velocity that the earth's surface moves with, as well in respect of the diurnal rotation, as of the annual revolution about the sun, which is about 30 times swifter.

Dr. Halley therefore substitutes another cause, capable of producing a like constant effect, not liable to the same objections, but more agreeable to the known properties of the elements of air and water, and the laws of the motion of fluid bodies. And that is the action of the sun's beams, as he passes every day over the air, earth, and water, combined with the situation of the adjoining continents. Thus, the air which is less rarefied or expanded by heat, must have a motion towards those parts which are more rarefied, and less ponderous, to bring the whole to an equilibrium; and as the sun keeps continually shifting to the westward, the tendency of the whole body of the lower air is that way. Thus a general easterly Wind is formed, which being impressed upon the air of a vast ocean, the parts impel one another, and so keep moving till the next return of the sun, by which so much of the motion as was lost, is again restored; and thus the easterly Wind is made perpetual. But as the air towards the north and south is less rarefied than in the middle, it follows that from both sides it ought to tend towards the equator.

This motion, compounded with the former easterly Wind, accounts for all the phenomena of the general trade-Winds, which, if the whole surface of the globe were sea, would blow quite round the world, as they are found to do in the Atlantic and the Ethiopic oceans. But the large continents of land in this middle tract, being excessively heated, communicate their heat to the air above them, by which it is exceedingly rarefied, which makes it necessary that the cooler and denser air should rush in towards it, to restore the equilibrium. This is supposed to be the cause why, near the coast of Guinea, the wind always sets in upon the land, blowing westerly instead of easterly.

From the same cause it happens, that there are such constant calms in that part of the ocean called the *rains*; for this tract being placed in the middle, between the westerly Winds blowing on the coast of Guinea, and the easterly trade-Winds blowing to the westward of it; the tendency of the air here is indifferent to either, and so stands in equilibrio between both; and the weight of the incumbent atmosphere being diminished by the continual contrary Winds blowing from hence, is the reason that the air here retains not the copious vapour it receives, but lets it fall in so frequent rains.

It is also to be considered, that to the northward of the Indian ocean there is every where land, within the usual limits of the latitude of 30°, viz, Arabia, Persia, India, &c, which are subject to excessive heats when the sun is to the north, passing nearly vertical; but which are temperate enough when the sun is removed towards the other tropic, because of a ridge of mountains at some distance within the land, said to be often in winter covered with snow, over which the air as it passes must needs be much chilled. Hence it happens that the air coming, according to the general rule, out of the north-east, to the Indian sea, is sometimes hotter, sometimes colder, than that which, by a circulation of one current over another, is returned out of the south-west; and consequently sometimes the under current, or Wind, is from the north-east, sometimes from the south-west.

That this has no other cause, appears from the times when these Winds set, viz, in April: when the sun begins to warm these countries to the north, the south-west monsoons begin, and blow during the heats till October, when the sun being retired, and all things growing cooler northward, but the heat increasing to the south, the north-east Winds enter, and blow all the winter, till April again. And it is doubtless from the same principle, that to the southward of the equator, in part of the Indian ocean, the north-west Winds succeed the south-east, when the sun draws near the tropic

tropic of Capricorn. Philos. Transf. num. 183; or Abridg. vol. 2, pa. 193.

But some philosophers, not satisfied with Dr. Halley's theory above recited, or thinking it not sufficient for explaining the various phenomena of the Wind, have had recourse to another cause, viz, the gravitation of the earth and its atmosphere towards the sun and moon, to which the tides are confessedly owing. They allege that, though we cannot discover aërial tides, of ebb or flow, by means of the barometer, because columns of air of unequal height, but different density, may have the same pressure or weight; yet the protuberance in the atmosphere, which is continually following the moon, must, say they, occasion a motion in all parts, and so produce a Wind more or less to every place, which conspiring with, or being counteracted by the Winds arising from other causes, makes them greater or less. Several dissertations to this purpose were published, on occasion of the subject proposed by the Academy of Sciences at Berlin, for the year 1746. But Musschenbroek will not allow that the attraction of the moon is the cause of the general Wind; because the east Wind does not follow the motion of the moon about the earth; for in that case there would be more than 24 changes, to which it would be subject in the course of a year, instead of two. Introd. ad Phil. Nat. vol. 2, pa. 1102.

And Mr. Henry Eeles, conceiving that the rarefaction of the air by the sun cannot simply be the cause of all the regular and irregular motions which we find in the atmosphere, ascribes them to another cause, viz, the ascent and descent of vapour and exhalation, attended by the electrical fire or fluid; and on this principle he has endeavoured to explain at large the general phenomena of the weather and barometer. Philos. Transf. vol. 49, pa. 124.

Laws of the Production of Wind.

The chief laws concerning the production of Wind, may be collected under the following heads.

1. If the spring of the air be weakened in any place more than in the adjoining places, a Wind will blow through the place where the diminution is; because the less elastic or forcible will give way to that which is more so, and thence induce a current of air into that place, or a Wind. Hence, because the spring of the air increases, as the compressing weight increases, and compressed air is denser than that which is less compressed; all Winds blow into rarer air, out of a place filled with a denser.

2. Therefore, because a denser air is specifically heavier than a rarer; an extraordinary lightness of the air in any place must be attended with extraordinary Winds, or storms. Now, an extraordinary fall of the mercury in the barometer shewing an extraordinary lightness of the atmosphere, it is no wonder if that foretels storms of Wind and rain.

3. If the air be suddenly condensed in any place, its spring will be suddenly diminished: and hence, if this diminution be great enough to affect the barometer, a Wind will blow through the condensed air. But since the air cannot be suddenly condensed, unless it has before been much rarefied, a Wind will blow through the air, as it cools, after having been violently heated.

4. In like manner, if air be suddenly rarefied, its spring is suddenly increased; and it will therefore flow through the air not acted on by the rarefying force. Hence a Wind will blow out of a place, in which the air is suddenly rarefied; and on this principle, probably it is, that the sun, by rarefying the air, must have a great influence on the production of Winds.

5. Most caves are found to emit Wind, either more or less. Musschenbroek has enumerated a variety of causes that produce Winds, existing in the bowels of the earth, on its surface, in the atmosphere, and above it. See Introd. ad Phil. Nat. vol. 2, pa. 1116.

6. The rising and changing of the Winds are determined by weathercocks, placed on the tops of high buildings, &c. But these only indicate what passes about their own height, or near the surface of the earth. And Wolfius assures us, from observations of several years, that the higher Winds, which drive the clouds, are different from the lower ones, which move the weathercocks. Indeed it is no uncommon thing to see one tier of clouds driven one way by a Wind, and another tier just over the former driven the contrary way, by another current of air, and that often with very different velocities. And the late experiments with air balloons have proved the frequent existence of counter Winds, or currents of air, even when it was not otherwise visible, nor at all expected; by which they have been found to take very different and unexpected courses, as they have ascended higher and higher in the atmosphere.

Laws of the Force and Velocity of the Wind.

Wind being only air in motion, and the motion of a fluid against a body at rest, creating the same resistance as when the body moves with the same velocity through the fluid at rest; it follows, that the force of the Wind, and the laws of its action upon bodies, may be referred to those of their resistance when moved through it; and as these circumstances have been treated pretty fully under the article Resistance *of the Air*, there is no occasion here to make a repetition of them. We there laid down both the quantity and laws of such a force, upon bodies of different shapes and sizes, moving with all degrees of velocity up to 2000 feet per second, and also for planes set at all degrees of obliquity, or inclination to the direction of motion; all which circumstances having, for the first time, been determined by real experiments.

As to the Velocity of the Wind: philosophers have made use of various methods for determining it. The method employed by Dr. Derham, was by letting light downy feathers fly in the air, and nicely observing the distance to which they were carried in any number of half seconds. He says that he thus measured the velocity of the Wind in the great storm of August 1705, which he found moved at the rate of 33 feet in half a second, or 45 miles per hour: whence he concludes, that the most vehement Wind does not fly at the rate of above 50 or 60 miles an hour; and that at a medium the velocity of Wind is at the rate of 12 or 15 miles per hour. Philos. Transf. number 313, or Abridg. vol. 4, p. 411.

Mr. Brice observes however, that experiments with feathers are liable to much uncertainty; as they hardly ever

ever go forward in a ſtraight direction, but ſpirally, or elſe irregularly from ſide to ſide, or up and down.

He therefore conſiders the motion of a cloud, by means of its ſhadow over the ſurface of the earth, as a much more accurate meaſure of the velocity of the Wind. In this way he found that the Wind, in a conſiderable ſtorm, moved at the rate of near 63 miles an hour; and when it blew a freſh gale, at the rate of 21 miles per hour; and in a ſmall breeze it was near 10 miles an hour. Philoſ. Tranſ. vol. 56, p. 226.

The velocity and force of the Wind are alſo determined experimentally by various machines, called *anemometers*, *wind-meaſurers*, or *wind-gages*; the deſcription of which ſee under theſe articles.

In the Philoſ. Tranſ. for 1759, p. 165, Mr. Smeaton has given a table, communicated to him by a Mr. Rouſe, for ſhewing the force of the Wind, with ſeveral different velocities, which I ſhall inſert below, as I find the numbers nearly agree with my own experiments made on the reſiſtance of the air, when the reſiſting ſurfaces are reduced to the ſame ſize, by a due proportion for the reſiſtance, which is in a higher degree than that of the ſurfaces.

N. B. The table of my reſults is printed in pa. 111, vol. 1, under the article ANEMOMETER; where it is to be noted, that the numbers in the third column of that table, for the velocity of the Wind per hour, are all erroneouſly printed, only the 4th part of what each of them ought to be; ſo that thoſe numbers muſt be all multiplied by 4.

A Table of the different Velocities and Forces of the Wind, according to their common appellations.

Velocity of the Wind: Miles in one hour.	Velocity of the Wind: = feet in one ſecond.	Perpendicular force on one ſq. foot, in averdupois pounds.	Common appellations of the Winds.
1	1·47	·005	Hardly perceptible.
2	2·93	·020	Juſt perceptible.
3	4·40	·044	
4	5·87	·079	Gentle pleaſant wind.
5	7·33	·123	
10	14·67	·492	Pleaſant briſk gale.
15	22·00	1·107	
20	29·34	1·968	Very briſk.
25	36·67	3·075	
30	44·01	4·429	High Winds.
35	51·34	6·027	
40	58·68	7·873	Very high.
45	66·01	9·963	
50	73·35	12·300	A ſtorm or tempeſt.
60	88·02	17·715	A great ſtorm.
80	117·36	31·490	A hurricane.
100	146·70	49·200	A hurricane that tears up trees, and carries buildings &c before it.

The force of the Wind is nearly as the ſquare of the velocity, or but little above it, in theſe velocities. But the force is much more than in the ſimple ratio of the ſurfaces, with the ſame velocity, and this increaſe of the ratio is the more, as the velocity is the more. By accurate experiments with two planes, the one of $17\frac{7}{8}$ ſquare inches, the other of 32, which are nearly in the ratio of 5 to 9, I found their reſiſtances, with a velocity of 20 feet per ſecond, to be, the one 1·196 ounces, and the other 2·542 ounces; which are in the ratio of 8 to 17, being an increaſe of between $\frac{1}{5}$ and $\frac{1}{6}$ part more than the ratio of the ſurfaces.

WIND-*Gage*, in Pneumatics, an inſtrument ſerving to determine the velocity and force of the Wind. See ANEMOMETER, ANEMOSCOPE, and the article juſt above concerning the Force and Velocity of the Wind.

Dr. Hales had various contrivances for this purpoſe. He found (Statical Eſſays, vol. 2, p. 326) that the air ruſhed out of a ſmith's bellows, at the rate of 68$\frac{1}{2}$ feet in a ſecond of time, when compreſſed with a force of half a pound upon every ſquare inch lying on the whole upper ſurface of the bellows. The velocity of the air, as it paſſed out of the trunk of his ventilators, was found to be at the rate of 3000 feet in a minute, which is at the rate of 34 miles an hour. The ſame author ſays, that the velocity with which impelled air paſſes out at any orifice, may be determined by hanging a light valve over the nole of a bellows, by pliant leathern hinges, which will be much agitated and lifted up from a perpendicular to a more than horizontal poſition by the force of the ruſhing air. There is alſo another more accurate way, he ſays, of eſtimating the velocity of air, viz, by holding the orifice of an inverted glaſs ſiphon full of water, oppoſite to the ſtream of air, by which the water will be depreſſed in one leg, and raiſed in the other, in proportion to the force with which the water is impelled by the air. Deſcrip. of Ventilators, 1743, p. 12. And this perhaps gave Dr. Lind the idea of his Wind-gage, deſcribed below.

M. Bouguer contrived a ſimple inſtrument, by which may be immediately diſcovered the force which the Wind exerts on a given ſurface. This is a hollow tube AABB (fig. 14, pl. 30), in which a ſpiral ſpring CD is fixed, that may be more or leſs compreſſed by a rod FSD, paſſing through a hole within the tube at AA. Then having obſerved to what degree different forces or given weights are capable of compreſſing the ſpiral, mark diviſions on the rod in ſuch a manner, that the mark at S may indicate the weight requiſite to force the ſpring into the ſituation CD: afterwards join at right angles to this rod at F, a plane ſurface CFE of any given area at pleaſure; then let this inſtrument be oppoſed to the Wind, ſo that it may ſtrike the ſurface perpendicularly, or parallel to the rod; then will the mark at S ſhew the weight to which the force of the Wind is equivalent.

Dr. Lind has alſo contrived a ſimple and eaſy apparatus of this kind, nearly upon the laſt idea of Dr. Hales mentioned above. This inſtrument is fully explained at the article ANEMOMETER, vol. 1, pa. 111, and a figure of it given, pl. 3, fig. 4.

Mr. Benjamin Martin, from a hint firſt ſuggeſted by Dr. Burton, contrived an anemoſcope, or Wind-gage, of a conſtruction like a Wind-mill, with four ſails; but the axis which the ſails turn, is not cylindrical, but conical, like the fuſee of a watch; about this fuſee winds a cord, having a weight at the end, which is wound

wound always, by the force of the Wind, upon the fails, till the weight juft balances that force, which will be at a thicker part of the fufee when the Wind is ftrong, and at a fmaller part of it when it is weaker. But although this inftrument fhews when a Wind is ftronger or weaker, it will neither fhew what is the actual velocity of the Wind, nor yet its force upon a fquare foot of direct furface; becaufe the fails are fet at an uncertain oblique angle to the Wind, and this acts at different diftances from the axis or centre of motion. Martin's Phil. Brit. vol. 2, p. 211. See the fig. 5, plate 3, vol. 1.

WIND-*Gun*, the fame as AIR-*Gun*; which fee.

WIND-*Mill*, a kind of mill which receives its motion from the impulfe of the Wind.

The internal ftructure of the Windmill is much the fame with that of watermills: the difference between them lying chiefly in an external apparatus, for the application of the power. This apparatus confifts of an axis EF (fig. 11, pl. 36), through which pafs perpendicular to it, and to each other, two arms or yards, AB and CD, ufually about 32 feet long: on thefe yards are formed a kind of fails, vanes, or flights, in a trapezoid form, with parallel ends; the greater of which HI is about 6 feet, and the lefs FG are determined by radii drawn from the centre E, to I and H.

Thefe fails are to be capable of being always turned to the wind, to receive its impulfe: for which purpofe there are two different contrivances, which conftitute the two different kinds of Windmills in common ufe.

In the one, the whole machine is fupported upon a moveable arbor, or axis, fixed upright on a ftand or foot; and turned round occafionally to fuit the wind, by means of a lever.

In the other, only the cover or roof of the machine, with the axis and fails, in like manner turns round with a parallel or horizontal motion. For this purpofe, the cover is built turret-wife, and encompaffed with a wooden ring, having a groove, at the bottom of which are placed, at certain diftances, a number of brafs truckles; and within the groove is another ring, upon which the whole turret ftands. To the moveable ring are connected beams *ab* and *fe*; and to the beam *ab* is faftened a rope at *b*, having its other end fitted to a windlafs, or axis-in-peritrochio: this rope being drawn through the iron hook G, and the windlafs turned, the fails are moved round, and fet fronting the wind, or with the axis pointing ftraight againft the wind.

The internal mechanifm of a Windmill is exhibited in fig. 12; where AHO is the upper room, and H*o*Z the lower one; AB the axle-tree paffing through the mill; STVW the fails covered with canvas, fet obliquely to the wind, and turning round in the order of the letters; CD the cogwheel, having about 48 cogs or teeth, *a*, *a*, *a*, &c, which carry round the lantern EF, having 8 or 9 trundles or rounds *c*, *c*, *c*, &c, together with its upright axis GN; IK is the upper millftone, and LM the lower one; QR is the bridge, fupporting the axis or fpindle GN; this bridge is fupported by the beams *cd*, XY, wedged up at *c*, *d* and X; ZY is the lifting tree, which ftands upright; *ab* and *ef* are levers, whofe centres of motion are Z and *e*; *fghi* is a cord, with a ftone *i*, going about the pins *g* and *h*, and ferving as a balance or counterpoife. The fpindle *t*N is fixed to the upper millftone IK, by a piece of iron called the rynd, and fixed in the lower fide of the ftone, which is the only one that turns about, and its whole weight refts upon a hard ftone, fixed in the bridge QR at N. The trundle EF, and its axis G*t*, may be taken away; for it refts by its lower part at *t* by a fquare focket, and the top runs in the edge of the beam *w*. By bearing down the end *f* of the lever *fe*, *b* is raifed, which raifes ZY, and this raifes YX, which lifts up the bridge QR, with the axis NG, and the upper ftone IK; and thus the ftones are fet at any diftance. The lower or immoveable ftone is fixed upon ftrong beams, and is broader than the upper one: the flour is conveyed through the tunnel *no* into a cheft; P is the hopper, into which is put the corn, which runs through the fpout *r* into the hole *t*, and fo falls between the ftones, where it is ground to meal. The axis G*t* is fquare, which fhaking the fpout *r*, as it goes round, makes the corn run out; *rs* is a ftring going about the pin *s*, and ferving to move the fpout nearer to the axis or farther from it, fo as to make the corn run fafter or flower, according to the velocity and force of the wind. And when the wind is ftrong, the fails are only covered in part, or on one fide, or perhaps only one half of two oppofite fails. Toward the end B of the axletree is placed another cogwheel, trundle, and millftones, with an apparatus like that juft defcribed; fo that the fame axis moves two ftones at once; and when only one pair is to grind, one of the trundles and its fpindle are taken out: *xyl* is a girth of pliable wood, fixed at the end *x*; the other end *l* being tied to the lever *km*, moveable about *k*; and the end *m* being put down, draws the girth *xyl* clofe to the cogwheel, which gently and gradually ftops the motion of the mill, when required: *pq* is a ladder for afcending to the higher part of the mill; and the corn is drawn up by means of a rope, rolled about the axis AB, when the mill is at work. See MILL.

Theory of the WINDMILL, *Pofition of the Sails*, &c.

Were the fails fet fquare upon their arms or yards, and perpendicular to the axletree, or to the wind, no motion would enfue, becaufe the direct wind would keep them in an exact balance. But by fetting them obliquely to the common axis, like the fails of a fmoke-jack, or inclined like the rudder of a fhip, the wind, by ftriking the furface of them obliquely, turns them about. Now this angle which the fails are to make with their common axis, or the degree of *weathering*, as the mill-wrights call it, fo as that the wind may have the greateft effect, is a matter of nice enquiry, and has much occupied the thoughts of the mathematician and the artift.

In examining the compound motions of the rudder of a fhip, we find that the more it approaches to the direction of the keel, or to the courfe of the water, the more weakly this ftrikes it; but, on the other hand, the greater is the power of the lever to turn the veffel about. The obliquity of the rudder therefore has, at the fame time, both an advantage and a difadvantage. It has been a point of inquiry therefore to find the pofition of the rudder when the ratio of the advantage over the difadvantage is the greateft. And M. Renau, in his

his theory of the working of ships, has found, that the best situation of the rudder is when it makes an angle of about 55 degrees with the keel.

The obliquity of the sails, with regard to their axis, has precisely the same advantage, and disadvantage, with the obliquity of the rudder to the keel. And M. Parent, seeking by the new analysis the most advantageous situation of the sails on the axis, finds it the same angle of about 55 degrees. This obliquity has been determined by many other mathematicians, and found to be more accurately 54° 44'. See Maclaurin's Fluxions, p. 733; Simpson's Fluxions, prob. 17, p. 521; Martin's Philos. Britan. vol. 1, p. 220, vol. 2, p. 212; &c.

This angle, however, is only that which gives the wind the greatest force to put the sail in motion, but not the angle which gives the force of the wind a maximum upon the sail when in motion: for when the sail has a certain degree of velocity, it yields to the wind; and then that angle must be increased, to give the wind its full effect. Maclaurin, in his Fluxions, p. 734, has shewn how to determine this angle.

It may be observed, that the increase of this angle should be different according to the different velocities from the axletree to the further extremity of the sail. At the beginning, or axis, it should be 54° 44'; and thence continually increasing, giving the vane a twist, and so causing all the ribs of the vane to lie in different planes.

It is farther observed, that the ribs of the vane or sail ought to decrease in length from the axis to the extremity, giving the vane a curvilinear form; so that no part of the force of any one rib be spent upon the rest, but all move on independent of each other. The twist above mentioned, and the diminution of the ribs, are exemplified in the wings of birds.

As the ends of the sail nearest the axis cannot move with the same velocity which the tips or farthest ends have, although the wind acts equally strong upon them both, Mr. Ferguson (Lect. on Mech. pa. 52) suggests, that perhaps a better position than that of stretching them along the arms directly from the centre of motion, might be, to have them set perpendicularly across the farther ends of the arms, and there adjusted lengthwise to the proper angle: for in that case both ends of the sails would move with the same velocity; and being farther from the centre of motion they would have so much the more power, and then there would be no occasion for having them so large as they are generally made; which would render them lighter, and consequently there would be so much the less friction on the thick neck of the axle, when it turns in the wall.

Mr. Smeaton (Philos. Trans. 1759), from his experiments with Windmill sails, deduces several practical maxims: as,

1. That when the wind falls upon a concave surface, it is an advantage to the power of the whole, though every part, taken separately, should not be disposed to the best advantage. By several trials he has found that the curved form and position of the sails will be best regulated by the numbers in the following table.

6th Parts of the radius or sail.	Angle with the axis.	Angle with the plane of motion.
1	72°	18°
2	71	19
3	72	18 middle.
4	74	16
5	77½	12½
6	83	7 end.

2. That a broader sail requires a greater angle; and that when the sail is broader at the extremity, than near the centre, this shape is more advantageous than that of a parallelogram.

3. When the sails, made like sectors of circles, joining at the centre or axis, filled up about 7 8ths of the whole circular space, the effect was the greatest.

4. The velocity of Windmill sails, whether unloaded, or loaded so as to produce a maximum of effect, is nearly as the velocity of the Wind; their shape and position being the same.

5. The load at the maximum is nearly, but somewhat less than, as the square of the velocity of the wind.

6. The effects of the same sails at a maximum, are nearly, but somewhat less than, as the cubes of the velocity of the wind.

7. In sails of a similar figure and position, the number of turns in a given time, are reciprocally as the radius or length of the sail.

8. The effects of sails of similar figure and position, are as the square of their length.

9. The velocity of the extremities of Dutch mills, as well as of the enlarged sails, in all their usual positions, is considerably greater than the velocity of the wind.

M. Parent, in considering what figure the sails of a Windmill should have, to receive the greatest impulse from the wind, finds it to be a sector of an ellipsis, whose centre is that of the axletree of the mill; and the less semiaxis the height of 32 feet; as for the greater, it follows necessarily from the rule that directs the sail to be inclined to the axis in the angle of 55 degrees.

On this foundation he assumes four such sails, each being a quarter of an ellipse; which he shews will receive all the wind, and lose none, as the common ones do. These 4 surfaces, multiplied by the lever, with which the wind acts on one of them, express the whole power the wind has to move the machine, or the whole power the machine has when in motion.

A Windmill with 6 elliptical sails, he shews, would still have more power than one with only four. It would only have the same surface with the four; since the 4 contain the whole space of the ellipsis, as well as the 6. But the force of the 6 would be greater than that of the 4, in the ratio of 245 to 231. If it were desired to have only two sails, each being a semiellipsis, the surface would be still the same; but the power would be diminished by near 1-3d of that with 6 sails; because the greatness of the sectors would much shorten the lever with which the wind acts.

The same author has also considered which form, among the rectangular sails, will be most advantageous; i. e.

i. e. that which shall have the product of the surface by the lever of the wind, the greatest. The result of this enquiry is, that the width of the rectangular sail should be nearly double its length; whereas usually the length is made almost 5 times the width.

The power of the mill, with four of these new rectangular sails, M. Parent shews, will be to the power of four elliptic sails, nearly as 13 to 23; which leaves a considerable advantage on the side of the elliptic ones; and yet the force of the new rectangular sails will still be considerably greater than that of the common ones.

M. Parent also considers what number of the new sails will be most advantageous; and finds that the fewer the sails, the more surface there will be, but the power the less. Farther, the power of a Windmill with 6 sails is denoted by 14, that of another with 4 will be as 13, and another with 2 sails will be denoted by 9. That as to the common Windmill, its power still diminishes as the breadth of the sails is smaller, in proportion to the length: and therefore the usual proportion of 5 to 1 is exceedingly disadvantageous.

WINDWARD, in Sea Language, denotes any thing towards that point from whence the wind blows, in respect of a ship.

Sailing to WINDWARD. See SAILING.

WINDWARD *Tide*, denotes a tide that runs against the wind.

WINDAGE *of a Gun*, is the difference between the diameter of the bore of the gun and the diameter of the ball.

Heretofore the Windage appointed in the English service, viz, 1-20th of the diameter of the ball, which has been used almost from the beginning, has been far too much, owing perhaps to the first want of roundness in the ball, or to rust, foulness, or irregularities in the bore of the gun. But lately a beginning has been made to diminish the Windage, which cannot fail to be of very great advantage; as the shot will both go much truer, and have less room to bounce about from side to side, to the great damage of the gun; and besides much less powder will serve for the same effect, as in some cases $\frac{1}{4}$ or $\frac{1}{3}$ the inflamed powder escapes by the Windage. The French allowance of Windage is 1-25th of the diameter of the ball.

WINDLASS, or WINDLACE, a particular machine used for raising heavy weights, as guns, stones, anchors, &c.

This is a very simple machine, consisting only of an axis or roller, supported horizontally at the two ends by two pieces of wood and a pulley: the two pieces of wood meet at top, being placed diagonally so as to prop each other; and the axis or roller goes through the two pieces, and turns in them. The pulley is fastened at top where the pieces join. Lastly, there are two staves or hand-spikes which go through the roller, to turn it by; and the rope, which comes over the pulley, is wound off and on the same.

WINDLASS, in a Ship, is an instrument in small ships, placed upon the deck, just abaft the foremast. It is made of a long and thick piece of timber, either cylindrical, or octagonal, &c, in form of an axletree, placed horizontally across the ship, a foot or more above the deck; and it is turned about by the help of handspikes put into holes made for that purpose.

This machine will purchase or raise much more than a capstan, and that without any danger to those that heave; for if in heaving the Windlass about, any of the handspikes should happen to slip or break, the Windlass will stop of itself, as it does at the end of every pull or heave of the men, being prevented from returning by means of a catch that falls into notches. See fig. 15, pl. 35.

WINDOW, q. d. *wind-door*, an aperture or opening in the wall of a house, to admit the air and light.

Before the use of glass became general, which was not till towards the end of the 12th century, the Windows in England seem generally to have been composed of paper, oiled, both to defend it against the weather, and to make it more transparent; as now is sometimes used in workshops and unfinished buildings. Some of the better sort were furnished with lattices of wood or sheets of linen. These it seems were fixed in frames, called *capsamenta*, and hence our *casements* still so common in some of the counties.

The chief rules with regard to Windows are, 1. That they be as few in number, and as moderate in dimensions, as may be consistent with other respects; inasmuch as all openings are weakenings.

2. That they be placed at a convenient distance from the angles or corners of the buildings: both for strength and beauty.

3. That they be made all equal one with another, in their rank and order; so that those on the right hand may answer to those on the left, and those above be right over those below: both for strength and beauty.

As to their dimensions, care is to be taken, to give them neither more nor less than is needful; regard being had to the size of the rooms, and of the building. The apertures of Windows in middle-sized houses, may be from 4 to 5 feet; in the smaller ones less; and in large buildings more. And the height may be double their width at the least: but in lofty rooms, or large buildings, the height may be a 4th, or 3d, or half their breadth more than the double.

Such are the proportions for Windows of the first story; and the breadth must be the same in the upper stories; but as to the height, the second story may be a 3d part lower than the first, and the third story a 4th part lower than the second.

WINTER, one of the four seasons or quarters of the year.

Winter properly commences on the day when the sun's distance from the zenith of the place is the greatest, or when his declination is the greatest on the contrary side of the equator; and it ends on the day when that distance is a mean between the greatest and least, or when he next crosses the equinoctial.

At and near the equator, the Winter, as well as the other seasons, return twice every year; but all other places have only one Winter in the year; which in the northern hemisphere begins when the sun is in the tropic of Capricorn, and in the southern hemisphere when he is in the tropic of Cancer: so that all places in the same hemisphere have their Winter at the same time.

Notwithstanding the coldness of this season it is proved in astronomy, that the sun is really nearer to the earth in our Winter than in summer: the reason of the defect

defect of heat being owing to the lowness of the sun, or to the obliquity of his rays.

WOLFF, WOLFIUS, (CHRISTIAN), baron of the Roman empire, privy counsellor to the king of Prussia, and chancellor to the university of Halle in Saxony, as well as member of many of the literary academies in Europe, was born at Breslau in 1679. After studying philosophy and mathematics at Breslau and Jena, he obtained permission to give lectures at Leipsic; which, in 1703, he opened with a dissertation called *Philosophia Practica Universalis, Methodo Mathematica conscripta*, which served greatly to enhance the reputation of his talents. He published two other dissertations the same year; the first *De Rotis Dentatis*, the other *De Algorithmo Infinitesimali Differentiali*; which obtained him the honourable appellation of Assistant to the Faculty of Philosophy at Leipsic.

He now accepted the professorship of mathematics at Halle, and was elected into the society at Leipsic, at that time engaged in publishing the *Acta Eruditorum*. After having inserted in this work many important pieces relating to mathematics and physics, he undertook, in 1709, to teach all the various branches of philosophy, beginning with a small Logical treatise in Latin, being Thoughts on the Powers of the Human Understanding. He carried himself through these great pursuits with amazing assiduity and ardour: the king of Prussia rewarded him with the office of counsellor to the court in 1721, and augmented the profits of that post by very considerable appointments: he was also chosen a member of the Royal Society of London and of Prussia.

In the midst of all this prosperity however, Wolff raised an ecclesiastical storm against himself, by a Latin oration he delivered in praise of the Chinese philosophy: every pulpit immediately resounded against his tenets; and the faculty of theology, who entered into a strict examination of his productions, resolving that the doctrine he taught was dangerous to the last degree, an order was obtained in 1723 for displacing him, and commanding him to leave Halle in 24 hours

Wolff now retired to Cassel, where he obtained the professorship of mathematics and philosophy in the university of Marbourg, with the title of Counsellor to the Landgrave of Hesse; to which a profitable pension was annexed. Here he renewed his labours with redoubled ardour; and it was in this retreat that he published the greatest part of his numerous works.

In 1725, he was declared an honorary professor of the academy of sciences at Petersburg, and in 1733 was admitted into that of Paris. The king of Sweden also declared him one of the council of regency; but the pleasing situation of his new abode, and the multitude of honours which he had received, were too alluring to permit him to accept of many advantageous offers; among which was the office of president of the academy at Petersburg.

The king of Prussia too, who was now recovered from the prejudices he had been made to conceive against Wolff, wanted to re-establish him in the university of Halle in 1733, and made another attempt to effect it in 1739; which Wolff for a time thought fit to decline, but at last submitted: he returned therefore in 1741, invested with the characters of privy counsellor, vice chancellor, and professor of the law of nature and of nations. The king afterwards, upon a vacancy, raised him to the dignity of chancellor of the university; and the elector of Bavaria created him a baron of the empire. He died at Halle in Saxony, of the gout in his stomach, in 1754, in the 76th year of his age, after a life filled up with a train of actions as wise and systematical as his writings, of which he composed in Latin and German more than 60 distinct pieces. The chief of his mathematical compositions, is his *Element. Matheseos Universæ*, the best edition of which is that of 1732 at Geneva, in 5 vols 4to; which does not however comprise his Mathematical Dictionary in the German language, in 1 vol. 8vo, nor many other distinct works on different branches of the mathematics, nor his System of Philosophy, in 23 vols. in 4to.

WORKING *to Windward*, in Sea Language, is the operation by which a ship endeavours to make a progress against the wind.

WREN (Sir CHRISTOPHER), a great philosopher and mathematician, and one of the most learned and eminent architects of his age, was the son of the rev. Christopher Wren, dean of Windsor, and was born at Knoyle in Wiltshire in 1632. He studied at Wadham college, Oxford; where he took the degree of master of arts in 1653, and was chosen fellow of Allsouls college there. Soon after, he became one of that ingenious and learned society, who then met at Oxford for the improvement of natural and experimental philosophy, and which at length produced the Royal Society.

When very young, he discovered a surprising genius for the mathematics, in which science he made great advances before he was 16 years of age.—In 1657 he was made professor of astronomy in Gresham college, London; and his lectures, which were much frequented, tended greatly to the promotion of real knowledge: in his inaugural oration, among other things, he proposed several methods by which to account for the shadows returning backward 10 degrees on the dial of king Ahaz, by the laws of nature. One subject of his lectures was upon telescopes, to the improvement of which he had greatly contributed: another was on certain properties of the air, and the barometer. In the year 1658 he read a description of the body and different phases of the planet Saturn; which subject he proposed to investigate while his colleague, Mr. Rooke, then professor of geometry, was carrying on his observations upon the satellites of Jupiter. The same year he communicated some demonstrations concerning cycloids to Dr. Wallis, which were afterwards published by the doctor at the end of his treatise upon that subject. About that time also, he resolved the problem proposed by Pascal, under the feigned name of John de Montford, to all the English mathematicians; and returned another to the mathematicians in France, formerly proposed by Kepler, and then resolved likewise by himself, to which they never gave any solution.—In 1660, he invented a method for the construction of solar eclipses: and in the latter part of the same year, he with ten other gentlemen formed themselves into a society, to meet weekly, for the improvement of natural and experimental philosophy; being the foundation of the Royal Society.—In the beginning of 1661, he was chosen Savilian professor of astronomy at Oxford,

in

in the room of Dr. Seth Ward; where he was the same year created Doctor of Laws.

Among his other accomplishments, Dr. Wren had gained so considerab'e a skill in architecture, that he was sent for the same year, from Oxford, by order of king Charles the 2d, to assist Sir John Denham, surveyor general of the works.—In 1663, he was chosen fellow of the Royal Society; being one of those who were first appointed by the Council after the grant of their charter. Not long after, it being expected that the king would make the society a visit, the lord Brounker, then president, by a letter requested the advice of Dr. Wren, concerning the experiments which might be most proper on that occasion: to whom the doctor recommended principally the Torricellian experiment, and the weather needle, as being not mere amusements, but useful, and also neat in their operation. Indeed upon many occasions Dr. Wren did great honour to that illustrious body, by many curious and useful discoveries, in astronomy, natural philosophy, and other sciences, related in the History of the Royal Society, where Dr. Sprat has inserted them from the registers and other books of the society to 1665. Among others of his productions there enumerated, is a lunar globe; representing the spots and various degrees of whiteness upon the moon's surface, with the hills, eminences and cavities: the whole contrived so, that by turning it round to the light, it shews all the lunar phases, with the various appearances that happen from the shadows of the mountains and valleys, &c: this lunar model was placed in the king's cabinet. Another of these productions, is a tract on the Doctrine of Motion that arises from the impact between two bodies, illustrated by experiments. And a third is, The History of the Seasons, as to the temperature, weather, productions, diseases, &c, &c. For which purpose he contrived many curious machines, several of which kept their own registers, tracing out the lines of variations, so that a person might know what changes the weather had undergone in his absence: as windgages, thermometers, barometers, hygrometers, raingages, &c.—He made also great additions to the new discoveries on pendulums; and among other things shewed, that there may be produced a natural standard for measure from the pendulum for common use.—He invented many ways to make astronomical observations more easy and accurate: He fitted and hung quadrants, sextants, and radii more commodiously than formerly: he made two telescopes to open with a joint like a sector, by which observers may infallibly take a distance to half minutes, &c. He made many sorts of retes, screws, and other devices, for improving telescopes to take small distances, and apparent diameters, to seconds: He made apertures for taking in more or less light, as the observer pleases, by opening and shutting, the better to fit glasses for crepusculine observations.—He added much to the theory of dioptrics; much to the manufacture of grinding good glasses.—He attempted, and not without success, the making of glasses of other forms than spherical. He exactly measured and delineated the spheres of the humours of the eye, the proportions of which to one another were only guessed at before: a discussion shewing the reasons why we see objects erect, and that reflection conduces as much to vision as refraction. He displayed a natural and easy theory of refractions, which exactly answered every experiment. He fully demonstrated all dioptrics in a few propositions, shewing not only, as in Kepler's Dioptrics, the common properties of glasses, but the proportions by which the individual rays cut the axis, and each other, upon which the charges of the telescopes, or the proportion of the eye-glasses and apertures, are demonstrably discovered.—He made constant observations on Saturn, and a true theory of that planet, before the printed discourse by Huygens, on that subject, appeared.—He made maps of the Pleiades and other telescopic stars: and proposed methods to determine the great question as to the earth's motion or rest, by the small stars about the pole to be seen in large telescopes.—In navigation he made many improvements. He framed a magnetical terella, which he placed in the midst of a plane board with a hole, into which the terella is half immersed, till it be like a globe with the poles in the horizon: the plane is then dusted over with steel filings from a sieve: the dust, by the magnetical virtue, becomes immediately figured into furrows that bend like a sort of helix, proceeding as it were out at one pole, and returning in by the other; the whole plane becoming figured like the circles of a planisphere.—It being a question in his time among the problems of navigation, to what mechanical powers sailing against the wind was reducible; he shewed it to be a wedge: and he demonstrated, how a transient force upon an oblique plane would cause the motion of the plane against the first mover: and he made an instrument mechanically producing the same effect, and shewed the reason of sailing on all winds. The geometrical mechanism of rowing, he shewed to be a lever on a moving or cedent fulcrum: for this end, he made instruments and experiments, to find the resistance to motion in a liquid medium; with other things that are the necessary elements for laying down the geometry of sailing, swimming, rowing, flying, and constructing of ships—He invented a very speedy and curious way of etching. He started many things towards the emendation of water-works. He likewise made some instruments for respiration, and for straining the breath from fuliginous vapours, to try whether the same breath, so purified, will serve again.—He was the first inventor of drawing pictures by microscopical glasses. He found out perpetual, or at least longlived lamps, for keeping a perpetual regular heat, in order to various uses, as hatching of eggs and insects, production of plants, chemical preparations, imitating nature in producing fossils and minerals, keeping the motion of watches equal, for the longitude and astronomical uses.—He was the first author of the anatomical experiment of injecting liquor into the veins of animals. By this operation, divers creatures were immediately purged, vomited, intoxicated, killed, or revived, according to the quality of the liquor injected. Hence arose many other new experiments, particularly that of transfusing blood, which has been prosecuted in sundry curious instances. This is a short account of the principal discoveries which Dr. Wren presented, or suggested, to the Royal Society, or were improved by him.

As to his architectural works: It has before been observed

observed that he had been sent for to assist Sir John Denham. In 1665 he travelled into France, to examine the most beautiful edifices and curious mechanical works there, when he made many useful observations. Upon his return home, he was appointed architect, and one of the commissioners for repairing St. Paul's cathedral. Within a few days after the fire of London, 1666, he drew a plan for a new city, and presented it to the king; but it was not approved of by the parliament. In this model, the chief streets were to cross each other at right angles, with lesser streets between them; the churches, public buildings, &c, so disposed as not to interfere with the streets, and four piazzas placed at proper distances.—Upon the death of Sir John Denham, in 1668, he succeeded him in the office of surveyor-general of the king's works; and from this time he had the direction of a great many public edifices, by which he acquired the highest reputation. He built the magnificent theatre at Oxford, St. Paul's cathedral, the Monument, the modern part of Hampton Court, Chelsea-college, one of the wings of Greenwich hospital, the churches of St. Stephen Walbrook, and St. Mary-le-bow, with upwards of 60 other churches and public works, which that dreadful fire made necessary. In the management of which business, he was assisted in the measurements, and laying out of private property, by the ingenious Dr. Robert Hook. The variety of business in which he was by this means engaged, requiring his constant attendance and concern, he resigned his Savilian professorship at Oxford in 1673; and the year following he received from the king the honour of knighthood.—He was one of the commissioners who, on the motion of Sir Jonas Moore, surveyor-general of the ordnance, had been appointed to find out a proper place for erecting an observatory; and he proposed Greenwich, which was approved of; the foundation stone of which was laid the 10th of August 1675, and the building was presently finished under the direction of Sir Jonas, with the advice and assistance of Sir Christopher.

In 1680 he was chosen president of the Royal Society; afterwards appointed architect and commissioner of Chelsea-college; and, in 1684, principal officer or comptroller of the works in Windsor-castle. Sir Christopher sat twice in Parliament, as a representative for two different boroughs. While he continued surveyor-general, his residence was in Scotland-yard; but after his removal from that office, in 1718, he lived in St. James's-street, Westminster. He died the 25th of February 1723, at 91 years of age; and he was interred with great solemnity in St. Paul's cathedral, in the vault under the south wing of the choir, near the east end.

As to his person, Sir Christopher Wren was of a low stature, and thin frame of body; but by temperance and skilful management he enjoyed a good state of health, to a very unusual length of life. He was modest, devout, strictly virtuous, and very communicative of his knowledge. Besides his peculiar eminence as an architect, his learning and knowledge were very extensive in all the arts and sciences, and especially in the mathematics.

Sir Christopher never printed any thing himself, but several of his works have been published by others; some in the Philosophical Transactions, and some by Dr. Wallis and other friends.—His posthumous works and draughts were published by his son.

WRIGHT (Edward), a noted English mathematician, who flourished in the latter part of the 16th century, and beginning of the 17th; dying in the year 1615. He was contemporary with Mr. Briggs, and much concerned with him in the business of the logarithms, the short time they were published before his death. He also contributed greatly to the improvement of navigation and astronomy. The following memoirs of him are translated from a Latin paper in the annals of Gonvile and Caius college in Cambridge, viz, "This year (1615) died at London, Edward Wright of Garveston in Norfolk, formerly a fellow of this college; a man respected by all for the integrity and simplicity of his manners, and also famous for his skill in the mathematical sciences: so that he was not undeservedly styled a most excellent mathematician by Richard Hackluyt, the author of an original treatise of our English navigations. What knowledge he had acquired in the science of mechanics, and how usefully he employed that knowledge to the public as well as private advantage, abundantly appear both from the writings he published, and from the many mechanical operations still extant, which are standing monuments of his great industry and ingenuity. He was the first undertaker of that difficult but useful work, by which a little river is brought from the town of Ware in a new canal, to supply the city of London with water; but by the tricks of others he was hindered from completing the work he had begun. He was excellent both in contrivance and execution, nor was he inferior to the most ingenious mechanic in the making of instruments, either of brass or any other matter. To his invention is owing whatever advantage Hondius's geographical charts have above others; for it was Wright who taught Jodocus Hondius the method of constructing them, which was till then unknown; but the ungrateful Hondius concealed the name of the true author, and arrogated the glory of the invention to himself. Of this fraudulent practice the good man could not help complaining, and justly enough, in the preface to his treatise of the Correction of Errors in the Art of Navigation; which he composed with excellent judgment, and after long experience, to the great advancement of naval affairs. For the improvement of this art he was appointed mathematical lecturer by the East-India Company, and read lectures in the house of that worthy knight Sir Thomas Smith, for which he had a yearly salary of 50 pounds. This office he discharged with great reputation, and much to the satisfaction of his hearers. He published in English a book on the doctrine of the sphere, and another concerning the construction of sun-dials. He also prefixed an ingenious preface to the learned Gilbert's book on the loadstone. By these and other his writings, he has transmitted his fame to latest posterity. While he was yet a fellow of this college, he could not be concealed in his private study, but was called forth to the public business of the nation, by the queen, about the year 1593. [Other accounts say 1589.] He was ordered to attend the earl of Cumberland in some

fome maritime expeditions. One of these he has given a faithful account of, in the manner of a journal or ephemeris, to which he has prefixed an elegant hydrographical chart of his own contrivance. A little before his death he employed himfelf about an Englifh tranflation of the book of logarithms, then lately difcovered by lord Napier, a Scotchman, who had a great affection for him. This pofthumous work of his was publifhed foon after, by his only fon Samuel Wright, who was alfo a fcholar of this college. He had formed many other ufeful defigns, but was hindered by death from bringing them to perfection. Of him it may truly be faid, that he ftudied more to ferve the public than himfelf; and though he was rich in fame, and in the promifes of the great, yet he died poor, to the fcandal of an ungrateful age." So far the memoir; other particulars concerning him, are as follow.

Mr. Wright firft difcovered the true way of dividing the meridian line, according to which the Mercator's charts are conftructed, and upon which Mercator's failing is founded. An account of this he fent from Caius college, Cambridge, where he was then a fellow, to his friend Mr. Blondeville, containing a fhort table for that purpofe, with a fpecimen of a chart fo divided, together with the manner of dividing it. All which Blondeville publifhed, in 1594, among his Exercifes. And, in 1597, the reverend Mr. William Barlowe, in his Navigator's Supply, gave a demonftration of this divifion as communicated by a friend.

At length, in 1599, Mr. Wright himfelf printed his celebrated treatife, intitled, *The Correction of certain Errors in Navigation*, which had been written many years before; where he fhews the reafon of this divifion of the meridian, the manner of conftructing his table, and its ufes in navigation, with other improvements. In 1610 a fecond edition of Mr. Wright's book was publifhed, and dedicated to his royal pupil, prince Henry; in which the author inferted farther improvements; particularly he propofed an excellent way of determining the magnitude of the earth; at the fame time recommending very judicioufly, the making our common meafures in fome certain proportion to that of a degree on its furface, that they might not depend on the uncertain length of a barley-corn. Some of his other improvements were; The Table of Latitudes for dividing the meridian, computed as far as to minutes: An inftrument, he calls the Sea-rings, by which the variation of the compafs, the altitude of the fun, and the time of the day, may be readily determined at once in any place, provided the latitude be known: The correcting of the errors arifing from the eccentricity of the eye in obferving by the crofs-ftaff: A total amendment in the Tables of the declinations and places of the fun and ftars, from his own obfervations, made with a fix-foot quadrant, in the years 1594, 95, 96, 97: A fea-quadrant, to take altitudes by a forward or backward obfervation; having alfo a contrivance for the ready finding the latitude by the height of the pole-ftar, when not upon the meridian. And that this book might be the better underftood by beginners, to this edition is fubjoined a tranflation of Zamorano's Compendium; and added a large table of the variation of the compafs as obferved in very different parts of the world, to fhew it is not occafioned by any magnetical pole. The work has gone through feveral other editions fince. And, befide the books above mentioned, he wrote another on navigation, intitled, *The Haven-finding Art.* Other accounts of him fay alfo, that it was in the year 1589 that he firft began to attend the earl of Cumberland in his voyages. It is alfo faid that he made, for his pupil, prince Henry, a large fphere with curious movements, which, by the help of fpring-work, not only reprefented the motions of the whole celeftial fphere, but fhewed likewife the particular fyftems of the fun and moon, and their circular motions, together with their places and poffibilities of eclipfing each other: there is in it a work for a motion of 17100 years, if it fhould not be ftopt, or the materials fail. This fphere, though thus made at a great expence of money and ingenious induftry, was afterwards in the time of the civil wars caft afide, among duft and rubbifh, where it was found, in the year 1646, by Sir Jonas Moore, who at his own expence reftored it to its firft ftate of perfection, and depofited it at his own houfe in the Tower, among his other mathematical inftruments and curiofities.

X.

XENOCRATES, an eminent philofopher among the ancient Greeks, was born at Chalcedon, and died 314 years before Chrift, at about 90 years of age. He became early a difciple of Plato, ftudying under this great mafter at the fame time with Ariftotle, though he was not poffeffed of equal talents; the former wanting a fpur, and the latter a bridle. He was fond of the mathematics; and permitted none of his fcholars to be ignorant of them. There was fomething flovenly in the behaviour of Xenocrates; for which reafon Plato frequently exhorted him to facrifice to the graces. Serioufnefs and feverity were always feen in his deport-

deportment; yet notwithstanding this severe cast of mind, he was very compassionate. There was something extraordinary in the rectitude of his morals: he was absolute master of his passions; and was not fond of pleasure, riches, or applause. Indeed, so great was his reputation for sincerity and probity, that he was the only person whom the magistrates of Athens dispensed from confirming his testimony with an oath. And yet he was so ill treated by them, as to be sold because he could not pay the poll-tax laid upon foreigners. Demetrius Phalereus bought Xenocrates, paid the debt to the Athenians, and immediately gave him his liberty. At Alexander's request, he composed a treatise on the Art of Reigning; 6 books on Nature; 6 books on Philosophy; one on Riches, &c; but none of them have come down to these times:—His theology it seems was but poor stuff: Cicero refutes him in the first book of the Nature of the Gods.

XENOPHANES, a Greek philosopher, born in Colophon, was, according to some authors, the disciple of Archelaus; in which case he must have been contemporary with Socrates. Others relate, that he taught himself all he knew, and that he lived at the same time with Anaximander: according to which account he must have flourished before Socrates, and about the 60th Olympiad, as Diogenes Laertius affirms. He founded the Eleatic sect; and wrote several poems on philosophical subjects; as also a great many on the foundation of Colophon, and on that of the colony of Elea. He wrote also against Homer and Hesiod. He was banished from his country, withdrew to Sicily, and lived in Zanche and Catana. His opinion with regard to the nature of God differs not much from that of Spinoza.—When he saw the Egyptians pour forth lamentations during their festivals, he thus advised them: "If the objects of your worship are Gods, do not weep: if they are men, offer not sacrifices to them." The answer he made to a man with whom he refused to play at dice, is highly worthy of a philosopher: This man calling him a coward, "Yes, replied he, I am excessively so with regard to all shameful actions."

XENOPHON, a celebrated Greek general, philosopher, and historian, was born at Athens, and became early a disciple of Socrates, who, says Strabo, saved his life in battle. About the 50th year of his age he engaged in the expedition of Cyrus, and accomplished his immortal retreat in the space of 15 months. The jealousy of the Athenians banished him from his native city, for engaging in the service of Sparta and Cyrus. On his return therefore he retired to Scillus, a town of Elis, where he built a temple to Diana, which he mentions in his epistles, and devoted his leisure to philosophy and rural sports. But commotions arising in that country, he removed to Corinth, where it seems he wrote his Grecian History, and died at the age of 90, in the year 360 before Christ.

By his wife Philesia he had two sons, Diodorus and Gryllus. The latter rendered himself immortal by killing Epaminondas in the famous battle of Mantinea, but perished in that exploit, which his father lived to record.

The best editions of his works are those of Franckfort in 1674, and of Oxford, in Greek and Latin, in 1703, 5 vols. 8vo. Separately have been published his *Cyropædia*, Oxon. 1727, 4to, and 1736, 8vo. *Cyri Anabasis*, Oxon. 1735, 4to, and 1747, 8vo. *Memorabilia Socratis*, Oxon. 1741, 8vo.—His *Cyropædia* has been admirably translated into English by Spelman.

XIPHIAS, in Astronomy, is the Dorado or Sword-fish, a constellation of the southern hemisphere; being one of the new constellations added by modern astronomers; and consisting of 6 stars only. See DORADO.

Y.

YARD, a lineal measure, or measure of length, used in England and Spain chiefly to measure cloth, stuffs, &c. The Yard was settled by Henry the 1st, from the length of his own arm.

The English Yard contains 3 feet; and it is equal
- to 4-5ths of the English ell,
- to 7-9ths of the Paris ell,
- to 4-3ds of the Flemish ell,
- to 56-51sts of the Spanish vara or Yard.

YARD, or *Golden* YARD, is also a popular name given to the 3 stars which compose the belt of Orion.

YEAR, in the full extent of the word, is a system or cycle of several months, usually 12. Others define Year, in the general, a period or space of time, measured out by the revolution of some celestial body in its orbit. Thus, the time in which the fixed stars make a revolution, is called the *great Year*; and the times in which Jupiter, Saturn, the Sun, Moon, &c, complete their courses, and return to the same point of the zodiac, are respectively called the Years of Jupiter, and Saturn, and the Solar, and Lunar Years, &c.

As Year denoted originally a revolution, and was not limited to that of the sun; accordingly we find by the oldest accounts, that people have, at different times, expressed other revolutions by it, particularly that of the moon: and consequently that the Years of some accounts, are to be reckoned only months, and sometimes periods of 2, or 3, or 4 months. This will help us greatly in understanding the accounts that certain nations give of their own antiquity, and perhaps

haps of the age of men. We read expressly, in several of the old Greek writers, that the Egyptian Year, at one period, was only a month; and we are farther told that at other periods it was 3 months, or 4 months: and it is probable that the children of Israel followed the Egyptian account of their Years. The Egyptians talked, almost 2000 years ago, of having accounts of events 48 thousand Years distance. A great deal must be allowed to fallacy, on the above account; but beside this, the Egyptians had, in the time of the Greeks, the same ambition which the Chinese have at present, and wanted to pass themselves upon that people, as these others do upon us, for the oldest inhabitants of the earth. They had recourse also to the same means, and both the present and the early impostors have pretended to ancient observations of the heavenly bodies, and recounted eclipses in particular, to vouch for the truth of their accounts. Since the time in which the solar Year, or period of the earth's revolution round the sun, has been received, we may account with certainty; but for those remote ages, in which we do not know of a certainty what is meant by the term Year, it is impossible to form any conjecture of the duration of time in the accounts. The Babylonians pretend to an antiquity of the same romantic kind; they talk of 47 thousand Years in which they had kept observations; but we may judge of these as of the others, and of the observations as of the Years. The Egyptians speak of the stars having four times altered their courses in that period which they claim for their history, and that the sun set twice in the east. They were not such perfect astronomers, but, after a round-about voyage, they might perhaps mistake the east for the west when they came in again.

Year, or Solar Year, properly, and by way of eminence so called, is the space of time in which the sun moves through the 12 signs of the ecliptic. This, by the observations of the best modern astronomers, contains 365 days, 5 hours, 48 min. 48 seconds: the quantity assumed by the authors of the Gregorian calendar is 365 days, 5 hours, 49 min. But in the civil or popular account, this Year only contains 365 days; except every 4th Year, which contains 366.

The vicissitude of seasons seems to have given occasion to the first institution of the Year. Man, naturally curious to know the cause of that diversity, soon found it was the proximity and distance of the sun; and therefore gave the name Year to the space of time in which that luminary performed his whole course, by returning to the same point of his orbit. According to the accuracy in their observations, the Year of some nations was more perfect than that of others, but none of them quite exact, nor whose parts did not shift with regard to the parts of the sun's course.

According to Herodotus, it was the Egyptians who first formed the Year, making it to contain 360 days, which they subdivided into 12 months, of 30 days each. Mercury Trismegistus added 5 days more to the account. And on this footing it is said that Thales instituted the Year among the Greeks; though that form of the Year did not hold throughout all Greece. Also, the Jewish, Syrian, Roman, Persian, Ethiopic, Arabic, &c Years, were all different. In fact, considering the imperfect state of astronomy in those ages, it is no wonder that different people should disagree in the calculation of the sun's course. We are even assured by Diod. Siculus, lib. 1. Plutarch, in Numa, and Pliny, lib. 7, cap. 48, that the Egyptian Year itself was at first very different from that now represented.

The solar Year is either *astronomical* or *civil*.

The *Astronomical Solar* Year, is that which is determined precisely by astronomical observations; and is of two kinds, *tropical*, and *sidereal* or *astral*.

Tropical, or *Natural* Year, is the time the sun takes in passing through the zodiac; which, as before observed, is 365d. 5h. 48m. 48sec.; or 365d. 5h. 49min. This is the only proper or natural Year, because it always keeps the same seasons to the same months.

Sidereal or *Astral* Year, is the space of time the sun takes in passing from any fixed star, till his return to it again. This consists of 365 d. 6h. 9m. 17 sec.; being 20 m. 29 sec. longer than the true solar year.

Lunar Year, is the space of 12 lunar months. Hence, from the two kinds of synodical lunar months, there arise two kinds of lunar Years; the one *astronomical*, the other *civil*.

Lunar Astronomical Year, consists of 12 lunar synodical months; and therefore contains 354d. 8h. 48m. 38sec. and is therefore 10d. 21h. 0m. 10s. shorter than the solar Year. A difference which is the foundation of the Epact.

Lunar Civil Year, is either common or embolismic.

The *Common Lunar* Year consists of 12 lunar civil months; and therefore contains 354 days. And

The *Embolismic* or *Intercalary Lunar* Year, consists of 13 lunar civil months, and therefore contains 384 days.

Thus far we have considered Years and months, with regard to astronomical principles, upon which the division is founded. By this, the various forms of civil Years that have formerly obtained, or that do still obtain, in divers nations, are to be examined.

Civil Year, is that form of Year which every nation has contrived or adopted, for computing their time by. Or the civil is the tropical Year, considered as only consisting of a certain number of whole days: the odd hours and minutes being set aside, to render the computation of time, in the common occasions of life, more easy. As the tropical Year is 365 d. 5 h. 49 m. or almost 365d. 6h. which is 365 days and a quarter; therefore if the civil Year be made 365 days, every 4th year it must be 366 days, to keep nearly to the course of the sun. And hence the civil Year is either *common* or *bissextile*. The

Common Civil Year, is that consisting of 365 days; having seven months of 31 days each, four of 30 days, and one of 28 days; as indicated by the following well known memorial verses:

Thirty days hath September,
April, June, and November;
February twenty-eight alone,
And all the rest have thirty-one.

Bissextile or *Leap* Year, consists of 366 days; having one day extraordinary; called the intercalary, or bissextile day; and takes place every 4th Year. This additional day to every 4th Year, was first introduced by

by Julius Cæsar; who, to make the civil Years keep pace with the tropical ones, contrived that the 6 hours which the latter exceeded the former, should make one day in 4 years, and be added between the 24th and 23d of February, which was their 6th of the calends of March; and as they then counted this day twice over, or had *bis sexto calendas*, hence the Year itself came to be called *bis sextus*, and *bissextile*.

However, among us, the intercalary day is not introduced by counting the 23d of February twice over, but by adding a day at the end of that month, which therefore in that Year contains 29 days.

A farther reformation was made in this year by Pope Gregory. See *Gregorian* YEAR, CALENDAR, BISSEXTILE, and LEAP-*Year*.

The Civil or Legal Year, in England, formerly commenced on the day of the Annunciation, or 25th of March; though the historical Year began on the day of the Circumcision, or 1st of January; on which day the German and Italian Year also begins. The part of the Year between these two terms was usually expressed both ways: as 1745-6, or 174⅚. But by the act for altering the stile, the civil Year now commences with the 1st of January.

Ancient Roman YEAR. This was the lunar Year, which, as first settled by Romulus, contained only ten months, of unequal numbers of days in the following order: viz,

March 31; April 30; May 31; June 30; Quintilis 31; Sextilis 30; September 30; October 31; November 30; December 30; in all 304 days; which came short of the true lunar Year by 50 days; and of the solar by 61 days. Hence, the beginning of Romulus's Year was vague, and unfixed to any precise season; to remove which inconvenience, that prince ordered so many days to be added yearly as would make the state of the heavens correspond to the first month, without calling them by the name of any month.

Numa Pompilius corrected this irregular constitution of the Year, composing two new months, January and February, of the days that were used to be added to the former Year. Thus Numa's year consisted of 12 months, of different days, as follow; viz,

January - 29;	February 28;	March - - 31;
April - - 29;	May - - 31;	June - - - 29;
Quintilis 31;	Sextilis 29;	September 29;
October - 31;	November 29;	December 29;

in all 355 days; therefore exceeding the quantity of a lunar civil Year by one day; that of a lunar astronomical Year by $15^h\ 11^m\ 22^s$; but falling short of the common solar Year by 10 days; so that its beginning was still vague and unfixed.

Numa, however, desiring to have it begin at the winter solstice, ordered 22 days to be intercalated in February every 2d Year, 23 every 4th, 22 every 6th, and 23 every 8th Year.

But this rule failing to keep matters even, recourse was had to a new way of intercalating; and instead of 23 days every 8th Year, only 15 were to be added. The care of the whole was committed to the pontifex maximus; who however, neglecting the trust, let things run to great confusion. And thus the Roman Year stood till Julius Cæsar reformed it. See CALENDAR. And for the manner of reckoning the days of the Roman months, see CALENDS, NONES, and IDES.

Julian YEAR. This is in effect a solar Year, commonly containing 365 days; though every 4th Year, called Bissextile, it contains 366. The months of the Julian Year, with the number of their days, stood thus:

January - 31;	February - 28;	March - 31;
April - - 30;	May - - 31;	June - - 30;
July - - 31;	August - - 31;	September 30;
October - 31;	November 30;	December 31.

But every Bissextile Year had a day added in February, making it then to contain 29 days.

The mean quantity therefore of the Julian Year is 365¼ days, or $365^d\ 6^h$; exceeding the true solar Year by somewhat more than 11 minutes; an excess which amounts to a whole day in almost 131 years. Hence the times of the equinoxes go backward, and fall earlier by one day in about 130 or 131 Years. And thus the Roman Year stood, till it was farther corrected by pope Gregory.

For settling this Year, Julius Cæsar brought over from Egypt, Sosigenes, a celebrated mathematician; who, to supply the defect of 67 days, which had been lost through the neglect of the priests, and to bring the beginning of the Year to the winter solstice, made one Year to consist of 15 months, or 445 days; on which account that Year was used to be called *annus confusionis*, the *Year of confusion*. See *Julian* CALENDAR.

Gregorian YEAR. This is the Julian Year corrected by this rule, viz, that instead of every secular or 100th Year being a bissextile, as it would be in the former way, in the new way three of them are common Years, and only the 4th is bissextile.

The error of 11 minutes in the Julian Year, by continual repetition, had accumulated to an error of 13 days from the time when Cæsar made his correction; by which means the equinoxes were greatly disturbed. In the Year 1582, the equinoxes were fallen back 10 days, and the full moons 4 days, more backward than they were in the time of the Nicene council, which was in the Year 325; viz, the former from the 20th of March to the 10th, and the latter from the 5th to the 1st of April. To remedy this increasing irregularity, pope Gregory the 13th, in the year 1582, called together the chief astronomers of his time, and concerted this correction, throwing out the 10 days above mentioned. He exchanged the lunar cycle for that of the epacts, and made the 4th of October of that Year to be the 15th; by that means restoring the vernal equinox to the 21st of March. It was also provided, by the omission of 3 intercalary days in 400 Years, to make the civil Year keep pace nearly with the solar Year, for the time to come. See CALENDAR.

In the Year 1700, the error of 10 days was grown to 11; upon which, the protestant states of Germany, to prevent farther confusion, adopted the Gregorian correction. And the same was accepted also in England in the year 1752, when 11 days were thrown out after the 2d of September that Year, by accounting the 3d to be the 14th day of the month: calling this the new stile, and the former the old stile. And the Gregorian, or new-

new stile, is now in like manner used in most countries of Europe.

Yet this last correction is still not quite perfect; for as it has been shewn that in 4 centuries, the Julian Year gains $3^d\ 2^h\ 40^m$; and as it is only the 3 days that are kept out in the Gregorian Year; there is still an excess of $2^h\ 40^m$ in 4 centuries, which amounts to a whole day in 36 centuries, or in 3600 Years. See CALENDAR, *New* or *Gregorian* STILE, &c.

Egyptian YEAR, called also the *Year of Nabonassar*, on account of the epoch of Nabonassar, is the solar Year of 365 days, divided into 12 months, of 30 days each, beside 5 intercalary days, added at the end. The order and names of these months are as follow:

1. Thoth; - -	2. Paophi; - -	3. Athyr;
4. Chojac; - -	5. Tybi; - -	6. Mecheir;
7 Phamenoth;	8. Pharmuthi;	9. Pachon;
10. Pauni; - -	11. Epiphi; -	12. Mesori.

As the Egyptian Year, by neglecting the 6 hours, in every 4 Years loses a whole day of the Julian Year, its beginning runs through every part of the Julian Year in the space of 1460 Years; after which, they meet again; for which reason it is called the *erratic* Year. And because this return to the same day of the Julian Year, is performed in the space of 1460 Julian Years, this circle is called the Sothic period.

This Year was applied by the Egyptians to civil uses, till Anthony and Cleopatra were defeated; but the mathematicians and astronomers used it till the time of Ptolomy, who made use of it in his Almagest; so that the knowledge of it is of great use in astronomy, for comparing the ancient observations with the modern.

The ancient Egyptians, we are told by Diodorus Siculus, (Plutarch, lib. 1, in the life of Numa, and Pliny, lib. 7, cap. 48) measured their Years by the course of the moon. At first they were only one month, then 3, then 4, like that of the Arcadians; and then 6, like that of the people of Acarnania. Those authors add, that it is on this account that they reckon such a vast number of Years from the beginning of the world; and that in the history of their kings, we meet with some who lived 1000, or 1200 Years. The same thing is maintained by Kircher; Oedip Egypt. tom. 2, pa. 252. And a late author observes, that Varro has affirmed the same of all nations, that has been quoted of the Egyptians. By which means many account for the great ages of the more ancient patriarchs; expounding the gradual decrease in their ages, by the successive increase of the number of months in their years.

Upon the Egyptians being subdued by the Romans, they received the Julian Year, though with some alteration; for they still retained their ancient months, with the five additional days, and every 4th Year they intercalated another day, for the 6 hours, at the end of the Year, or between the 28th and 29th of August. Also, the beginning of their Year, or the first day of the month Thoth, answered to the 29th of August of the Julian Year, or to the 30th if it happened to be leap Year.

The Ancient Greek YEAR.—This was a lunar Year, consisting of 12 months, which at first had each 30 days, then alternately 29 and 30 days, computed from the first appearance of the new moon; with the addition of an embolismic month of 30 days, every 3d, 5th, 8th, 11th, 14th, 16th, and 19th Year of a cycle of 19 Years; in order to keep the new and full moons to the same terms or seasons of the Year.

Their Year commenced with that new moon which was nearest to the summer solstice And the order of the months, with the number of their days, were as follow: 1. Εκατομβαιων, of 29 days; 2. Μηταγειτνιων 30; 3. Βοηδρομιων 29; 4. Μαιμακτηριων 30; 5. Πυανεψιων 29; 6. Ποσειδεων 30; 7. Γαμηλιων 29; 8. Ανθεστηριων 30; 9. Ελαφηβολιων 29; 10. Μανυχιων 30; 11. Θαργηλιων 29; 12. Σκιροφοριων 30.—But many of the Greek nations had other names for their months.

The Ancient Jewish YEAR.—This is a lunar Year, usually consisting of 11 months, containing alternately 30 and 29 days. And it was made to agree with the solar Year, by adding 11, and sometimes 12 days, at the end of the Year, or by an embolismic month. The order and quantities of the months were as follow. 1. Nisan or Abib 30 days; 2. Jiar or Zius 29; 3. Siban or Sievan 30; 4. Thamuz or Tamuz 29; 5. Ab 30; 6. Elul 29; 7. Tisri or Ethanim 30, 8. Marchesvam or Bul 29; 9. Cisleu 30; 10. Tebeth 29; 11. Sabat or Schebeth 30; 12. Adar 30 in the embolismic year, but 29 in the common year.—Note, in the defective Year, Cisleu was only 29 days; and in the redundant Year, Marchesvam was 30.

The Modern Jewish YEAR is likewise lunar, consisting of 12 months in common Years, but of 13 in embolismic Years; which, in a cycle of 19 Years, are the 3d, 6th, 8th, 11th, 14th, 17th, and 19th. Its beginning is fixed to the new moon next after the autumnal equinox. The names and order of the months, with the number of the days, are as follow: 1. Tisri 30 days; 2. Marchesvan 29; 3. Cisleu 30; 4. Tebeth 29; 5. Schebeth 30; 6. Adar 29; 7. Veadar, in the embolismic year, 30; 8. Nisan 30; 9. Ilar 29, 10. Sivan 30; 11. Thamuz 29; 12. Ab 30; 13. Elul 29.

The Syrian YEAR, is a solar one, having its beginning fixed to the beginning of October in the Julian Year; from which it only differs in the names of the months, the quantities being the same; as follow: 1. Tishrin, answering to our October, and containing 31 days; 2. Latter Tishrin, containing, like November, 30 days; 3. Canun 31; 4. Latter Canun 31; 5. Shabat 28, or 29 in a leap-year; 6. Adar 31; 7. Nisan 30; 8. Aiyar 31; 9. Haziram 30; 10. Thamuz 31; 11. Ab 31; 12. Elul 30.

The Persian YEAR, is a solar one, of 365 days, consisting of 12 months of 30 days each, with 5 intercalary days added at the end. The months are as follow: 1. Asrudia meh; 2. Ardihascht meh; 3. Cardi meh; 4. Thir meh; 5. Merded meh; 6. Schahaurmeh meh; 7. Mehar meh; 8. Aben meh; 9. Adar meh; 10. Di meh; 11. Behen meh; 12. Assirer meh. This Year is the same as the Egyptian Nabonassarean, and is called the *yezdegerdic Year*, to distinguish it from the fixed solar Year, called the Gelalean Year, which the Persians began to use in the Year 1079, and which was formed

formed by an intercalation, made fix or feven times in four Years, and then once every 5th Year.

The Arabic, Mahometan, and Turkish YEAR, called alfo the Year of the *Hegira*, is a lunar Year, equal to $354^d\ 8^h\ 48^m$, and confifts of 12 months, containing alternately 30 and 29 days. Though fometimes it contains 13 months; the names &c being as follow: 1. Muharram of 30 days; 2. Saphar 29; 3. Rabia 30; 4. Latter Rabia 29; 5. Jomada 30; 6. Latter Jomada 29; 7. Rajab 30; 8. Shaaban 29; 9. Ramadan 30; 10. Shawal 29; 11. Dulkaadah 30; 12. Dulheggia 29, but in the embolifmic year 30. An intercalary day is added every 2d, 5th, 7th, 10th, 13th, 15th, 18th, 21st, 24th, 26th, 29th, in a cycle of 29 Years. The months commence with the firft appearance of the new moons after the conjunctions.

Ethiopic YEAR, is a folar Year perfectly agreeing with the Actiac, except in the names of the months, which are; 1. Maskaram; 2. Tykympt; 3. Hydar; 4. Tyfhas; 5. Tyr; 6. Jacatil; 7 Magabit; 8. Miyazia; 9. Giabat; 10. Syne; 11. Hamel; 12. Hahafe. Intercalary days 5. It commences with the Egyptian Year, on the 29th of Auguft of the Julian Year.

YESDEGERDIC YEAR. See *Perfian* YEAR.

Z.

ZENITH, in Aftronomy, the vertical point, or point in the heavens directly overhead. Or, the Zenith is a point in the furface of the fphere, from which a right line drawn through the place of any fpectator, paffes through the centre of the earth.

The Zenith of any place, is alfo the pole of the horizon, being 90 degrees diftant from every point of it. And through the Zenith pafs all the azimuths, or vertical circles.

The point diametrically oppofite to the Zenith, is called the *nadir*, being the point in the fphere directly under our feet: and it is the Zenith to our antipodes, as our Zenith is their nadir.

ZENITH-*Diftance*, is the diftance of the fun or ftar from our Zenith; and is the complement of the altitude, or what it wants of 90 degrees.

ZENO, ELEATES, or of *Elea*, one of the greateft philofophers among the Ancients, flourifhed about 500 years before the Chriftian æra. He was the difciple of Parmenides, and even, according to fome writers, his adopted fon. Ariftotle afferts that he was the inventor of logic: but his logic feems to have been calculated and employed to perplex all things, and not to clear up any thing. For Zeno employed it only to difpute againft all comers, and to filence his opponents, whether they argued right or wrong. Among many other fubtleties and embarraffing arguments, he propofed fome with regard to motion, denying that ther was any fuch thing in nature; and Ariftotle, in the 6th book of his phyfics, has preferved fome of them, which are extremely fubtile, efpecially the famous argument named Achilles; which was to prove this propofition, that the fwifteft animal could never overtake the floweft, as a greyhound a tortoife, if the latter fet out a little fore the former: for fuppofe the tortoife to be 100 yards before the dog, and that this runs 100 times as faft as the other; then while the dog runs the firft 100 yards, the tortoife runs 1, and is therefore 1 yard before the dog; again, while the dog runs over this yard, the tortoife will run the 100th part of a yard, and will be fo much before the dog; and again, while the dog runs over this 100th part of a yard, the tortoife will have got the 100th part of that 100th part before him; and fo on continually, fays he, the dog will always be fome fmall part behind the tortoife. But the fallacy will foon be detected, by confidering where the tortoife will be when the dog has run over 200 yards; for as the former can have run only two yards in the fame time, and therefore muft then be 98 yards behind the dog, he confequently muft have overtaken and paffed the tortoife. It has been faid that, to prove to him, or fome difciple of his, that there is fuch a thing as motion, Diogenes the Cynic rofe up and walked over the floor.—Zeno fhewed great courage in fuffering pain; for having joined with others to endeavour to reftore liberty to his country, which groaned under the oppreffion of a tyrant, and the enterprize being difcovered, he fupported with extraordinary firmnefs the fharpeft tortures. It is even faid that he had the courage to bite off his tongue, and fpit it in the tyrant's face, for fear of being forced, by the violence of his torments, to difcover his accomplices. Some fay that he was pounded to death in a mortar.

ZENO, a celebrated Greek philofopher, was born at Citium, in the Ifle of Cyprus, and was the founder of the Stoics; a fect which had its name from that of a portico at Athens, where this philofopher chofe to hold his difcourfes. He was caft upon that coaft by fhipwreck; and he ever after regarded this as a great happinefs, praifing the winds for having fo happily driven him into the port of Piræum.—Zeno was the difciple of Crates, and had a great number of followers. He made the fovereign good to confift in dying in conformity to nature, guided by the dictates of right reafon. He acknowledged but one God; and admitted an inevitable deftiny over all events. His

fervant taking advantage of this last opinion, cried, while he was beating him for dishonesty, "I was destined to steal;" to which Zeno replied, "Yes, and to be beaten too." This philosopher used to say, "That if a wise man ought not to be in love, as some pretended, none would be more miserable than beautiful and virtuous women, since they would have none for their admirers but fools." He also said, "That a part of knowledge consists in being ignorant of such things as ought not to be known: that a friend is another self: that a little matter gives perfection to a work, though perfection is not a little matter." He compared those who spoke well and lived ill, to the money of Alexandria, which was beautiful, but composed of bad metal.—It is said that being hurt by a fall, he took that as a sign he was then to quit this life, and laid violent hands on himself, about 264 years before Christ.

Cleanthes, Crysippus, and the other successors of Zeno maintained, that with virtue we might be happy in the midst even of disgrace and the most dreadful torments. They admitted the existence of only one God, the soul of the world, which they considered as his body, and both together forming a perfect being. It is remarked that, of all the sects of the ancient philosophers, this was one of those which produced the greatest men.

We ought not to confound the two Zenos above mentioned, with

Zeno, a celebrated Epicurean philosopher, born at Sidon, who had Cicero and Pomponius Atticus for his disciples, and who wrote a book against the mathematics, which, as well as that of Possidonius's refutation of it, is lost; nor with several other Zenos mentioned in history.

ZENSUS, or Zenzus, in Arithmetic and Algebra, a name used by some of the older authors, especially in Germany, for a square number, or the 2d power: being a corruption from the Italic *censi*, of Pacioli, Tartalea, &c, or the Latin *census*, which signified the same thing.

ZETETICE, or Zetetic *Method*, in Mathematics, was the method made use of to investigate, or find out the solution of a problem; and was much the same thing as analytics, or the analytic method.

Vieta has an ingenious work of this kind in 5 books; *Zeteticorum libri quinque.*

ZOCCO, Zoccolo, Zocle, or Socle, in Architecture, a square body, less in height than breadth, placed under the bases of pedestals, statues, vases, &c. See Socle and Plinth.

ZODIAC, in Astronomy, an imaginary ring or broad circle, in the heavens, in form of a belt or girdle, within which the planets all make their excursions. In the very middle of it runs the ecliptic, or path of the sun in his annual course; and its breadth, comprehending the deviations or latitudes of the planets, is by some authors accounted 16°, some 18, and others 20 degrees.

The Zodiac, cutting the equator obliquely, makes with it the same angle as the ecliptic, which is its middle line, which angle, continually varying, is now nearly equal to 23° 28′; which is called the obliquity of the Zodiac or ecliptic, and is also the sun's greatest declination.

The Zodiac is divided into 12 equal parts, of 30 degrees each, called the signs of the Zodiac, being so named from the constellations which anciently passed them. But, the stars having a motion from west to east, those constellations do not now correspond to their proper signs; from whence arises what is called the *precession of the equinoxes*. And therefore when a star is said to be in such a sign of the Zodiac, it is not to be understood of that constellation, but only of that dodecatemory or 12th part of it.

Cassini has also observed a tract in the heavens, within whose bounds most of the comets, though not all of them, are observed to keep, and which he therefore calls the *Zodiac of the comets*. This he makes as broad as the other Zodiac, and marks it with signs or constellations, like that; as Antinous, Pegasus, Andromeda, Taurus, Orion, the Lesser Dog, Hydra, the Centaur, Scorpion, and Sagittary.

ZODIACAL *Light*, a brightness sometimes observed in the zodiac, resembling that of the galaxy or milky way. It appears at certain seasons, viz, towards the end of winter and in spring, after sunset, or before his rising, in autumn and beginning of winter, resembling the form of a pyramid, lying lengthways with its axis along the zodiac, its base being placed obliquely with respect to the horizon. This phenomenon was first described and named by the elder Cassini, in 1683. It was afterwards observed by Fatio, in 1684, 1685, and 1686; also by Kirch and Eimmart, in 1688, 1689, 1691, 1693, and 1694. See Mairan, Suite des Mem. de l'Acad. Royale des Sciences 1731, pa. 3.

The Zodiacal light, according to Mairan, is the solar atmosphere, a rare and subtile fluid, either luminous by itself, or made so by the rays of the sun surrounding its globe; but in a greater quantity, and more extensively, about his equator, than any other part.

Mairan says, it may be proved from many observations, that the sun's atmosphere sometimes reaches as far as the earth's orbit, and there meeting with our atmosphere, produces the appearance of an Aurora borealis.

The length of the Zodiacal light varies sometimes in reality, and sometimes in appearance only, from various causes.

Cassini often mentions the great resemblance between the Zodiacal light and the tails of comets. The same observation has been made by Fatio: and Euler endeavoured to prove that they were owing to similar causes. See Decouverte de la Lumiere Celeste que paroit dans le Zodiaque, art. 41. Lettre à M. Cassini, printed at Amsterdam in 1686. Euler, in Mem. de l'Acad. de Berlin, tom. 2.

This light seems to have no other motion than that of the sun itself: and its extent from the sun to its point, is seldom less than 50 or 60 degrees in length, and more than 20 degrees in breadth: but it has been known to extend to 100 or 103°, and from 8 to 9° broad.

It is now generally acknowledged, that the electric fluid is the cause of the aurora borealis, ascribed by Mairan

Mairan to the solar atmosphere, which produces the Zodiacal light, and which is thrown off chiefly and to the greatest distance from the equatorial parts of the sun, by means of the rotation on his axis, and extending visibly as far as the orbit of the earth, where it falls into the upper regions of our atmosphere, and is collected chiefly towards the polar parts of the earth, in consequence of the diurnal revolution, where it forms the aurora borealis. And hence it has been suggested, as a probable conjecture, that the sun may be the fountain of the electrical fluid, and that the Zodiacal light, and the tails of comets, as well as the aurora borealis, the lightning, and artificial electricity, are its various and not very dissimilar modifications.

ZONE, in Geography and Astronomy, a division of the earth's surface, by means of parallel circles, chiefly with respect to the degree of heat in the different parts of that surface.

The ancient astronomers used the term Zone, to explain the different appearances of the sun and other heavenly bodies, with the length of the days and nights; and the geographers, as they used the climates, to mark the situation of places; using the term climate when they were able to be more exact, and the term Zone when less so.

The Zones were commonly accounted five in number; one a broad belt round the middle of the earth, having the equator in the very middle of it, and bounded, towards the north and south, by parallel circles passing through the tropics of Cancer and Capricorn. This they called the *torrid Zone*, which they supposed not habitable, on account of its extreme heat. Though sometimes they divided this into two equal torrid Zones, by the equator, one to the north, and the other south; and then the whole number of Zones was accounted 6.

Next, from the tropics of Cancer and Capricorn, to the two polar circles, were two other spaces called *temperate Zones*, as being moderately warm; and these they supposed to be the only habitable parts of the earth.

Lastly, the two spaces beyond the temperate Zones, about either pole, bounded within the polar circles, and having the poles in the middle of them, are the two *frigid* or *frozen Zones*, and which they supposed not habitable, on account of the extreme cold there.

Hence, the breadth of the torrid Zone, is equal to twice the greatest declination of the sun, or obliquity of the ecliptic, equal to 46° 56′, or twice 23° 28′. Each frigid Zone is also of the same breadth, the distance from the pole to the polar circle being equal to the same obliquity 23° 28′. And the breadth of each temperate Zone is equal to 43° 4′, the complement of twice the same obliquity. See these Zones exhibited in plate 35, fig. 16.

The difference of Zones is attended with a great diversity of phenomena. 1. In the torrid Zone, the sun passes through the zenith of every place in it twice a year; making as it were two summers in the year; and the inhabitants of this Zone are called *amphiscians*, because they have their noon-day shadows projected different ways in different times of the year, northward at one season, and southward at the other.

2. In the temperate and frigid Zones, the sun rises and sets every natural day of 24 hours. Yet every where, but under the equator, the artificial days are of unequal lengths, and the inequality is the greater, as the place is farther from the equator. The inhabitants of the temperate Zones are called *heteroscians*, because their noon-day shadow is cast the same way all the year round, viz, those in the north Zone toward the north pole, and those in the south Zone toward the south pole.

3. Within the frigid Zones, the inhabitants have their artificial days and nights extended out to a great length; the sun sometimes skirting round a little above the horizon for many days together: and at another season never rising above the horizon at all, but making continual night for a considerable space of time. The inhabitants of these Zones are called *periscians*, because sometimes they have their shadows going quite round them in the space of 24 hours.

After l. 9, *add*, Since this article was printed, I observe, in the 3d volume of the Edinburgh Philosophical Transactions, an account of a curious set of experiments on the unequal refrangibility of light, with observations on Achromatic telescopes, by Dr. Robert Blair. This ingenious gentleman sets out with observing, "If the theory of the Achromatic telescope is so complete as it has been represented, may it not reasonably be demanded, whence it proceeds, that Hugenius and others could execute telescopes with single object glasses 8 inches and upwards in diameter, while a compound object glass of half these dimensions, is hardly to be met with? or how it can arise from any defect in the execution, that reflectors can be made so much shorter than Achromatic refractors of equal apertures, when it is well known that the latter are much less affected by any imperfections in the execution of the lenses composing the object glass, than reflectors are by equal defects in the figure of the great speculum?—The general answer made by artists to enquiries of this kind, is, that the fault lies in the imperfection of glass, and particularly in that kind of glass of which the concave lens of the compound object glass is formed, called flint glass.—It was in order to satisfy myself concerning the reality of this difficulty, and to attempt to remove it, that I engaged in the following course of experiments."

Dr. Blair describes the apparatus and manner of making the experiments. He employed various prisms of different kinds of glass; also lenses of glass, and of a great variety of fluid mediums, having different degrees of refraction. Having detailed the whole at considerable length, for which a reference must be made to the work itself, and it is very deserving of attentive perusal, he concludes with the following recapitulation of the contents and scope of the whole discourse.

"The unequal refrangibility of light, as discovered and fully explained by Sir Isaac Newton, so far stands its ground uncontroverted, that when the refraction is made in the confine of any medium whatever, and a vacuum, the rays of different colours are unequally refracted, the red-making rays being the least refrangible, and the violet-making rays the most refrangible.

"The discovery of what has been called a different dispersive power in different refractive mediums, proves those theorems of Sir Isaac Newton not to be universal, in which he concludes that the difference of refraction of the most and least refrangible rays, is always in a given proportion to the refraction of the mean refrangible ray. There can be no doubt that this position is true with respect to the mediums on which he made his experiments; but there are many exceptions to it.

"For the experiments of Mr. Dollond prove, that the difference of refraction between the red and violet rays, in proportion to the refraction of the whole pencil, is greater in some kinds of glass than in water, and greater in flint-glass than in crown-glass.

"The first set of experiments above recited, prove, that the quality of dispersing the rays in a greater degree than crown-glass, is not confined to a few mediums, but is possessed by a great variety of fluids, and by some of these in a most extraordinary degree. Solutions of metals, essential oils, and mineral acids, with the exception of the vitriolic, are most remarkable in this respect.

"Some consequences of the combinations of mediums of different dispersive powers, which have not been sufficiently attended to, are then explained. Although the greater refrangibility of the violet rays than of the red rays, when light passes from any medium whatever into a vacuum, may be considered as a law of nature, yet in the passage of light from one medium into another, it depends entirely on the qualities of the mediums, which of these rays shall be the most refrangible, or whether there shall be any difference in their refrangibility.

"The

"The application of the demonstrations of Hugenius to the correction of the aberration from the spherical figures of lenses, whether solid or fluid, is then taken notice of, as being the next step towards perfecting the theory of telescopes.

"Next it appears from trials made with object-glasses of very large apertures, in which both aberrations are corrected as far as the principles will admit, that the correction of colour which is obtained by the common combination of two mediums which differ in dispersive power, is not complete. The homogeneal green rays emerge most refracted, next to these the united blue and yellow, then the indigo and orange united, and lastly the united violet and red, which are least refracted.

"If this production of colour were constant, and the length of the secondary spectrum were the same in all combinations of mediums when the whole refraction of the pencil is equal, the perfect correction of the aberration from difference of refrangibility would be impossible, and would remain an insurmountable obstacle to the improvement of dioptrical instruments.

"The object of the next experiment is, therefore, to search whether nature affords mediums which differ in the degree in which they disperse the rays composing the prismatic spectrum, and at the same time separate the several orders of rays in the same proportion. For if such could be found, the above-mentioned secondary spectrum would vanish, and the aberration from difference of refrangibility might be removed. The result of this investigation was unsuccessful with respect to its principal object. In every combination that was tried, the same kind of uncorrected colour was observed, and it was thence concluded, that there was no direct method of removing the aberration.

"But it appeared in the course of the experiments, that the breadth of the secondary spectrum was less in some combinations than in others, and thence an indirect way opened, leading to the correction sought after; namely by forming a compound concave lens of the materials which produce most colour, and combining it with a compound convex lens formed of the materials which produce least colour; and it was observed in what manner this might be effected by means of three mediums, though apparently four are required.

"In searching for mediums best adapted for the above purpose, a very singular and important quality was detected in the muriatic acid. In all the dispersive mediums hitherto examined, the green rays, which are the mean refrangible in crown-glass, were found among the less refrangible, and thence occasion the uncorrected colour which has been described. In the muriatic acid, on the contrary, these same rays make a part of the more refrangible; and in consequence of this, the order of the colours in the secondary spectrum, formed by a combination of crown glass with this fluid, is inverted, the homogeneal green being now the least refrangible, and the united red and violet the most refrangible.

"This remarkable quality found in the marine acid led to complete success in removing the great defect of optical instruments, that dissipation or aberration of the rays, arising from their unequal refrangibility, which has rendered it impossible hitherto to converge all of them to one point either by single or opposite refractions. A fluid in which the particles of marine acid and metalline particles hold a due proportion, at the same time that it separates the extreme rays of the spectrum much more than crown-glass, refracts all the orders of rays exactly in the same proportion as the glass does; and hence rays of all colours, made to diverge by the refraction of the glass, may either be rendered parallel by a subsequent refraction made in the confine of the glass and this fluid, or by weakening the refractive density of the fluid, the refraction which takes place in the confine of it and glass, may be rendered as regular as reflexion, while the errors arising from unavoidable imperfections of workmanship, are far less hurtful than in reflexion, and the quantity of light transmitted by equal apertures of the telescopes much greater.

"Such are the advantages which the theory presents. In reducing this theory to practice, difficulties must be expected in the first attempts. Many of these it was necessary to surmount before the experiments could be completed. For the delicacy of the observations is such as to require a considerable degree of perfection in the execution of the object-glasses, in order to admit of the phenomena being rendered more apparent by means of high magnifying powers. Great pains seem to have been taken by mathematicians to little purpose, in calculating the radii of the spheres requisite for Achromatic telescopes, from their not considering that the object-glass itself is a much nicer test of the optical properties of refracting mediums than the gross experiments made by prisms, and that the results of their demonstrations cannot exceed the accuracy of the data, however much they may fall short of it.

"I shall conclude this paper, which has now greatly exceeded its intended bounds, by enumerating the several cases of unequal refrangibility of light, that their varieties may at once be clearly apprehended.

"In the refraction which takes place in the confine of every known medium and a vacuum, rays of different colours are unequally refrangible, and the red-making rays are least refrangible, and the violet-making rays are most refrangible.

"This difference of refrangibility of the red and violet rays is not the same in all mediums. Those mediums in which the difference is greatest, and which, by consequence, separate or disperse the rays of different colours most, have been distinguished by the term dispersive, and those mediums which separate the rays least have been called indispersive. Dispersive mediums differ from indispersive, and still more from each other, in another very essential circumstance.

"It appears from the experiments which have been made on indispersive mediums, that the mean refrangible light is always the same, and of a green colour.

"Now, in by far the largest class of dispersive mediums, including flint glass, metallic solutions, essential oils, the green light is not the mean refrangible order, but forms one of the less refrangible orders of light, being found in the prismatic spectrum nearer to the deep red than the extreme violet.

"In another class of dispersive mediums, which includes the muriatic and nitrous acids, this same green light becomes one of the more refrangible orders, being now found nearer to the extreme violet than the deep red.

"These

"These are the varieties in the refrangibility of light, when the refraction takes place in the confine of a vacuum; and the phenomena will scarce differ sensibly in refractions made in the confine of dense mediums and air.

"But when light passes from one dense medium into another, the cases of unequal refrangibility are more complicated.

"In refractions made in the confine of mediums which differ only in strength, not in quality, as in the confine of water and crown-glass, or in the confine of the different kinds of dispersive fluids more or less diluted, the difference of refrangibility will be the same as above stated in the confine of dense mediums and air, only the whole refraction will be less.

"In the confine of an indispersive medium, and a rarer medium belonging to either class of the dispersive, the red and violet rays may be rendered equally refrangible. If the dispersive power of the rare medium be then increased, the violet rays will become the least refrangible, and the red rays the most refrangible. If the mean refractive density of the two mediums be rendered equal, the red and violet rays will be refracted in opposite directions, the one towards, the other from the perpendicular.

"Thus it happens to the red and violet rays, whichsoever class of dispersive mediums be employed. But the refrangibility of the intermediate orders of rays, and especially of the green rays, will be different when the class of dispersive mediums is changed.

"Thus, in the first case, where the red and violet rays are rendered equally refrangible, the green rays will emerge most refrangible if the first class of dispersive mediums is used, and least refrangible if the second class is used. And in the other two cases, where the violet becomes least refrangible, and the red most refrangible, and where these two kinds of rays are refracted in opposite directions, the green rays will join the red if the first class of dispersive mediums be employed, and will arrange themselves with the violet if the second class be made use of.

"Only one case more of unequal refrangibility remains to be stated; and that is, when light is refracted in the confine of mediums belonging to the two different classes of dispersive fluids. In its transition, for example, from an essential oil, or a metallic solution, into the muriatic acid, the refractive density of these fluids may be so adjusted, that the red and violet rays shall suffer no refraction in passing from the one into the other, how oblique soever their incidence be. But the green rays will then suffer a considerable refraction, and this refraction will be from the perpendicular, when light passes from the muriatic acid into the essential oil, and towards the perpendicular, when it passes from the essential oil into the muriatic acid. The other orders of rays will suffer similar refractions, which will be greatest in those adjoining the green, and will diminish as they approach the deep red on the one hand, and the extreme violet on the other, where the refraction ceases entirely.

"The manner of the production of these effects, by the attraction of the several mediums, may be thus explained. We shall suppose the attractive forces, which produce the refractions of the red, green and violet light, to be represented by the numbers, 8, 12, and 16, in glass; 6, 9, 14, in the metallic solution; 6, 11, 14, in the muriatic acid; and 6, 10, 14, in a mixture of these two fluids. The excess of attraction of glass for the red and violet light is equal to 2, whichsoever of the three fluids be employed. The refraction of these two orders of rays will therefore be the same in all the three cases. But the excess of attraction for the green light is equal to 3, when the metallic solution is used, and therefore the green light will be more refracted than the red and violet, in this case. When the muriatic acid is used, the excess of attraction of glass for the green light is only 1, and therefore the green light will now be less refracted than the red and violet.

"We shall next suppose the metallic solution and the acid to adjoin each other. The attractions of both these mediums, for the red light being 6, and for the violet light 14, these two orders of rays will suffer no refraction in the confine of the two fluids, the difference of their attractions being equal to nothing.

"But the attractive force of the metallic solution for the green ray being only 9, and that of the muriatic acid for the same ray being 11, the green light will be attracted towards the muriatic acid with the force 2; and therefore the difference between the refraction of the green light and the unrefracted red and violet light, which takes place in the confine of these fluids, will greatly exceed the difference of refraction of the green light, and equally refracted red and violet light, which is produced in the confine of glass and either of the fluids.

"Lastly, in a mixture of the two kinds of fluids, the attraction for the red, green and violet rays, being 6, 10 and 14, and that of the glass, 8, 12 and 16, the excess of the attraction of the glass for the green rays, is the same which it is for the red and violet rays. These three orders of rays will therefore suffer an equal refraction, being each of them attracted towards the glass with the force 2; and when this is the case, it appears, from the observations, that the indefinite variety of rays of intermediate colours and shades of colours, which altogether compose solar light, will also be regularly bent from their rectilinear course, constituting what has been termed a planatic refraction."

In short, Dr. Blair says, that he "uses more transparent mediums than the common ones; avoids or greatly diminishes the reflections at the surfaces of the mediums; applies fluid mediums more homogeneous than thick flint or crown glass, which at the same time disperse the different coloured rays of light in the same proportion, by which means an image is produced perfectly Achromatic, which is but imperfectly so in Dollond's object glasses made of flint and crown glass combined.

AFFECTED *Equations*, *add* (from Francis Maseres, Esq.)—"This expression of *Affected Equations* seems to require some further explanation. It was introduced by the celebrated Vieta, the great father and restorer of Algebra. He has many expressions peculiar to himself, and which have not been adopted by subsequent Algebraists. Amongst these are the following ones. He calls a set of quantities in continual geometrical proportion, (such as the quantities $1, x, x^2, x^3, x^4, x^5, x^6, x^7$, &c,) a set of *scalar* quantities, or *magnitudines scalares*; and, when there are several of these *scalar* quantities mentioned together, (as in the compound quantity $x^5 + ax^4 - b^2x^3$,) he calls the highest quantity, or that which is farthest in the scale of quantities $1, x, x^2, x^3, x^4, x^5, x^6, x^7$, &c. (to wit, the quantity x^5 in the said compound quantity $x^5 + ax^4 - b^2x^3$,) *the power* of the fundamental quantity x, or of the second term in the said scale; and he calls the lower scalar quantities which are involved in the second and third terms of the said compound quantity $x^5 + ax^4 - b^2x^3$, to wit, the quantities x^4 and x^3, (or, in our present language, the inferior powers of x,) scalar quantities of a *parodic* degree to x^5, or the power of the fundamental quantity x. This word *parodic* I take to be derived (though Vieta does not tell us so) from the Greek words παρὰ and ὁδὸς, which signify *near* and *a way* or *road*, because these inferior scalar quantities x^3 and x^4 lie *in the way* as you pass along in the scale of the aforesaid quantities $1, x, x^2, x^3, x^4, x^5, x^6, x^7$, &c, from 1 to x^5, which he calls the power of x in the said compound quantity $x^5 + ax^4 - b^2x^3$. These inferiour scalar quantities x^3 and x^4 are therefore *parodic*, or *situated in the way to*, or are *leading to*, the higher scalar quantity x^5. He then proceeds to define *a pure power* and *an affected power*, and tells us that *a pure power* is a scalar quantity that is not affected with any *parodic*, or *inferiour* scalar quantity, and that *an affected power* is a scalar quantity that is connected by addition, or subtraction with one, or more, *inferiour*, or *parodic*, scalar quantities, combined with co-efficients that raise them to the same dimension as the power itself, or make them *homogeneous* to it, and consequently capable of being added to it, or subtracted from it. Thus x^5 alone is a *pure power* of x, namely, its fifth power; and $x^5 + ax^4 - b^2x^3$ is *an affected power* of x, namely, its fifth power *affected by*, or *connected with*, the two *parodic*, or *inferiour*, scalar quantities x^3 and x^4, which are multiplied into bb and a, in order to make them *homogeneous* to, or *of the same dimension with*, x^5 itself, and capable of being added to it or subtracted from it. See Schooten's Edition of Vieta's works, published at Leyden in Holland in the year 1646, pages 3 and 4.

"This, then, being the meaning of the expression, *a pure power* and *an affected power*, the meaning of the corresponding expressions of *a pure equation* and *an affected equation* follows from it of course: *a pure equation* signifying an equation in which a pure power of an unknown quantity is declared to be equal to some known quantity; such as the equation $x^5 = 79$; and *an affected equation* signifying an equation in which a power of an unknown quantity affected by, or connected, either by addition or subtraction, with, some inferiour powers of the same unknown quantity, (multiplied into proper co-efficients in order to make them *homogeneous* to the said highest power of the said unknown quantity,) is declared to be equal to some known quantity; such as the equation $x^5 + ax^4 - b^2x^3 = 79$. This I take to be the original meaning of the expression *an affected equation*. But, as the language of *Vieta* has not been adopted by subsequent writers of Algebra, I should think it would be more convenient to call them by some other name. And, perhaps those of *binomial*, *trinomial*, *quadrinomial*, *quinquinomial*, and, in general, that of *multinomial* equations, would be as convenient as any. Thus, $xx + ax = rr$, and $x^3 + ax^2 = r^3$, and $x^3 + a^2x = r^3$, and $x^4 + a^3x = r^4$, and $x^4 + ax^3 = r^4$, might all be called *binomial* equations, because they would be equations in which a *binomial* quantity, or quantity consisting of two terms that involved the unknown quantity x, is declared to be equal to a known quantity; and, for a like reason, the equations $x^3 + ax^2 + b^2x = r^3$, and $x^4 - ax^3 + b^2x^2 = r^4$, and $x^4 - ax^3 + b^3x = r^4$, and $x^5 + ax^4 + b^2x^3 = r^5$, and $x^5 + ax^4 - b^2x^3 = r^5$, and $x^5 + b^2x^3 + c^4x = r^5$, might be called *trinomial* equations. And the like names might be given to equations of a greater number of terms. Dr. Hutton, I observe, in his excellent new Mathematical and Philosophical Dictionary, just now published, (Feb. 2. 1795,) calls them *compound* equations; which is likewise a very proper name for them, and less obscure than that of *affected* equations."

Pa. 76, col. 1, l. 25, *for* $\sqrt{3+1} - \sqrt{3-1}$, *read* $\sqrt{3}+1 - \sqrt{3}-1$.

Pa. 94, col. 2, l. 34, *for* Spaniard, *read* Portuguese.

Pa. 95, col. 2, after l. 21, or the end of the paragraph relating to Dr. Barrow, add as follows:—Of these lectures, the 13th deserves the most special notice, being entirely employed upon Equations, delivered in a very curious way. He there treats of the nature and number of their roots, and the limits of their magnitudes, from the description of lines accommodated to each, viz, treating the subject as a branch of the doctrine of maxima and minima, which, in the opinion of some persons, is the right way of considering them, and far preferable to the so much boasted invention of the generation of Equations from each other, discovered by Harriot and Descartes.

Pa. 97, col. 2, after l. 3, *add*—Dr. Waring and the Rev. M. Vince, of Cambridge, have both given many improve-

improvements and discoveries in series and in other branches of analysis. Those of Mr. Vince are chiefly contained in the latter volumes of the Philosophical Transactions; where also are several of Dr. Waring's; but the bulk of this gentleman's improvements are contained in his separate publications, particularly the *Meditationes Algebraicæ*, published in 1770; the *Proprietates Algebraicarum Curvarum*, 1772; and the *Meditationes Analyticæ*, 1776; an account of the chief contents of which, a friend has favoured me with, as follows.

Of Dr. Waring's Meditationes Algebraicæ.

The first chapter treats of the transformation of algebraical equations into others, of which the roots have given algebraical relation to the roots of the given equations.

The general resolution of this problem requires the finding the aggregates of each of the values of algebraical functions of the roots of the given equation: for this purpose the author begins with finding the sum of the m^{th} power of each of the roots of the equation $x^n - px^{n-1} + qx^{n-2} - \&c = 0$ by a series proceeding according to the dimensions of p the sum of the roots: this series (when continued in infinitum and converges) finds also the sum of any root of the above-mentioned quantities. From this series is deduced the law of the reversion of the series $y = ax + bx^2 + cx^3 + \&c$, which finds x in terms of y; and also the law of a series, which expresses the greatest or least roots, and their powers or roots of a given algebraical equation, and which may be applied whether that root is possible or impossible, if the root be much greater or less than each of the remaining ones. All the powers and roots of this series, when continued in infinitum, observe the same law.

On this subject are further added some elegant theorems; of which, one finds the sum of all quantities of this kind $\alpha^a\beta^b\gamma^c$, &c; where α, β, γ, &c, denote the roots of the given equation. This has been since published by the celebrated mathematician Mr. le Grange in the Academy of Sciences at Paris.

There is also added a method of considerable utility in these matters; viz, the assuming equations whose roots are known, and thence deducing the coefficients of the equations sought: and also from the terms of an inferior equation deducing the terms of a superior.

The second chapter principally treats of the limits and number of impossible and affirmative and negative roots of algebraical equations.

Some new properties are added, of the limiting equations resulting from multiplying the successive terms of the given equation into an arithmetical series; and a method of finding limits between each of the roots of a given equation, since published in the Berlin Acts, and also some new methods of finding equations whose roots are limits between the roots of other equations. In theor. 4 and 5 are contained quantities which are always greater than certain others, when they are all possible; from whence may be deduced Newton's and several other rules for finding the number of impossible roots: these rules may be rendered somewhat more general by multiplying the given equations into others, whose roots are all possible, and finding whether impossible roots may be deduced by the rule in the resulting equation, which cannot from it be discovered in the given one. A rule is given, deduced from each successive four terms of the given equation, and consequently much more general than rules deduced from each successive three terms. The former always discovers the true number of impossible roots contained in quadratic and cubic equations, the latter in quadratic only. There is also a rule given for finding the number of impossible roots from an equation, of which the roots are the squares, &c, of the roots of a given equation; and a second from an equation of which the roots are the squares of the differences of the roots of a given equation; and a third rule for finding an equation, of which the root is $z = rx^{n-1} - \overline{n-1}\,px^{n-2} + \&c$; if $x^n - px^{n-1} + qx^{n-2} - \&c = 0$ be the given equation, &c, these latter resolutions always discover the true number of impossible roots contained in cubic, biquadratic and surfolid equations; and also whether or not any impossible roots are contained in any given equation; and also from the last term whether the number of impossible roots contained be 2, 6, 10, &c, or 0, 4, 8, &c. The principle of a 4th rule is given by finding when two roots once, twice, thrice, &c, or four, &c, roots become equal. From a method given of finding the number of impossible roots contained in an equation involving only one unknown quantity, is deduced a method of discovering limits between which are contained any number of impossible roots in an equation involving two or more unknown quantities. From the number of impossible, affirmative and negative roots contained in a given equation, is delivered a method of finding the number of impossible, &c roots contained in an equation of which the roots have a given algebraical relation to the roots of the given equation.

The principles are subjoined of finding the number of affirmative and negative roots contained in an algebraical equation: but this necessarily supposes a method of finding the number of its impossible roots known. It is demonstrated, that if the equation $x^n - px^{n-1} + qx^{n-2} - \&c = 0$ be multiplied by $x - a$, then every change of signs in the given, will have one, or three, or five, &c in the resulting equation; and if it be multiplied by $x + a$, then every continuation from + to + or − to −, will produce one, or three, or five, &c such continuations in the resulting, whence every equation $x^n - px^{n-1} + \&c = 0$ will contain at least so many changes of signs in its successive terms as there are affirmative roots, and so many continued progressions from + to + and − to −, as there are negative. In a biquadratic $x^4 + px^3 + qx^2 + rx + s = 0$, of which two roots are impossible, and s an affirmative quantity, then it is demonstrated that the two possible ones will be both negative or both affirmative, according as $p^3 - 4pq + 8r$ is an affirmative or negative quantity, if the signs of the coefficients, p, q, r, s are neither all affirmative, nor alternately − and +. The number of impossible and affirmative and negative roots contained in the equation $x^n + Ax^m + B = 0$ is likewise given, &c. If $lx^m - px^{m-1} + qx^{m-2} - \&c = 0$ and $bx^n - ax^{n-1} + bx^{n-2} - \&c = v$, and further $lx^n - ax^{n-1} + bx^{n-2}$ &c $= 0$ and $lx^m - px^{m-1} + \&c = w$, then the content of all the values of

of the quantity x will be to the content of all the values of the quantity x :: $\pm p$: b^m, from whence are deduced some properties of parabolic curves. *Ex. gr.* Let the equation expressing the relation between the abscissa and ordinate y be $y = ax^n + bx^{n-1} + cx^{n-2} + \&c.$ Then will the content under the $(\mu - 1)$ greatest ordinates be to the square of the content of all the distances between any two points in which the abscissa cuts the curve :: a^{n-1} : $n^n - 2$. The quotient of the content of all the lines divided by the content of all the cosines to the points in which the abscissa cuts the curve, will be to the content of all the abovementioned greatest ordinates :: $n^n a$: 1. Similar propositions are deduced concerning the ordinates to the points of contrary flexure, &c.

The third chapter is versant, concerning, 1st finding the roots of equations or irrational quantities, which have given relations to each other: this is performed by substitution or division and finding the common divisors of the quantities resulting; and 2d concerning more (n) equations containing a less number (m) of supposed unknown quantities, which consequently require $n-m$ equations, since named equations of condition; these are likewise deduced from the method of finding common divisors. 3dly, Concerning the resolution of equations; in this case is given, 1. The reduction or resolution of some recurring equations. 2. Some properties of the roots of the equation $x^n \pm 1 = 0$. 3. Resolution of a biquadratic $x^4 + px^3 + qx^2 + rx + s = 0$, by reducing it to an equation $x^4 + ax^2 + b = 0$. 4. A resolution of the biquadratic $x^4 + 2px^3 + qx^2 + rx + s$ by adding $(p^2 + 2n)x^2 + 2pnx + n^2$ to both sides of the equation, so as to complete the square; and the deducing that the values of n are $\frac{\alpha\beta + \gamma\delta}{2}$, $\frac{\alpha\gamma + \beta\delta}{2}$, $\frac{\alpha\delta + \beta\gamma}{2}$; the values of $\sqrt{(q + p^2 + 2n)}$ are $\frac{\alpha + \beta - \gamma - \delta}{2}$, $\frac{\alpha + \gamma - \beta - \delta}{2}$, &c, and the values of $\sqrt{(s + n^2)}$ are $\frac{\alpha\beta - \gamma\delta}{2}$, $\frac{\alpha\gamma - \beta\delta}{2}$, &c; if α, β, γ, δ, are the roots of the given equation. 5. A resolution of equations as general as any yet discovered, viz, the assuming $x = a\sqrt[n]{p} + b\sqrt[n]{p^2} + c\sqrt[n]{p^3} + \&c$; and exterminating the irrational quantities, viz, from assuming $x = a\sqrt[3]{p} + b\sqrt[3]{p^2}$ are deduced different resolutions of cubic; from $x = a\sqrt[4]{p} + b\sqrt[4]{p^2} + c\sqrt[4]{p^3}$ different resolutions of biquadric; from the equations $x = a\sqrt[n]{p} + b\sqrt[n]{p^2}$, $x = a\sqrt[n]{p} + b\sqrt[n]{p^{n-1}}$, $x = a\sqrt[n]{p} + b\sqrt[n]{p^3}$, $x = a\sqrt[n]{p} + b\sqrt[n]{p^{n-2}}$, &c, are deduced De Moivre's equation, and several others of new formula not before delivered. 6. The resolution $x = \sqrt[n]{\alpha} + \sqrt[n]{\beta} + \sqrt[n]{\gamma} + \&c$, first given by Euler, shewn to be a very particular; but this is rendered here much more general by assuming a more general resolution. 7. The resolution and reduction of equations from exterminating irrational quantities. 8. Reduction of some equations, when they are deduced from others by reducing them to the original equations. 9. The finding a quantity, which multiplied into a given irrational will produce a rational quantity, and thence deducing, from a given equation involving irrational quantities the dimensions to which the equation freed from them will ascend. 10. Let P = a series either ascending or descending, according to the dimensions of x, from thence is deduced the sum of a series consisting of its alternate terms, or terms at (n) distance from each other. 11. It is proved, that Cardan's resolution of a cubic, is a resolution of an equation of 9 dimensions or three different cubics: similar principles are applied to some other equations. 12. General principles are given for the deducing the function of the roots of the given, which constitute the coefficients or roots of the transformed equation. E. g. Let a cubic equation $x^3 + qx - r = 0$ and $z - \frac{q}{3z} = x$, thence is shewn the function of the roots of x, which constitute z, and further the cases of the cubic, which are resolvable by the transformed equation, whose root is z: the same principles are applied to biquadratics. 13. The correspondent impossible roots of a given irrational quantity are deduced; and also the different roots of a given resolution. 14. The biquadratic of the formula $x^2 - 2(a + b\sqrt{-1})x - c - d\sqrt{-1} = 0$ is distinguished into two quadratic equations involving only possible quantities, and thence every algebraic equation is proved to consist of simple and quadratic divisors involving only possible quantities. 15. A method is delivered of transforming irrational quantities into others; but it is cautioned, that in reduction and transformation correspondent roots should be used, otherwise it is probable that we shall fall into errors, of which examples are given. 16. The convergency of a root found by the common method of approximations is given; and it is discovered that the convergency principally depends on the quantity assumed for the root being much more near to one root than to any other; and independent of it, not on how near it is to a root.

The fourth chapter is principally conversant concerning more algebraical equations and their reductions to one. 1. It gives the law of the resolution of any number of simple equations; and the reduction of n simple equations to $n - 1$ by means of others. 2. The method of reducing more (n) equations into one so as to exterminate $n - 1$ unknown quantities by the method of common divisors, and further delivers the principles of investigating the roots or values of the unknown quantities, which result from this, or, which is much the same, from the common method of Erasmus Bartholinus, and which are not contained in the given equations. 3. If two algebraical equations of n and m dimensions of the unknown quantities x and y are reduced to one so as to exterminate one of the unknown quantities, the principles are given of finding the dimensions to which the other will ascend: if it ascends to $n \times m$ dimensions; then the sum of the roots depends on the terms of n and $n - 1$, dimensions in the one, and m and $m - 1$ in the other, and similarly of the products of every two; &c. From this principle are deduced several properties of algebraical curves. The

The same principles are applied to more equations involving more unknown quantities. 4. Some two equations of given formulæ are reduced to one so as to exterminate one unknown quantity. 5. Two equations are likewise reduced to one so as to exterminate unknown quantities by means of infinite series. 6. A method of finding whether some equations contain the same roots of the unknown quantities as others. 7. From the correspondent roots of the unknown quantities in given equations are found the constitution of their coefficients; and from thence the aggregates of the functions of the roots of two or more equations. 8. Some things are given concerning the transformations of more equations than one, of their impossible roots, of their roots which have a given relation to each other. 9. Some reductions and resolutions of more equations involving more unknown quantities. 10. If two equations similarly involve two unknown quantities x and y; then the equation of which the root is x or y is demonstrated to have twice the dimensions of the equation whose root is any rational function of $x + y$ or $x^2 + y^2$ or any rational recurring function of x and y; and if for y be substituted $-y$; then in the equation whose root is the resulting quantity the dimensions will be the same as in the equations whose root is x or y, but its formula will be of half the number of dimensions. The same principles are applied to more equations similarly involving more unknown quantities. 11. If there are two equations involving two unknown quantities, one deduced from the other, by some substitutions investigated from equations similarly involving two unknown quantities; then the equation whose root is one of the unknown quantities will be recurring. 12. Let A and B be functions of x and y, a method is given of finding, whether A is a function of B. 13. Methods of approximations to the roots of equations when they are unequal, or two or more nearly equal, possible or impossible; and also some remarks on the increments or decrements of the roots, in passing from one equation to others of the same number of dimensions are given.

The fifth chapter treats of rational and integral values of the unknown quantities of given equations.

1. It finds the rational and integral simple, quadratic, &c divisors (by a method different to Waessaner's) of a given equation, which involves one or more unknown quantities. 2. If two equations involve two unknown quantities x and y; the same irrationality, which is contained in x will likewise be contained in its correspondent value of y, unless two or more values of the quantity (x or y) are equal, &c. 3. A method is given of finding integral correspondent values of the unknown quantities of two or more equations involving as many unknown quantities. 4. A method is also delivered of deducing when a given equation can be resolved by means of square, cube, &c roots; and when by similar methods it can be reduced to equations of 4, 5, &c, its dimensions. 5. A method is given of finding a quantity or number, in which are contained all the divisors of any given rational or integral quantities. 6. A method different from Schooten's, Newton's, and Euler's, of extracting the root of a binomial surd $a + \sqrt{b}$ is given, and the principle demonstrated on which all the rules are founded given by Schooten, viz, the multiplying the binomial surd so that the n^{th} root of $A^2 - B$ can be extracted, where $A + \sqrt{B}$ is the resulting surd; and it is further proved that multiplying the given surd $a + \sqrt{b}$ into 2^n will render Newton's resolution as general as the others; and lastly the extraction of the (m^{th}) root of the quantity $A + B\sqrt[n]{p} + C\sqrt[n]{p^2} + \cdots + \sqrt[n]{p^{n-1}}$ is given. 7. The law of Dr. Wallis's approximations in terms of the successive quotients, as also of continual fractions is deduced. 8. A method of deducing the integral values of each of the unknown quantities x, y, z, v, &c, contained in the equation $ax + by + cz + dv \pm$ &c $+ f = 0$ in terms of quantities, for which may be assumed any whole numbers. 9. Two or more equations are reduced to one, so as to exterminate unknown quantities; and if the unknown quantities of the resulting equations be integral or fractional, then the unknown quantities of the given equations will also be integral or fractional. 10. Principles are delivered of deducing equations of which the unknown quantities admit of correspondent and known integral or rational values. 11. Correspondent integral or rational values of the unknown quantities in several equations are given, and from some values of the abovementioned kind given, are deduced others. 12. A method of denoting any numbers either by fours, fives, sixes, &c, and their powers; and similar properties deduced as in decimal arithmetic. 13. It is demonstrated that the sum of the divisors of the number $1, 2, 3 \ldots x = N$ has to N a greater ratio than the sum of the divisors of any number L less than N has to L; and some other similar properties. 14. In the Philosophical Transactions are given properties similar to Mr. Euler's of the sum of divisors of the natural numbers, and some others. 15. Let $N = a^2 + rb^2$, where a, b, r, p and q are whole numbers, then N^{2m+1} and N^{2m+2} can be compounded by $(m+1)$ different ways of the quantities $p^2 + rq^2$; the different ways were first given in the Medit. 16. Every number consists of 1, 2, 3 or 4 squares, and of 1, 2, 3, 4, .. 9 cubes, and therefore if a number N is equal to 3 squares or 8 cubes, the problem may not be possible. 17. Let x and z be any whole numbers, and a and b numbers prime to each other, then $ax + bz$ can constitute any number, which exceeds $a \times b - a - b$. 18. Let r the greatest common divisor of m and $n - 1$, where n is a prime number; the number of remainders from the division of the number $1^m, 2^m, 3^m$, &c, in infinitum by n will be $\frac{n-1}{r} + 1$: from which are deduced several propositions. 19. Sir John Wilson's property delivered and demonstrated, viz, $1.2.3 \ldots n - 1 + 1$ will be divisible by n, if n be a prime number. 20. The sum of the powers $1^r + 2^r + 3^r + \ldots x^r$ are found divisible by x. $x + 1$, if r be a whole number; from whence is deduced an elegant property of all parabolas, correspondent to the property of Archimedes of the inscribed triangles in a conical parabola. 21. Some properties of exponential equations; several other new properties of algebraical quantities and equations are given in these Meditations. They were sent to the Royal Society in 1757, and since published in the years 1760, 62, and 69.

Properties

Properties of Algebraical Curves.

The equation expressing the relation between the abscis and its correspondent ordinates of a curve is transformed into another which expresses the relation between different abscissæ and their ordinates, from which is deduced, that there may be n and not more different diameters in a curve of $n - 1$ order, which cuts its ordinates in a given angle; and likewise that a diameter can have no more than $n - 1$ different inclinations of its ordinates, unless the diameter be a general one. 2. The formula of the equations to curves, all whose diameters are parallel, or cut each other in a given point, or which have a general diameter to which the lines any how inclined are ordinates. 3. It is proved that there cannot be more than $\frac{n}{m}$ different inclinations of parallel ordinates; which cut the curve in $n - m$ points only, possible or impossible. 4. Something is added concerning diameters, which cut their ordinates on both sides into equal parts. 5. It is demonstrated that there are curves of any number of odd orders, that cut a right line in 2, 4, 6, &c, points only; and of any number of even orders that cut a right line in 3, 5, 7, &c points; and consequently that the order of the curve cannot be denounced from the number of points, in which it cuts a right line. 6. The principles are delivered of finding the asymptotes, parabolical legs, ovals, points, &c, of a curve, of which the equation marking the relation between the abscis and its ordinates is given; and also given the number of asymptotes, parabolical legs of different kinds, ovals, points of different kinds, the least order of a curve, which receives them, is deduced. 7. An equation expressing the relation between an abscis and its ordinates, is transformed into an equation expressing the relation between the distances from two or more points, the latter may be varied an infinite number of ways; and thence are deduced some properties. Many resolutions of this kind are only resolutions of a particular case contained in it; and consequently can never be deduced from any general reasoning; they are often deduced from some particular cases, which are known to answer several conditions of the problem. Transformations of a given curve into others by substitutions, and properties of the loci of some points are deduced, from which Mr. Cotes's property of algebraical curves, and others of a similar and somewhat different nature are derived. 8. Let a curve of n dimensions have n asymptotes, then the content of the n abscissæ will be to the content of the n ordinates, in the same ratio in the curve and asymptotes, the sum of their (n) subnormals to ordinates perpendicular to their abscissæ will be equal to the curve and the asymptotes; and they will have the same central and diametrial curves. 9. Some propositions are added concerning the construction of equations, and some equations are constructed from the principles of Slusius.—If two curves of n and m dimensions have a common asymptote; or the terms of the equations to the curves of the greatest dimensions have a common divisor, then the curves cannot intersect each other in $n \times m$ points, possible or impossible. If the two curves have a common general centre, and intersect each other in $n \times m$ points, then the sum of the affirmative abscissæ &c to those points will be equal to the sum of the negative; and the sum of the n subnormals to a curve which has a general centre will be proportional to the distance from that centre. 10. Something is added on the description of curves. 11. No curve which has an hyperbolical leg of the conical kind can in general be squared. 12. It is demonstrated that no oval figure, which does not intersect itself in a given point, can in general be expressed in finite algebraical terms. 13. Given an algebraical equation, and similarly equations expressing a relation between x and y, &c; and also a fluxional quantity which is an algebraical function (z) of x and y and their fluxions; a method is given of deducing an equation whose root is z; and thence some properties of curves. 14. Properties similar to the subsequent of conic sections, are extended to curves of superior orders, viz, if lines be drawn from given points in them in given angles to four lines inscribed in the conic section, then will the rectangle under two of those lines be to the rectangle under the other two in a given ratio. Several properties are added, which follow from the application of algebraical propositions invented in the Medit. Algebr. to curve lines.

The second chapter treats of curvoids and epicurvoids, or curves generated by the rotation of given curves on right lines or curves, and gives a method of rectifying and squaring them; and from the radii of curvature of the generating curves being given, it deduces the length and radius of curvature of the curve generated at the correspondent point; it also asserts that from them may be deduced the construction of the fluxional equations of the different orders.

The third chapter treats of algebraical solids. 1 It deduces the equation to every section of a solid generated by the rotation of a curve round its axis; and from thence the different sections generated by the rotation of conic sections round their axis. 2. The equation to solids contains the relation between the two abscissæ and their ordinates, and the order of the solid may be distinguished according to the dimensions of the equation; or the solid may be defined by two equations expressing the relation between the three abovementioned quantities, and a fourth which may be the axis of the section: there is further given a method of deducing the equation to any section of these solids, and from it the equation to the curve projected on a plane by a given curve. 3. A method of deducing the projection of a curve or solid on each other. 4. If the equation be $x - a = 0$, (x being the distance from a given point) then it may denote the periphery of a circle if one plane, or the surface of a globe if it refers to a solid. 5. Let x and y denote the distances from two respective points, then an equation expressing the relation between x and y designs the periphery of a curve, if contained in the same plane, or the surface of a solid generated by the rotation of a curve round its axis, passing through the two given points, if a solid. 6. An equation expressing the relation between lines drawn from three or more points may denote an equation to a solid. 7. If x, z and y denote the two abscisses and correspondent ordinates to a solid, and the terms of x and y, or x and z, or y and z; or x, z and y be similarly involved; then may the solid be divided into two or

of six similar and equal parts; and if no unequal power of x or y or of y, or x and y, &c; or x, y and z be contained in the equation, then the curve may further be divided in general into twice, four or six times the preceding number of equal parts. 7. Curves of double curvature are designed by two equations expressing the relation between two abscissæ and correspondent ordinates, or between lines drawn from three or more points; similar properties may be deduced from these as from the equations to curves.

Chapter the 4th treats of the maxims and minims of polygons inscribed and circumscribed about curves, and thence deduces certain quantities equal to each other, when maxims and minims are contained at every point of the curve: it further contains several properties of conic sections. 1. If any rectilinear figure circumscribes an ellipse, the content under the alternate segments of the line made by the points in which the line touches the ellipse will be equal. 2. If a right line cuts a conic section, and the parts of the line without the conic section on both sides are equal; and any rectilinear figure, which begins and ends at the bounds of the abovementioned line, be described round the conic section, then the contents under the alternate segments of the circumscribing lines as divided in the points of contact will be equal. 3. If two polygons be circumscribed about an ellipse, and the sides are cut by the points of contacts in the same ratios in the one as in the other; then will the areas of the two polygons be equal. 4. If two lines cut a conic section proportionally, i. e. they are divided by the conic section in the same ratio in the one as in the other, and if polygons be described round the conic section, terminated at the ends of those lines, of which the sides are divided by the points of contact in the same ratio in the one as in the other, then will the area of the two polygons be equal, as likewise the curvilinear area. 5. If all the sides of two polygons inscribed in an ellipse make the two angles at the same point equal, and two polygons of this kind be inscribed in the curve, then will the sum of the sides of the one polygon be equal to the sum of the sides of the other. Several other similar properties are added, as also properties of solids generated by the rotation of a conic section round its axis; to which I shall mention the three or four following. 1. The diagonals of a parallelogram circumscribing an ellipse or hyperbola will be conjugate diameters. 2. The sections of a solid generated by the rotation of a conic section round its axis, which pass through its focus, will have that point for the focus of all the sections. 3. If 4 perpendiculars be drawn from any point in an hyperbola to its periphery; and two lines from the same point to the asymptotes and the ordinates from the 4 points of the curve and the 2 of the asymptotes be drawn to the abscis; then will the sum of the resulting abscissæ to the former be double to the sum of the abscissæ to the latter. 4. If an arc of the periphery of a circle be divided into n equal parts, a, $2a$, $3a$, &c, and $p =$ chord of the arc $180 - na$, and α and β be the roots of the quadratic $x^2 - px + 1 = 0$ and radius 1: then will $\alpha^n + \beta^n =$ chord of the arc $180 - na$, from whence may be deduced the divisors of the quantity $x^{2n} - Ax^n + 1$; and also the equation whose roots are the distances of a point in the circle from those points of equal division, and further may be deduced the sum of all the values of any algebraical function of those lines.

Most of the properties of circles given by Archimedes are extended to conic sections, and some of the algebraical and geometrical properties of Pappus are rendered more general; and the principles invented applied to many other cases. In the first edition of this book published in 1762 were nearly enumerated the lines of the fourth order on the same principles as Newton's enumeration of lines of the third order; but this has since been rejected by the author as not sufficiently distinguishing the curve, and as being of no great utility.

Meditationes Analyticæ.

The first *chapter* treats of finding the fluxion of a fluent, when the quantity or fluent is considered as generated by motion; or the parts from the whole when the whole or quantity is considered as consisting of innumerable parts. It further gives the law of a series, which expresses the fluxion of an exponential of any order.

Chapter 2, is versant about the fluents of fluxions. 1. It finds the general fluent of a fluxion $P\dot{x}$, when P is any algebraical function of x however irrational but not exponential; for which intent it investigates the common divisors of any two quantities contained under the different vincula; and thence the common divisors of the resulting divisors, and so on; and likewise all the equal divisors contained in any of the abovementioned quantities; whence it so reduces the quantity P, that no equal nor common divisors may be contained in any of the resulting quantities under the different vincula; and from the common method deduces the terms of a series to the number, which the series is shewn to consist of, when it does not proceed in infinitum. 2. It demonstrates, that if the dimensions of x in the denominator of P exceed its dimensions in the numerator by 1, then the fluent cannot be expressed in finite terms; and also if one factor of P be $(A \pm (A^2 + a)^{\frac{1}{2}})^{\lambda}$, where a is an invariable quantity, and in some other cases the substitution required must be somewhat different. 3. The fluents of some fluential and exponential fluxions, or fluxions involving fluents and exponential quantities, are given. 4. A general method of discovering whether the fluent of any fluxion of any order involving one, two or more variable quantities, and their fluxions, can be expressed in terms of the variable quantities and their fluxions. 5. The correction of fluents of all orders, and thence the fluent contained between any values of the variable quantities and their fluxions, is given; in these corrections the same roots of the irrational quantities are to be used in the correction as in the fluent. 6. From the transformation of equations and the principles before delivered, are deduced fluents equal to each other. 7. Some exponential quantities given, which continually change from possibility to impossibility, and from impossibility to possibility. 8. Is a method of finding whether the fluent of any fluxion contained between any limits are finite or not. 9. The sum of the fluents of a fluxion which is an algebraical function of the letter x multiplied into $\dot{x}$ can always be expressed by finite terms, circular arcs and logarithms, the extraction of the roots of equations being granted.

10. Some

10. Some fluxions involving irrational quantities are reduced to others, in which no irrationality is contained. 11. The general principles of deducing whether the fluent of a given fluxion can generally be expressed by finite algebraical terms, their circular arcs and logarithms. 12. Some equal correspondent fluents are found by substitutions deduced from equations in which two variable quantities are similarly involved. 13. Some necessary corrections are given of finding the fluents of all the fluxions of the formula

$$x^{pn \pm \sigma n - 1} \dot{x} \times R^{m \pm \lambda} \times S^{\sigma \pm \mu} \times T^{t \times \nu} \times \&c,$$

(where σ, λ, μ, ν, &c denote any whole numbers,

$$\text{and } R = e + fx^n + gx^{2n} + \ldots x^{\alpha n},$$
$$S = h + kx^n + lx^{2n} + \ldots x^{\beta n},$$
$$T = q + rx^n + sx^{2n} + \ldots x^{\gamma n}, \&c)$$

from $\alpha + \beta + \gamma +$ &c, independent fluents; but perhaps not from $\alpha + \beta + \gamma +$ &c fluents, which have different values of the quantities, σ, λ, μ, ν, &c. 14. The number of independent fluents of the formula $x^{\theta + an + \beta m} \times (a + bx^n + cx^m)^{\lambda + \pi} \times \dot{x}$, where α, β and π denote whole affirmative numbers, &c; and the number of independent fluents of the formulæ $\dot{X} f Y \dot{x}$, where $\dot{X}$ is a fluxion of which the fluent can be found, from which can be deduced all of the same formula, is immediately known from the number of independent fluents of the formula $Y\dot{x}$ and $XY\dot{x}$ which determine all of those formulæ. 15. Let $a + bx^n + cx^{2n} + \ldots kx^{\mu n} = p$, and from some fluents of the fluxions of the formulæ $p \times x^{\mu n - 1} \dot{x}$, where μ is a whole affirmative number, are determined the remaining ones of the same formula. 16. Something is added concerning finding the value of a fraction, when both the numerator and denominator vanish; and lastly from the fluents of some fluxions being given, the method of deducing the fluents of others.

Chapter 3. principally treats of algebraical and fluxional equations. 1. It gives the method of transforming two or more fluxional equations into one so as to exterminate one or more variable quantities and their fluxions, and finds the order of the resulting equation. 2. It reduces some fluxional equations into more. 3. A method of reducing fluxional equations involving fluents so as to exterminate the fluents. 3. Some cases are given, in which the two variable quantities contained in a given equation are expressed in terms of a third. 4. Given an algebraical equation expressing the relation between x and y; a method is given of finding the fluent of $y\dot{x}^n$ or other fluxions in finite terms of x and y, if they can be expressed by such; or else by infinite series; this was first taught in the Philosophical Transactions in the year 1764. 5. Something is added concerning the correction of fluxional equations. 6. A method of investigating, whether a given equation is the general fluent of a given fluxional equation. 7. The method of deducing, whether a given equation is a particular or general fluent of a given fluxional equation. In both by substituting for the fluxions their values deduced from the fluential equation their values &c in the fluxional, the fluxional must result $= 0$; and in the general fluent there must be contained so many invariable quantities to be assumed at will independently as is the order of the fluent; and in both all the variable quantities must necessarily be variable, and no function of them vanish out of the fluxional equation from the substitution; for then all the conditions of the fluxional equation are answered by the fluential. 8. An investigation, when fluxional equations are integrable. 9. From some fluents are deduced others, *e.g.* if the area between any two ordinates to one abscissa can in general be found, then the area between any two ordinates of any other abscissa can be found &c. 10. From given fluxional equations and the fluents of some fluxions are deduced the fluents of many others. 11. The fluent of the first order of a fluxional equation of the nth order will have (n) different values and n different multipliers; and the fluent of the second order $n \cdot \frac{n-1}{2}$ different values, &c. 12. Let $\alpha = 0$, $\beta = 0$, $\gamma = 0$, &c, (n) general fluents of the fluxional equation, $\lambda = 0$, then will any function of the fluents α, β, γ, &c be a fluent of the same fluxional equation $\lambda = 0$. 13. From assuming equations, which contain only simple powers of the invariable quantities to be assumed at will, may easily be deduced fluxional equations, of which the general resolutions are known: 2. From assuming the values of any variable quantities and substituting then their fluxions for the variable quantities, &c. in any functions π, ϱ, &c of the variables assumed, let the quantities resulting be A, B, &c; then generally will $\pi = A$, $\varrho = B$, &c. be fluxional equations, of which the particular fluentials are known. It may be observed in this place as before, that from no general reasoning can particular fluents be deduced. 14. In the resolution of fluxional equations it is observed, that from the logarithmic and exponential quantities contained in the fluxional, may be deduced by chapter 1 the exponentials &c contained in the fluential: 2, and in a similar manner from the irrational quantities and denominators contained in it, the correspondent irrational quantities and denominators contained in the fluential: 3, the greatest dimensions of y multiplied into $\dot{x}$ must be greater than those of y into $\dot{y}$ by unity: when there are two of this kind &c, $ay\dot{x} + \beta x\dot{y} = x^m y^n$ ($\delta\dot{x} + \kappa\dot{y}$), the resolution is given; and so of more. 15. In the given equation, if the fluxion of the greatest order does not ascend to one dimension only; then by extraction &c to reduce the equation, that it may ascend to one dimension only; and thence find the fluent of any fluxion $P\dot{y} + Q^{n-1}\dot{y} + \&c, + R^{n}\dot{x} + \&c.$ 16. Let a fluxional equation be given involving x and y, in which x flows uniformly, a method is given of finding whether it admits of a multiplier, which is a function of x.·. and similarly of multipliers of other formulæ. 17. The method of deducing the multipliers of fluxional equations by infinite series. 18. Some fluxional equations are reduced by substitutions, which substitutions are commonly easily deducible from the fluxional equation given. 19. Somewhat concerning the reduction of some fluxional equations to homogeneous, and concerning homogeneous equations of different orders; and of reducing an homogeneous fluxional equation of n order to a fluxional equation of $n - 1$ order: and also

alfo of reducing m fluxional equations of n order to one of $m-1$ orders, and fo of all others to one degree lefs than the order generally occurring if they had not been homogeneous. 20. The fubftitution of an exponential for a variable quantity in equations which contain no exponential quantity; for fometimes n has been fubftituted for a quantity which flows uniformly, and then $\dot{w}$ fuppofed to flow uniformly, which leads to a falfe refolution. 21. A caution is given not to fubftitute homogeneous functions of no dimenfions for variable quantities; and in the general refolution to obferve, that there is contained an invariable quantity to be affumed at will, which is not contained in the fluxional equation. 22. Something more added concerning the fluents of $p^n\dot{y} + q^{n-1}\dot{x}\dot{y} + r^{n-3}\dot{y}\dot{x}^2 + \&c. = 0$, where p, q, r, &c. are functions of x, and fo of fome other fluxional equations. 23. Fluxional equations are deduced, of which the variable quantities cannot be expreffed in terms of each other, but both may be expreffed in terms of a third. 24. Every fluxion or fluent which is a function x, y, z, and x, y &c. is expreffed in terms of partial differences. 25. The refolution of fome equations expreffing the relation between partial differences &c is given. 26. Some obfervations on finding the fluents of fluxions, when the variable quantities become infinite.

The fecond book treats of increments and their integrals. 1. Some new laws of the increments are given. 2. The fluxion of the increment of P will be equal to the increment of the fluxion; where P is any function of x, if only the fluxion of the increment of x be equal to the increment of the fluxion. 3. Increments are reduced to others of given formulæ $e.g.\ \alpha + \frac{\beta}{x} + \frac{\gamma}{x(x+\dot{x})} +$, &c, and it is obferved that if β be not $= 0$, then the integral cannot be found in finite terms of the variable quantity, &c. It may be obferved, that Taylor, Monmort, &c, firft found the integral of the two increments $\frac{1}{x.\,\overline{x+\dot{x}}.\,\overline{x+2\dot{x}}\ldots\overline{x+\overline{n-1}\,\dot{x}}}$ and $x.\,\overline{x-\dot{x}}\ldots\overline{x-\overline{n-1}\,\dot{x}}$ but did not proceed much further (correfpondent to the finding the fluxion of the fluent x^n); the increments of fluents have been fince deduced, &c. In this book are difcovered propofitions correfpondent to moft of the inventions in fluxions, e.g. a method of finding the integral of any increment expreffed in algebraical or exponential terms of the variable quantity or quantities, and when the fluent cannot be expreffed: it is obferved that they cannot be expreffed in finite terms of the variable x, &c, if the dimenfions of x, &c, in the denominator exceed its dimenfions in the numerator by 1; or if any factor in the denominator of the fraction reduced to its lowest terms have not another contained likewife in the denominator, diftant by a whole number, multiplied into the increment of x.—The increments of fome integrals are deduced from the integrals of other increments; the integrals of fome incremental equations from different methods; their general integrals, and particular corrections, &c, &c; but here it is to be obferved, that the general problem of increments cannot be extended beyond the particular of fluxions, but fomewhat more may be added, when both are joined together. The third book is verfant concerning infinite feries. 1. It gives the ratio of the apparent and real convergency. 2. A method of finding limits between which the fum of the feries confifts; and alfo whether the fum of the feries is finite or not from the terms being given or equation between the terms. 3. The convergency of the whole feries is judged from the ratio of convergency of the terms at an infinite diftance. 4. The feries from the fluent converges, if the feries from the fluxion does, there are feveral propofitions on infinite feries deducible from the common algebra. 5. Let an equation $0 = a - bx + cx^2 - dx^3 + \&c$; and $\frac{b}{a}$ much greater than $\frac{c}{b}$, $\frac{c}{b}$ than $\frac{d}{c}$; &c. then will all the roots be poffible, and $\frac{a}{b}$ an approximation to the leaft root, $\frac{b}{c}$ to the next, &c: if an equation $y^n + ay^{n-1} + \ldots + fy^{n-m} + gy^{n-m-1} + \ldots = 0$, and if one root be much lefs than any m root, but much greater than the remaining; or if the equation be $x^n - px^{n-1} + qx^{n-2} \ldots \pm gx^{n-m+1} \mp hx^{n-m} \pm ix^{n-m-1} \mp kx^{n-m-2} \pm \&c. = 0$, then will the approximation to the above root be $\frac{i}{h} - (\frac{k}{i} - \frac{gi^2}{h^3}) + \&c.$ 6. Somewhat on the approximations when the approximation given is much more near to one, two, or more roots than to any other, and on the degree of convergency of the fubfequent approximations deduced; and their ultimate approximations. 7. Given approximations to m roots of a given equation are deduced more near approximations to them. 8. The incremental equation given and applied to approximations. 9. From given approximations to two or more unknown quantities contained in two or more equations are deduced more near approximations to them, either when the approximations given are more near to one, or to two, or more roots of one or more of the unknown quantities than to any others, and fo of infinite equations. 10. New feries are given for the fluents of different fluxions. 1. Log. $\overline{x \pm e} = \log. x \pm \frac{e}{x} - \frac{e^2}{2x^2} \pm$ &c.; the number whofe log. is $v \pm e$ (if N be log. of v) $= N \pm Ne \pm \frac{Ne^2}{2} \pm$ &c; the log. of $\frac{a+x+e}{a-x-e} = \log. \frac{a+x}{a-x} + \frac{e}{a^2-x^2} -$ &c. The fine of the arc $A \pm e$ is $S \pm Ce - \frac{1}{2} Se^2$, &c, and cofine of the fame arc $= C \pm Se - \frac{1}{2.3} Ce^2 \pm$ &c. S and C being the fine and cofine of A, the fluent of the fluxion of an elliptical arc $\frac{\sqrt{(1-cx^2)}\dot{x}}{\sqrt{(1-x^2)}}$ which differs little from the arc of a circle when e is a very fmall quantity $= A - \frac{e}{2} \times \frac{1.A - xP}{2} -$ &c, where $A = \int \frac{\dot{x}}{P}$, $B = \frac{1A - xP}{2}$, $C =$

$C = \frac{3B - x^2P}{3}$, &c. and $P = \sqrt{1-x^2}$, and A = arc of a circle of which the sine is x.

A similar series may be applied from the arc of an hyperbola or ellipse, to find a correspondent arc of an hyperbola or ellipse not much different from the preceding. In this method the series proceeds according to the dimensions of some small quantities, and the first term of the series is generally a near value of the quantity sought. These series properly instituted will generally converge the swiftest. 11. Something new is added concerning the fluent of the fluxional equation $\dot{y} = \dot{y}z^2$ viz $-y = E \times$ sin. arc: $(z) + F +$ cos. (ar. (z); E and F being any quantities to be assumed at will; and of correspondent equations to logarithms, and finding their values when z is increased by e. 12. A series for the increase of the arc from a small increase of the tangent, sine, &c. 12. When the terms a and x of the binomial $a \pm x$ are equal, the cases are given in which the series $a^m \pm ma^{m-1} x +$ &c, $= \overline{a \pm x}^m$ or the series $a^m x \pm \frac{m}{2} a^{m-1} x +$ &c, &c. will ultimately converge. 13. If any algebraical quantity V a function of x be reduced into a series proceeding according to the dimensions of x, a general method of finding what are the limits between which it converges; or the series from $\int V\dot{x}$, &c; and the method of interpolations so as to render them converging. 14. The convergency of different series are compared together, *e. g.* is given $\int \frac{\dot{x}}{1+x} = x - \frac{1}{2}x^2 + \frac{1}{3}x^3 -$, &c. $= \frac{x}{1+x} + \frac{x^2}{2(1+x)^2} + \frac{x^3}{3(1+x)^3} +$ &c. or $\int \frac{\dot{x}}{1 \pm x} = \frac{x}{1 \pm x} \pm \frac{x^2}{2(1+x)^2} +$ &c. there is an erratum contained in this example, for $a -$ is sometimes printed instead of $a +$: this series is easily deduced from Bernouilli's method of deducing infinite series, and has been since printed in the Philosophical Transactions. 15. Given algebraical or fluxional equations, and a fluxional quantity, a method is given of finding a series, which expresses the fluent of the fluxional quantity, from which principles are deduced new series for the area of a segment of a circle, the periphery of the ellipse, hyperbola, &c. 16. It is shewn, that serieses proceeding according to the dimensions of a quantity x always diverge, when serieses for the same purpose proceeding according to the reciprocal of its dimensions converge; unless sometimes in the case when they both become the same. 17. As series proceeding in infinitum according to the dimensions of the quantity x were first invented or used for the finding the fluents of fluxions, it being reduced into terms, whose fluents were known: so in finding integrals of increments it may be necessary to reduce the quantity into an infinite series of terms, whose integrals are known, and which converges. Examples of formulæ of serieses of this kind are given. 18. Methods are given of finding the value of one unknown quantity contained in one or more equations involving more unknown quantities, and the law of their convergencies and the interpolations necessary to render serieses for finding fluents converging, similar principles may be applied to incremental and fluxional equations. 19. It is observed, that in finding the value of any variable quantity in a series proceeding according to the dimensions of another, there will occur in a fluxional or incremental equation of (n) order in the series n invariable quantities to be assumed at will; and also the fluxional equations, &c. from whence they will arise. 20. The finding the integral of $\frac{x}{z}$, &c. 21. From the correspondent relation between the sums of two series resulting, which are functions of a variable quantity y, when the relation between x and z two values of y are given, is given a method of finding the coefficients of the series. 22. The rule generally called the reductio ad absurdum extended to more substitutions.

The fourth book treats of the summation of series, a method of correspondent values and several other problems. 1. Of finding the sum of a series expressed by a rational function of z into x^{z}; where z denotes successively the numbers 1, 2, 3, &c, in infinitum. 2. Given an equation expressing the relation between the successive sums, the relation between the successive terms is known, and the *vice versa*, &c. 3. It is found from an equation expressing the relation between the successive sums, terms and z the distance from the first term of the series, whether the sum of the series is finite or not. 4. The difference between z^{-o} and $\overline{z+1}^{-o}$, where z denotes the distance from the first term of the series, will be $-o \times z^{-o-1}$, which is greater than the simple ratio let o be as small as possible, and consequently the sum of the series finite. 5. If a series $a + bx + cx^2 + x^3$, of which at an infinite distance the preceding coefficients have to the subsequent the ratio of $r : 1$, be multiplied into a function $= 0$, when $x = \delta$, then if α be greater than r the series will diverge; if less converge. 6. From adding several terms of one or more series together may be formed a series, of which the sum from the sums of the preceding series is known. 6. Serieses are formed, of which the sums are known from varying the divisors, &c. 7. From given series are deduced others, of which the sums are known, and the sum of many series are deduced from finding the fluxions of fluents and fluents of fluxions. 8. From the relation between the different terms given is deduced the correspondent fluxional equation. 9. The finding the terms of any series, which can be deduced from given series; and thence deducing many series of which the sums can be found from the sum of the given series. 10. Series are given of which the sums can be found from finite terms, circular arcs, logarithms, elliptical and hyperbolical arcs. 11. From a general expression, when algebraical, fluxional, incremental, &c, for the sum of a series can be deduced a similar expression for the sum of every second, third, &c, terms. 12. An infinite series may be a particular resolution of infinite fluxional equations. 13. The terms of some series may be infinite and their sums known. 14. The general fluent of $\dot{y}^n = y\dot{x}^n$ is given by a series of the same kind, and the same of some other fluxional equations. 15. A quantity is found which multiplied into a series

more

more swiftly converging gives a given series. 16. The first differences of the terms of some series are given; if the terms are in geometrical ratio to each other the abovementioned differences will also be in geometrical ratio to each other: whence it appears, that the series from this method of differences will converge least when the given series converges swiftest, &c, but not always the contrary. Several other propositions are added concerning the method of differences applied to series. 17. A parabolico-hyperbolical curve is drawn through any number of points, as also an algebraical solid —. 18. Something is given concerning the convergency &c. of series deduced from the differences of the numerators of a given series, of which the denominators constitute a geometrical progression. 19. A rule is given for rendering series converging, in which it is observed that the sum of so many terms should be found that z the distance from the first term of the series may exceed the greatest root of the equation resulting from the quantity which expresses the term made $= 0$. 20. An equation expressing the relation between the sums and terms is reduced to an infinite fluxional equation expressing the relation between the sum or term, its fluxions, and z the distance from the first term of the series. 21. From a method being known of finding the sum of a series, which involves one variable only, is given a method of finding the sum of series which involve more variable quantities: and from assuming sums of serieses of this kind are deduced their terms. 22. The sums of series are found consisting of irrational terms. 23. The principle of the convergency of the approximations found in drawing parabolical curves through given points. 24. Something new is given concerning the interpolations of quantities.

$$25.\ \frac{e^{\alpha x}+e^{\beta x}+e^{\gamma x}+\&c}{n}=1+\frac{x^n}{1.2\,..\,n}+\frac{x^{2n}}{1.2..2n}+$$

&c. if α, β, γ, &c, are the roots of $x^n - 1 = 0$, &c. 26. Something is added concerning series from

$$\int\frac{\dot{x}}{x}\int\frac{\dot{x}}{x}\int\frac{\dot{x}}{x}, \&c, \times \int\frac{\dot{x}}{1+ax^n}.$$ 27. Nandens's Problems are somewhat extended. 28. Something is added on changing continual fractions into others. 29. A method of transforming series into continual factors.

30. A rule for finding the sine and cosine of $\frac{n}{m}$ the arc; and transforming an algebraical equation into an equation expressed in terms of sines and cosines, and thence from an approximation to the sine is found one more near; the same might have been performed by tangents, cotangents, secants, cosecants, &c. 31. From some fluents given have been found others, and consequently by reducing the fluents to infinite series from some infinite series given may others be deduced. 32. The fluent of $\frac{x^{\alpha}\dot{x}}{1\pm x^n}$ is found by approximation, where α is an irrational quantity, which method of finding approximations to the indices may be applied to other cases. 33. The sum of the fractions are found when the denominators $=0$, and consequently each particular infinite. 34. It is asserted, that the sum of certain fractions given become $= 0$, when the terms are expressed by a fraction of which the denominator is a rational function of the distance from the first term of the series. 35. $\int x^{\alpha-\beta-1}\dot{x}\int x^{\beta-\gamma-1}\dot{x}\int x^{\gamma-\delta-1}\dot{x}\times P$, where $P = Ax^n + Bx^{n+m} + Cx^{n+2m} + Dx^{n+3m} +$, &c, will be to $\int x^{\beta-\alpha-1}\dot{x}\int x^{\alpha-\gamma-1}\dot{x}\int x^{\gamma-\delta-1}\dot{x}\int$ &c. $\times P :: x^{\alpha} : x^{\beta}$ if the fluents are contained between the same values of x. 36. Are given some series consisting of two, of which the one converges, when the other diverges, and consequently the sum of both diverges; &c. 37. From the law of a series being given, the law of the series which expresses the square, or some function of the given series, is found.

1. A method of differences, which deduces from the sums given any successive sums, e. g. Let S^1, S^2, S^3, S^4, be the logarithms of the ratios $r : r + p$, $r : r + 2p$, $r : r + 3p$, $r : r + 4p$, then will the logarithm of $r : r + 5p$ be $5 \times (S^4 - S^1) + 10\,(S^2 - S^3)$ nearly: then rules are given in general, and likewise their errors from the true values.

2. A method of correspondent values is given, e. g. Let a, b, c, d, &c, be values of x; and S^a, S^b, S^c, S^d, &c, correspondent values of y; then may

$$y = \frac{(x-b)\ (x-c)\ (x-d)\ \&c}{(a-b)\ (a-c)\ (a-d)\ \&c}\times S^a + \frac{(x-a)\ (x-c)\ (x-d)\ \&c}{(b-a)\ (b-c)\ (b-d)\ \&c}\times S^b + \&c.$$

3. If the formula of the series be $A + Bx + Cx^2 +$ &c $= y$; or $y = \frac{x}{a}\times\frac{(x-b)\ (x-c)\ \&c}{(a-b)\ (a-c)\ \&c}\times S^a + \frac{x}{b}\times\frac{(x-a)\ (x-c)\ \&c}{(b-a)\ (b-c)\ \&c}\times S^b +$ &c; if the formula of the series be $Ax + Bx^2 + \&c = y$, which answers to Briggs's or Newton's method of interpolations; or the series will be

$$\frac{x^h}{a^h}\times\frac{(x^k-b^k)\ (x^k-c^k)\ (x^k-d^k)\ \&c}{(a^k-b^k)\ (a^k-c^k)\ (a^k-d^k)\ \&c}\times S^a + \frac{x^h}{b^h}\times\frac{(x^k-a^k)\ (x^k-c^k)\ (x^k-d^k)\ \&c}{(b^k-a^k)\ (b^k-c^k)\ (b^k-d^k)\ \&c}\times S^b +$$

&c; if the formula of the series be $Ax^h + Bx^{h+k} + Cx^{h+2k} + \&c, = y$; a general formula, which includes the preceding.

5. The series is given for deducing others when the number of correspondent values given are either even or odd, and the values of x are equidistant from each other. 6. And also from correspondent values of x and y to a number of equidistant values of x is deduced the value of y to the next successive or any successive value of x. 7. Some arithmetical theorems are deduced from the preceding propositions. 8. Another method is given of resolving the preceding problem. 9. A method of correcting the solution from a solution given

given which finds (n) values of y to (n) given values of x true, and m false to (m) other values. 10. A similar resolution is added from correspondent values of w, y, z, &c given; and more general resolutions. 11. Given the resolution of some cases, and formula in which the general is contained, a method is given in some cases of deducing it. 12. The principles of a method of deductions and reductions are added.

In a Pamphlet published at Cambridge, algebraical quantities are translated into probable relations, and some theorems on probabilities thence deduced; to which are adjoined,

1. The theorem $\overline{a+b}\cdot\overline{a+b\pm l}\cdot\overline{a+b\pm 2l}\cdot\overline{a+b\pm 3l}\ldots\overline{a+b\pm\overline{n-1}l} = a\cdot\overline{a\pm l}\cdot\overline{a\pm 2l}\ldots\overline{a\pm\overline{n-1}l} + n\times a\cdot\overline{a\pm l}\cdot\overline{a\pm 2l}\ldots\overline{a\pm\overline{n-2}l}\times b + n\cdot\frac{n-1}{2}\,a\cdot\overline{a\pm l}\cdot\overline{a\pm 2l}\ldots\overline{a\pm\overline{n-3}l}\times b\cdot\overline{b\pm l} + n\cdot\frac{n-1}{2}\cdot\frac{n-2}{3}\times a\cdot\overline{a\pm l}\cdot\overline{a\pm 2l}\ldots\overline{a\pm\overline{n-4}l}\times b\cdot\overline{b\pm l}\cdot\overline{b\pm 2l}$ + &c; this becomes the binomial theorem when $l=0$; and it will afford answers to similar cases when the whole number of chances are increased or diminished constantly by l, as the binomial does when they remain the same, a similar multinomial theorem is given. In the same pamphlet are further added some new propositions on chances, on the values of lives, survivorships, &c. In these books are also contained the inventions of others on similar subjects, which in the prefaces are ascribed to their respective authors.

In the Philosophical Transactions are given some properties of numbers, &c, of which some have been published in the books above mentioned; to which may be subjoined something in mixed mathematics, viz, a paper on central forces, which extends not only to central forces, but also to forces applied in any other direction, as in the direction of the tangent, and consequently includes resistances, &c. It gives a rule for finding the forces tending to two or more given points when the curve described and velocity of the body in every point of it is given, *e.g.* Let the curve be an ellipse, and the velocity the same at every point, and the two centres of force be the foci of the ellipse; then will the forces tending to the two foci be equal, and vary as the square of the sine of the angle contained between the distance from the centre of force to the point in which the body is situated, and the tangent to the curve at that point.

The method of deducing the fluxional equations which express the curve described by a body acted on by any forces tending to given points, or applied in any given directions: some other propositions are contained on similar subjects. 2. A paper on the fluxions of the attractions of lines, surfaces, and solids, and from the different methods of deducing them are found different fluents equal to each other: a third paper gives a solution of Kepler's problem of cutting the area of a circle described round a point by approximations, which also is applied to other cases; this likewise contains some other problems. Many of these discoveries have since been published, some in the London, and other foreign transactions.

Let $e^l = N$, then will l denote the log. of N to the modulus e. If e the modulus $= 10$, then will the system be the common or Briggs's system of logarithms. Logarithms, and the sums of some other serieses, of the formulæ $ax^h + bx^{h+k}$ + &c may be deduced in a manner similar to that which was used by the Ancients for finding the sines of the arcs of circles.

To particularise the numerous propositions contained in these works, would exceed the limits of our design. Besides those already mentioned, others are interspersed through the whole works.

ANEMOMETER, p. 111, col. 2, l. 1, *after* 12 ounces, *add* or $\frac{3}{4}$ of a pound. Owing to an oversight in the succeeding lines, of considering this 12 ounces as 12 pounds, in the calculations, several errors have been incurred, and the 3d column of the table of numbers, in that page, or the column for the velocity, has the numbers only $\frac{1}{4}$ of what they ought to be, or they require to be all multiplied by 4, the square-root of 16, the number of ounces in a pound. Hence, in line 6, *for* $\sqrt{12}$ *r.* $\sqrt{\frac{3}{4}}$; l. 7 and 8, *for* $22\frac{4}{5}$ *r.* $91\frac{1}{5}$; l. 8, *for* $15\frac{1}{2}$ *r.* 62. And the whole succeeding table corrected will be as follows:

Table of the corresponding Height of Water, Force on a Square Foot, and Velocity of Wind,

Height of Water.	Force of Wind.	Velocity of Wind per Hour
Inches.	Pounds.	Miles.
0¼	1·3	18·0
0½	2·6	25·6
1	5·2	36·0
2	10·4	50·8
3	15·6	62·0
4	20·8	76·0
5	26·0	80·4
6	31·25	88·0
7	36·5	95·2
8	41·7	101·6
9	46·9	108·0
10	52·1	113·6
11	57·3	119·2
12	62·5	124·0

In one instance Dr. Lind found that the force of the wind was such as to be equal $34\frac{9}{10}$ pounds, on a square foot; and this by proportion, in the foregoing table, will be found to answer to a velocity of 93 miles per hour.

ARCH, p. 137, col. 1, l. 29, *for* such cases as they, *read* such cases they. Line 30, *after* hanches, *add*, See BRIDGE.

ARCHIMEDES, p. 139, col. 1, l. 52 and 53, *for* preface, a commentary, *read* preface. We find here also Eutocius's commentary. Pa. 59, *after* college, *add*, who had the sole care of this edition.

ASSURANCE *on Lives*. Pa. 150, col. 2, in the 3d paragraph, for want of sufficient information concerning the London and Royal Exchange Assurance Offices, that paragraph gives an imperfect and, in some respect, erroneous account of them: it refers to their state 30 years ago, but the Companies have since that, altered their method of proceeding. Instead of that paragraph therefore, take the following account of their present constitution; viz,

The London ASSURANCE, is a corporation established by a charter of king George the 1st, viz, in 1720; under power of which, Assurances are made from the risk of sea-voyages, and from the danger of fire to houses and goods; the prices of which are regulated by the apparent risk to be assured. They also make Assurances on lives; the prices of which are formed on an estimation of the probable duration of life at different ages, on the consideration of the apparent health of the persons to be assured, and of their avocations in life.

This corporation, and the Royal Exchange corporation, gave each the sum of 150,000 pounds to government, for an *exclusive right* of making Assurances as *corporate bodies*. They are known to possess a large and undeniable fund to answer losses. And the prudent management of these corporations has enabled them, of late years, to increase gradually their dividends to the proprietors of their stock. This *exclusive privilege* to make Assurances as corporate bodies, is of great advantage and convenience to the public; and as they act under a common seal, the assured may have a speedy and easy mode of recovering losses, and cannot be subject to any calls or deductions whatever. When their charters were granted to them, it was enacted, that if a proprietor of the stock of one corporation should at the same time, directly or indirectly, be a proprietor of stock in the other corporation, the respective stock so held is to be forfeited, one moiety to the king, the other to the informer. This was evidently settled, to prevent their interest from becoming a joint one; so that they should be made to act in competition to each other, for the greater benefit of the public.

The Royal Exchange ASSURANCE, is a corporation established by charter, as above, under the power of which, Assurances are made from the risk of sea voyages, and from the danger of fire to houses and goods; the prices of which are regulated by the greater or less risk supposed to be assured. They also make Assurances on lives, the prices of which are formed on estimation of the probable duration of life at different ages, and under different circumstances. The present rates of Assurances on lives are as in the table below. And though a duty on these Assurances should take place on the plan lately proposed to the House of Commons, there is no great probability that these prices will be increased.

This corporation has also, like the former, been empowered to grant life annuities by an act of parliament, which requires that the prices of the annuities should be expressed in tables, hung up in some conspicuous place in their offices, for public inspection; and no agreement for any price is valid, but such as shall be expressed in the tables last made and published by the corporation.

From the Office of the Corporation *of the* ROYAL EXCHANGE ASSURANCE, *on the* ROYAL EXCHANGE, London.

N. B. THE CORPORATION ALSO GRANT ANNUITIES ON LIVES.

AUTOMATON. To the end of this article, in pa. 176, col. 2, may be added the following curious particulars, extracted from a letter of an ingenious gentleman since that article was published, viz, Thomas Collinson, Esq. nephew of the late ingenious Peter Collinson, Esq. F. R. S. " Turning over the leaves of your late valuable publication (says my worthy correspondent), part I. of the Mathematical and Philosophical Dictionary, I observed under the article *Automaton*, the following :" ' But all these seem to be inferior to M. Kempell's chess-player, which may truly be considered as the greatest master-piece in mechanics that ever appeared in the world ;' (upon which Mr. Collinson observes) " So it certainly would have been, had its scientific movements depended merely on mechanism. Being slightly acquainted with M. Kempell when he exhibited his chess-playing figure in London, I called on him about five years since at his house at Vienna; another gentleman and myself being then on a tour on the continent. The baron (for I think he is such) shewed me some working models which he had lately made— among them, an improvement on Arkwright's cotton-mill, and also one which he thought an improvement on Boulton and Watt's last steam-engine. I asked him after a piece of speaking mechanism, which he had shewn me when in London. It spoke as before, and I gave the same word as I gave when I first saw it, *Exploitation*, which it distinctly pronounced with the French accent. But I particularly noticed, that not a word passed about the chess-player; and of course I did not ask to see it. – In the progress of the tour I came to Dresden, where becoming acquainted with Mr. Eden, our envoy there, by means of a letter given me by his brother lord Auckland, who was ambassador when I was at Madrid, he obligingly accompanied me in seeing several things worthy of attention. And he introduced my companion and myself to a gentleman of rank and talents, named Joseph Freidrick Freyhere, who seems completely to have discovered the *Vitality* and soul of the chess-playing figure. This gentleman courteously presented me with the treatise he had published, dated at Dresden, Sept. 30, 1789, explaining its principles, accompanied with curious plates neatly coloured. This treatise is in the German language; and I hope soon to get a translation of it. A well-taught boy, very thin and small of his age (sufficiently so that he could be concealed in a drawer almost immediately under the chess-board), agitated the whole. Even after this abatement of its being strictly an automaton, much ingenuity remains to the contriver.— This discovery at Dresden accounts for the silence about it at Vienna; for I understand, by Mr. Eden, that Mr. Freyhere had sent a copy to baron Kempell: though he seems unwilling to acknowledge that Mr. F. has completely analysed the whole.

" I know that long and uninteresting letters are formidable things to men who know the value of time and science: but as this happens to be upon the subject, forgive me for adding one very admirable piece of mechanism to those you have touched upon. When at Geneva, I called upon Droz, son of the original Droz of la Chaux de Fonds (where I also was). He shewed me an oval gold snuff box, about (if I recollect right) 4 inches and a half long, by 3 inches broad, and about an inch and a half thick. It was double, having an horizontal partition; so that it may be considered as one box placed on another, with a lid of course to each box—One contained snuff—In the other, as soon as the lid was opened, there rose up a very small bird, of green enamelled gold, sitting on a gold stand. Immediately this minute curiosity wagged its tail, shook its wings, opened its bill of white enamelled gold, and poured forth, minute as it was (being only three quarters of an inch from the beak to the extremity of the tail) such a clear melodious song, as would have filled a room of 20 or 30 feet square with its harmony.—Droz agreed to meet me at Florence; and we visited the Abbé Fontana together. He afterwards joined me at Rome, and exhibited his bird to the pope and the cardinals in the Vatican palace, to the admiration, I may say to the astonishment of all who saw and heard it."

Another extract from a second letter upon the same subject, by Mr. Collinson, is as follows: " Permit me to speak of another Automaton of Droz's, which several years since he exhibited in England; and which, from my personal acquaintance, I had a commodious opportunity of particularly examining. It was a figure of a man, I think the size of life. It held in its hand a metal style; a card of Dutch vellum being laid under it. A spring was touched, which released the internal clockwork from its stop, when the figure immediately began to draw. Mr. Droz happening once to be sent for in a great hurry to wait upon some considerable personage at the west end of the town, left me in possession of the keys, which opened the recesses of all his machinery. He opened the drawing-master himself; wound it up; explained its leading parts; and taught me how to make it obey my requirings, as it had obeyed his own. Mr. Droz then went away. After the first card was finished, the figure rested. I put a second; and so on, to five separate cards, all different subjects: but five or six was the extent of its delineating powers. The first card contained, I may truly say, elegant portraits and likenesses of the king and queen, facing each other: and it was curious to observe with what precision the figure lifted up his pencil, in the transition of it from one point of the draft to another, without making the least slur whatever: for instance, in passing from the forehead to the eye, nose, and chin; or from the waving curls of the hair to the ear, &c. I have the cards now by me, &c, &c."

Pa. 177, col. 1, l. 2, *for* August *read* September.

B.

PAGE 195, col. 1, at the end of the article on Barometrical Meaſurements of Altitudes, *add*, See a learned paper in vol. 1. of the Tranſactions of the R. Soc. of Edinburgh, "On the Cauſes which affect the Accuracy of Barometrical Meaſurements; by John Playfair, A. M. F. R. S. Edin. and Profeſſor of Mathematics in the Univerſity of Edinburgh." Alſo another by Dr. Damen, late Profeſſor of Mathematics and Philoſophy in the Univerſity of Leyden, intitled, "Diſſertatio Phyſica & Mathematica de Montium Altitudine Barometro Metienda: Accedit Refractionis Aſtronomicæ Theoria; in 8vo, at the Hague, 1783.

Pa. 205, col. 1, after the life of Dan. Bernoulli, *add* the following life of James.

BERNOULLI (James), another mathematical branch of the foregoing celebrated family. He was born at Baſil in October 1759; being the ſon of John Bernoulli, and grandſon of the firſt John Bernoulli, before mentioned, and the nephew of Daniel Bernoulli laſt noticed above. Our author's elder brother John, who ſtill lives at Berlin, is alſo well known in the republic of ſcience, particularly for his aſtronomical labours.

The gentleman to whom this article relates, was educated, as moſt of his relations had been, for the profeſſion of law: but his genius led him very early into the ſtudy of mathematics; and at 20 years of age he read public lectures on experimental philoſophy in the univerſity of Baſil, for his uncle Daniel Bernoulli, whom he hoped to have ſucceeded as profeſſor. Being diſappointed in this view, he reſolved to leave his native place, and to ſeek his fortnne elſewhere; hence he accepted the office of ſecretary to Count Breuner, the emperor's envoy to the republic of Venice; and in this city he remained till the year 1786, when, on the recommendation of his countryman, M. Fuſs, he was invited to Peterſburgh to ſucceed M. Lexell in the academy there, where he continued till his death, which happened the 3d of July 1789, at not quite 30 years of age, and when he had been married only two months, to the youngeſt daughter of John Albert Euler, the ſon of the ſo celebrated Leonard Euler.

Impoſſible or Imaginary BINOMIAL. After this article, in pa. 208, the middle of col. 1, *add* what here follows.

In the foregoing article are given ſeveral rules for the roots of Binomials. Dr. Maſkelyne, the Aſtronomer Royal, has alſo given a method of finding any power of an Impoſſible Binomial, by another like Binomial. This rule is given in his Introduction prefixed to Taylor's Tables of Logarithms, pa. 56; and is as follows.

The logarithms of a and b being given, it is required to find the power of the Impoſſible Binomial $a \pm \sqrt{-b^2}$ whoſe index is $\frac{m}{n}$, that is, to find $(a \pm \sqrt{-b^2})^{\frac{m}{n}}$ by another Impoſſible Binomial; and thence the value of $(a+\sqrt{-b^2})^{\frac{m}{n}} + (a-\sqrt{-b^2})^{\frac{m}{n}}$, which is always poſſible, whether a or b be the greater of the two.

Solution. Put $\frac{b}{a} = \text{tang. } z$. Then

$$(a \pm \sqrt{-b^2})^{\frac{m}{n}} = (a^2+b^2)^{\frac{m}{2n}} \times (\text{cos.} \tfrac{m}{n} z \pm \sqrt{-\text{sin.}^2 \tfrac{m}{n} z}).$$

Hence $(a+\sqrt{-b^2})^{\frac{m}{n}} + (a-\sqrt{-b^2})^{\frac{m}{n}} = (a^2+b^2)^{\frac{m}{2n}} \times$ $2 \text{ cos.} \frac{m}{n} z = (a \times \text{sec. } z)^{\frac{m}{n}} \times 2 \text{ cosin.} \frac{m}{n} z = (b \times \text{cosec } z.)^{\frac{m}{n}}$ $\times 2 \text{ cosin.} \frac{m}{n} z$, where the firſt or ſecond of theſe two laſt expreſſions is to be uſed, according as z is an extreme or mean arc; or rather, becauſe $\frac{b}{a}$ is not only the tangent of z, but alſo of $z + 360°$, $z + 720°$, &c; therefore the factor in the anſwer will have ſeveral values, viz,

$2 \text{ cos.} \frac{m}{n} z$; $2 \text{ cos.} \frac{m}{n} (z + 360°)$; $2 \text{ cos.} \frac{m}{n} (z + 720°)$; &c; the number of which, if m and n be whole numbers, and the fraction $\frac{m}{n}$ be in its leaſt terms, will be equal to the denominator n; otherwiſe infinite.

By Logarithms. Put log. $b + 10 - $ log. $a = $ log. tan. z.

Then $\log \left((a+\sqrt{-b^2})^{\frac{m}{n}} + (a-\sqrt{-b^2})^{\frac{m}{n}} \right) =$

$$= \frac{m}{n} \times (\text{l.} a + 10 - \text{l. cos. } z) + \text{l. } 2 + \text{l. cos.} \frac{m}{n} z - 10$$

$$= \frac{m}{n} \times (\text{l.} b + 10 - \text{l. sin. } z) + \text{l. } 2 + \text{l. cos.} \frac{m}{n} z - 10;$$

where the firſt or ſecond expreſſion is to be uſed, according as z is an extreme or mean arc. Moreover by taking ſucceſſively, l. cos. $\frac{m}{n} z$; l. cos. $\frac{m}{n} (z + 360°)$; l. cos. $\frac{m}{n} (z + 720°)$; &c, there will ariſe ſeveral diſtinct anſwers to the queſtion, agreeably to the remark above.

BINOMIAL *Theorem.* Francis Maſeres, Eſq. (Curſitor Baron of the Exchequer) has communicated the

the following observations on the Binomial theorem, and its demonstration; viz, About the year 1666 the celebrated Sir Isaac Newton discovered that, if m were put for any whole number whatsoever, the coefficients of the terms of the mth power of $1 + x$ would be

$$1, \frac{m}{1}, \frac{m}{1}\cdot\frac{m-1}{2}, \frac{m}{1}\cdot\frac{m-1}{2}\cdot\frac{m-2}{3}, \&c,$$

till we come to the term $\frac{m-(m-1)}{m}$, which will be the last term. But how he discovered this proposition, he has not told us, nor has he even attempted to give a demonstration of it. Dr. John Wallis, of Oxford, informs us (in his Algebra, chap. 85, pa. 319) that he had endeavoured to find this manner of generating these coefficients one from another, but without success; and he was greatly delighted with the discovery, when he found that Mr. Newton had made it. But he likewise has omitted to give a demonstration of it, as well as Sir Isaac Newton; and probably he did not know how to demonstrate it.

Sir Isaac Newton, after he had discovered this rule for generating the coefficients of the powers of $1 + x$ when the indexes of those powers were whole numbers, conjectured that it might possibly be true likewise when they were fractions. He therefore resolved to try whether it was or not, by applying it to such indexes in a few easy instances, and particularly to the indexes $\frac{1}{2}$ and $\frac{1}{3}$, which, if the rule held good in the case of fractional indexes, would enable him to find serieses equal to the values of $\overline{1+x}|^{\frac{1}{2}}$ and $\overline{1+x}|^{\frac{1}{3}}$, or the square-root and the cube-root of the Binomial quantity $1 + x$. And, when he had in this manner obtained a series for $\overline{1+x}|^{\frac{1}{2}}$, which he suspected to be equal to $\overline{1+x}|^{\frac{1}{2}}$, or the square root of $1 + x$, he multiplied the said series into itself, and found that the product was $1 + x$; and when he had obtained a series for $\overline{1+x}|^{\frac{1}{3}}$ he multiplied the said series twice into itself, and found that the product was $1 + x$; and thence he concluded that the former series was really equal to the square-root of $1 + x$, and that the latter series was really equal to its cube-root. And from these and a few more such trials, in which he found the rule to answer, he concluded universally that the rule was always true, whether the index m stood for a whole number or a fraction of any kind, as $\frac{1}{2}$, $\frac{1}{3}$, $\frac{2}{3}$, $\frac{3}{2}$, $\frac{3}{5}$, $\frac{5}{3}$, or, in general $\frac{p}{q}$.

After the discovery of this rule by Sir Isaac Newton, and the publication of it by Dr. Wallis, in his Algebra, chap. 85, in the year 1685; (which I believe was the first time it was published to the world at large, though it was inserted in Sir Isaac Newton's first letter to Mr. Oldenburgh, the secretary to the Royal Society, dated June 13, 1676, and the said letter was shewn to Mr. Leibnitz, and probably to some other of the learned mathematicians of that time) it remained for some years without a demonstration, either in the case of integral powers or of roots. At last however it was demonstrated in the case of integral powers by means of the properties of the figurate numbers, by that learned, sagacious, and accurate mathematician Mr. James Bernoulli, in the 3d chapter of the 2d part of his excellent treatise *De Arte Conjectandi*, or, *On the Art of forming reasonable Conjectures concerning Events that depend on Chance*; which appears to me to be by much the best written treatise on the doctrine of Chances that has yet been published, though Mr. Demoivre's book on the same subject may have carried the doctrine something further. This treatise of Mr. James Bernoulli's was not published till the year 1713, which was some years after his death, which happened in August 1705; but there is reason to think that it was composed in the latter years of the preceding century, about the years 1696, 1697, 1698, 1699, and 1700, and even that some parts of it, or some of the propositions inserted in it, had been found out by the author in the years 1689, 1690, 1691, and 1692. For the first part of his very curious tract, intitled, *Positiones Arithmeticæ de Seriebus Infinitis* was published at Basil or Basle in Switzerland (which was his native place, and in which he was at that time professor of mathematics) in the year 1689; and the second part of the said *Positiones* (in the 19th Position of which those properties of the figurate numbers from which the Binomial theorem may be deduced, are set down) was published at the same place in the year 1692. But the demonstrations of those properties of the figurate numbers, and of the Binomial theorem, which depends upon them, were never as I believe communicated to the public till the year 1713, when the author's posthumous treatise *De Arte Conjectandi* made its appearance. These demonstrations are founded on clear and simple principles, and afford as much satisfaction as can well be expected on the subject. But the full display and explanation of these principles, and the deduction of the said properties of the figurate numbers, and ultimately of the Binomial theorem, from them, is a matter of considerable length. It will not therefore be amiss to give a shorter proof of the truth of this important theorem, that shall not require a previous knowledge of the properties of the figurate numbers, but yet shall be equally conclusive with that which is derived from those properties. Now this may be done in the manner following.

Let us suppose that the coefficients of the terms of the first six powers of the Binomial quantity $1 + x$ have been found, upon trial, to be such as would be produced by the general expressions

$$1, \frac{m}{1}, \frac{m}{1}\cdot\frac{m-1}{2}, \frac{m}{1}\cdot\frac{m-1}{2}\cdot\frac{m-2}{3}, \&c,$$

by substituting in them first 1, then 2, then 3, then 4, then 5, and lastly 6, instead of m. This may easily be tried by raising the said first six powers of $1 + x$ by repeated multiplications by $1 + x$ in the common way, and afterwards finding the terms of the same powers by means of the said general expressions above; which will be found to produce the very same terms as arose from the multiplications. After these trials we shall be sure that those general expressions are the true values of the coefficients of the powers of $1 + x$ at least in the said first six powers. And it will therefore only remain

remain to be proved that, since the rule is true in the said first six powers, it will also be true in the next following, or the 7th power, and consequently in the 8th, 9th and 10th powers, and in all higher powers whatsoever.

Now, if the coefficients of the 1st, 2d, 3d, 4th, and other following terms of $\overline{1+x}|^m$ be denoted by the letters a, b, c, d, &c, respectively, it is evident from the nature of multiplication, that the coefficients of the 1st, 2d, 3d, 4th, and other following terms of the next higher power of $1+x$, to wit, $\overline{1+x}|^{m+1}$ will be equal to a, $a+b$, $b+c$, $c+d$, &c, respectively, or to the sums of every two contiguous coefficients of the terms of the preceding series which is $=\overline{1+x}|^m$. This will appear from the operation of multiplication, which is as follows.

$$\begin{array}{l} a + bx + cx^2 + dx^3 + ex^4 + \&c \\ 1 + x \\ \hline a + bx + cx^2 + dx^3 + ex^4 + \&c \\ \quad + ax + bx^2 + cx^3 + dx^4 + \&c. \\ \hline \end{array}$$

Therefore, if $\overline{1+x}|^m$ is equal to the series

$$a + bx + cx^2 + dx^3 + ex^4 + \&c,$$

then $\overline{1+x}|^{m+1}$ will be equal to the series

$$a + \overline{a+b}.x + \overline{b+c}.x^2 + \overline{c+d}.x^3 + \&c.$$

Now let n be $= m+1$. We shall then have to prove that, if the coefficients a, b, c, d, &c, be respectively equal to

$$1,\ \frac{m}{1},\ \frac{m}{1}.\frac{m-1}{2},\ \frac{m}{1}.\frac{m-1}{2}.\frac{m-2}{3},\ \&c,$$

the coefficients a, $a+b$, $b+c$, &c, will be respectively equal to

$$1,\ \frac{n}{1},\ \frac{n}{1}.\frac{n-1}{2},\ \frac{n}{1}.\frac{n-1}{2}.\frac{n-2}{3},\ \&c.$$

In order to prove this, there is nothing more to do than to collect together every two terms of the former of these two series, and then substitute into these sums, n instead of $m+1$, when there will immediately come out the terms of the latter series as above, viz,

$$\overline{1+x}|^n = 1 + \frac{n}{1}x + \frac{n}{1}.\frac{n-1}{2}x^2 + \&c. \quad \text{Q. E. D.}$$

Binomial *Theorem, Improvement of.* Mr. Bonnycastle, of the Royal Mil. Acad. has lately discovered the following ingenious improvement of this theorem, which is now published for the first time.

This celebrated theorem has been given under various forms, since the time of its first invention; but the following property of it is conceived to be new, and capable of an application of which the original series is not susceptible.

The Newtonian theorem, in one of its most commodious forms, is

$$\overline{1+p}|^n = 1 + np + \frac{n.n-1}{2}p^2 + \frac{n.n-1.n-2}{2.3}p^3 + \frac{n.n-1.n-2.n-3}{2.3.4}p^4$$

&c; and the new theorem here alluded to, is

$$\overline{1+p}|^n = 1 + sn + \frac{1}{2}s^2n^2 + \frac{1}{2.3}s^3n^3 + \frac{1}{2.3.4}s^4n^4\ \&c;$$

where $s = p - \frac{1}{2}p^2 + \frac{1}{3}p^3 - \frac{1}{4}p^4 + \frac{1}{5}p^5$ &c.

Of which the investigation is as follows:

$$\overline{1+p}|^n = 1 + np + \frac{n.n-1}{2}p^2 + \frac{n.n-1.n-2}{2.3}p^3 + \frac{n.n-1.n-2.n-3}{2.3.4}p^4\ \&c$$

$$= 1 + np + (n^2-1)\frac{p^2}{2} + (n^3-3n^2+2n)\frac{p^3}{2.3} + (n^4-6n^3+11n^2-6n)\frac{p^4}{2.3.4}$$

$$+ (n^5-10n^4+35n^3-50n^2+24n)\frac{p^5}{2.3.4.5}$$

$$+ (n^6-15n^5+85n^4-225n^3+274n^2-120n)\frac{p^6}{2.3.4.5.6}\ \&c.$$

Then by connecting the several powers of p with all the like powers of n, the latter series will become

$$1 + (p - \frac{p^2}{2} + \frac{2p^3}{2.3} - \frac{6p^4}{2.3.4} + \frac{24p^5}{2.3.4.5} - \frac{120p^6}{2.3.4.5.6}\ \&c)n$$

$$+ (\frac{p^2}{2} - \frac{3p^3}{2.3} + \frac{11p^4}{2.3.4} - \frac{50p^5}{2.3.4.5} + \frac{274p^6}{2.3.4.5.6}\ \&c)n^2$$

$$+ (\frac{p^3}{2.3} - \frac{6p^4}{2.3.4} + \frac{35p^5}{2.3.4.5} - \frac{225p^6}{2.3.4.5.6}\ \&c)n^3$$

$$+ (\frac{p^4}{2.3.4} - \frac{10p^5}{2.3.4.5} + \frac{85p^6}{2.3.4.5.6}\ \&c)n^4$$

$$+ (\frac{p^5}{2.3.4.5} - \frac{15p^6}{2.3.4.5.6}\ \&c)n^5$$

$$+ (\frac{p^6}{2.3.4.5.6}\ \&c)n^6$$

&c;

which by abbreviation, &c, becomes

$$1 + (p - \frac{p^2}{2} + \frac{p^3}{3} - \frac{p^4}{4} + \frac{p^5}{5} - \frac{p^6}{6}\ \&c)n$$

$$+ \tfrac{1}{2}(p^2 - \frac{3p^3}{3} + \frac{11p^4}{3.4} - \frac{50p^5}{3.4.5} + \frac{274p^6}{3.4.5.6}\ \&c)n^2$$

$$+ \frac{1}{2.3}(p^3 - \frac{6p^4}{4} + \frac{35p^5}{4.5} - \frac{225p^6}{4.5.6}\ \&c)n^3$$

$$+ \frac{1}{2.3.4}(p^4 - \frac{10p^5}{5} + \frac{85p^6}{5.6}\ \&c)n^4$$

$$+ \frac{1}{2.3.4.5}(p^5 - \frac{15p^6}{6}\ \&c)n^5$$

$$+ \frac{1}{2.3.4.5.6}(p^6\ \&c)n^6$$

&c.

In which last series, the literal parts of the coefficients of the 3d, 4th, 5th, &c terms, are the square, cube, biquadrate, &c, of the coefficient of the 2d term, as will appear either from the actual involution of $p - \frac{p^2}{2} + \frac{p^3}{3} - \frac{p^4}{4}$ &c, or by comparing its several powers with the multinomial theorem of Demoivre.

From hence it follows that, $\overline{1+p}|^n$

$$\overline{1+p}|^n = 1 + (p - \frac{p^2}{2} + \frac{p^3}{3} \&c)n + \frac{1}{2}(p - \frac{p^2}{2} + \frac{p^3}{3} \&c)n^2$$
$$+ \frac{1}{2.3}(p - \frac{p^2}{2} + \frac{p^3}{3} \&c)n^3 + \frac{1}{2.3.4}(p - \frac{p^2}{2} + \frac{p^3}{3} \&c)n^4 \quad \&c.$$

And if $p - \frac{p^2}{2} + \frac{p^3}{3} - \frac{p^4}{4}$ &c be put $= s$, we ſhall have

$$\overline{1+p}|^n = 1 + sn + \frac{1}{2}s^2n^2 + \frac{1}{2.3}s^3n^3 + \frac{1}{2.3.4}s^4n^4 \ \&c,$$

as was to be ſhewn.

By a ſimilar mode of deduction, it may alſo be proved that

$$\overline{1-p}|^n = 1 - sn + \tfrac{1}{2}s^2n^2 - \frac{1}{2.3}s^3n^3 + \frac{1}{2.3.4}s^4n^4 \&c;$$

where in this caſe $s = p + \frac{p^2}{2} + \frac{p^3}{3} + \frac{p^4}{4}$ &c.

In each of which formulæ, the index n, may be conſidered either as a whole number, a fraction, a ſurd, a given or an unknown quantity, as the circumſtance may require.

For the application of theſe theorems, ſee LOGARITHMS, and EXPONENTIAL *Equations*, following.

C.

CANAL, in general, denotes a long, round, hollow inſtrument, through which a fluid matter may be conveyed. In which ſenſe, it amounts to the ſame as what is otherwiſe called a pipe, tube, channel, &c. Thus the Canal of an aqueduct, is the part through which the water paſſes; which, in the ancient works of this kind, is lined with a coat of maſtic of a peculiar compoſition.

CANAL more particularly denotes a kind of artificial river, often furniſhed with locks and ſluices, and ſuſtained by banks or mounds. They are contrived for divers purpoſes; ſome for forming a communication between one place and another; as the Canals between Bruges and Ghent, or between Bruſſels and Antwerp: Others for the decoration of a garden, or houſe of pleaſure; as the Canals of Verſailles, Fontainbleau, St. James's Park, &c: And others are made for draining wet and marſhy lands; which laſt however are more properly called water-gangs, drains, ditches, &c.

It is needleſs to enumerate the many advantages ariſing from Canals and artificial navigations. Their utility is now ſo apparent, that moſt nations in Europe give the higheſt encouragement to undertakings of this kind wherever they are practicable. Nor did their advantages eſcape the obſervation of the Ancients. From the earlieſt accounts of ſociety we read of attempts to cut through large iſthmuſes, to make communications by water, either between one ſea and another, or between different nations, or diſtant parts of the ſame nation, where land-carriage was long and expenſive.

Egypt is full of Canals, dug to receive and diſtribute the waters of the Nile, at the time of its inundation. They are dry the reſt of the year, except the Canal of Joſeph, and four or five others, which may be ranked as conſiderable rivers. There were alſo ſubterraneous Canals, or tunnels, dug by an ancient king of Egypt, by which thoſe lakes, formed by the inundations of the Nile, were conveyed into the Mediterranean ſea.

Herodotus relates, that the Cnidians, a people of Coria, in Aſia Minor, deſigned to cut through the iſthmus which joins that peninſula to the continent; but were ſuperſtitious enough to give up the undertaking, becauſe it was interdicted by an oracle.

Several kings of Egypt attempted to join the Red-Sea to the Mediterranean; a project which Cleopatra was very fond of. This Canal was begun, according to Herodotus, by Necus ſon of Pſammeticus, who deſiſted from the attempt on an anſwer from the oracle, after having loſt 120 thouſand men in the enterpriſe. It was reſumed and completed by Darius ſon of Hyſtaſpes, or, according to Diodorus and Strabo, by Ptolomy Philadelphus; who relate that Darius relinquiſhed the work on a repreſentation made to him by unſkilful engineers, that the Red-Sea, being higher than the land of Egypt, would overflow and drown the whole country. It was wide enough for two galleys to paſs abreaſt, and its length was four days ſailing. Diodorus adds, that it was alſo called Ptolomy's river; that this prince built a city at its mouth on the Red-Sea, which he called Arſinoë, from the name of his favourite ſiſter; and that the Canal might be either opened or ſhut, as occaſion required. Diod. Sic. lib. 1; Strabo, Geog. lib. 17; Herod. lib. 2. Soliman the 2d, emperor of the Turks, employed 50 thouſand men in this great work; which was completed under the caliphate of Omar, about the year 635; but was afterward allowed to fall into neglect and diſrepair; ſo that it is now difficult to diſcover any traces of it. Hiſt. Acad. Scienc. ann. 1703, pa. 110.

Both the Greeks and Romans intended to make a Canal acroſs the Iſthmus of Corinth, which joins the Morea and Achaia, for a navigable paſſage by the Ionian ſea into the Archipelago. Demetrius, Julius Cæſar, Caligula, and Nero, made ſeveral unſucceſsful efforts to open this paſſage. But as the Ancients were entirely ignorant of the uſe of water-locks, their whole attention

attention was employed in making level cuts, which is probably the chief reason why they so often failed in their attempts. Charlemagne formed a design of joining the Rhine and the Danube, to make a communication between the Ocean and the Black-Sea, by a Canal from the river Almutz which discharges itself into the Danube, to the Reditz, which falls into the Maine, which last falls into the Rhine near Mayence or Mentz: for this purpose he employed a prodigious number of workmen; but he met with so many obstacles from different quarters, that he was obliged to give up the attempt.

A new Canal for conveying the waters of the Nile from Ethiopia into the Red-Sea without passing into Egypt, was projected by Albuquerque, viceroy of India for the Portuguese, to render Egypt barren and unprofitable to the Turks.—M. Gaildereau attributes the frequency of the plague in Egypt, of late days, to the decay, or stopping up of these Canals; which happened upon the Turks becoming masters of the country.

In China, there is scarce a town or village without the advantage either of an arm of the sea, a navigable river, or a Canal, by which means navigation is rendered so common, that there are almost as many people on the water as the land. The great Canal of China, is one of the wonders of art, extending from north to south quite across the empire, from Pekin to Canton, a distance of 825 miles, and was made upwards of 800 years ago. Its breadth and depth are sufficient to carry barks of considerable burden, which are managed by sails and masts, as well as towed by hand. On this Canal it seems the emperor employs near ten thousand ships. It passes through, or by, 41 large cities; there are in it 75 vast locks and sluices, to keep up the water, and pass the ships where the ground will not admit of sufficient depth of channel, beside several thousand draw and other bridges. Indeed, F. Magaillane assures us, there are passages from one end of China to the other, the space of 600 French leagues, either by Canals or rivers, except a single day's journey by land, necessary to cross a mountain.

The French at present have many fine Canals. That of Briere, otherwise called the Canal of Burgundy, was begun under Henry IV, and finished under the direction of cardinal Richelieu in the reign of Louis XIII. This Canal makes a communication between the Loire and the Seine, and so to Paris. It extends 11 French great leagues from Briere to Montargis, and has 42 locks upon it.

The Canal of Orleans was begun in 1675, for establishing a communication also between the Seine and the Loire. It is considerably shorter than that of Briere, and has only 20 sluices.

The Canal of Bourbon was but lately undertaken: its design is to make a communication from the river Oise to Paris.

But the greatest and most useful work of this kind, is the junction of the Ocean with the Mediterranean by the Canal of Languedoc, called also the Canal of the two seas. It was proposed in the reigns of Francis I and Henry IV, and was begun and finished under Louis XIV; having been planned by Francis Riquet in the year 1666, and finished before his death, which happened in 1680. It begins with a large reservoir 4000 paces in circumference, and 24 feet deep, which receives many springs from the mountain Noire. The Canal is about 200 miles in length, extending from Narbonne to Tholouse, being supplied by a number of rivulets in the way, and furnished with 104 locks or sluices, of about 8 feet rise each. In some places it is carried over bridges and aqueducts of vast height, which give passage underneath to other rivers; and in some places it is cut through solid rocks for a mile together.

The new Canal of the lake Ladoga, cut from Volhowa to the Neva, by which a communication is made between the Baltic, or rather Ocean, and the Caspian sea, was begun by the czar Peter the 1st in 1719: by means of which the English and Dutch merchandize is easily conveyed into Persia, without being obliged to double the Cape of Good Hope.—There was a former Canal of communication between the Ladoga lake and the river Wolga, by which timber and other goods had been brought from Persia to Petersburg; but the navigation of it was so dangerous, that a new one was undertaken.

The Spaniards have several times had in view the digging a Canal through the Isthmus of Darien, between North and South America, from Panama to Nombre de Dios, to make a ready communication between the Atlantic and the South Sea, and thus afford a straight passage to China and the East Indies.

In the Dutch, Austrian, and French Netherlands, there is a great number of Canals: that from Bruges to Ostend carries vessels of 200 tons. But it would be an endless task to describe the numberless Canals in Holland, Germany, Russia, &c. We may therefore only take a view of those in our own country.

In England, that ancient Canal from the river Nyne, a little below Peterborough, to the river Witham, three miles below Lincoln; called by the modern inhabitants Caerdike; may be ranked among the monuments of the Roman grandeur, though it is now most of it filled up. Morton will have it made under the emperor Domitian. Urns and medals have been discovered on the banks of this Canal, which seem to confirm that opinion. Yet some authors take it to be a Danish work. It was 40 miles in length; and, so far as appears from the ruins, must have been very broad and deep. Notwithstanding that early beginning, it is not long since Canals have been revived in this country. They are now however become very numerous, particularly in the counties of York, Lincoln, and Cheshire. Most of the counties between the mouth of the Thames and the Bristol channel are connected together either by natural or artificial navigations; those upon the Thames and Isis reaching within about 20 miles of those upon the Severn.

The Canal for supplying London with water by means of the New River, was projected and begun by Mr. Edward Wright, author of the celebrated treatise on Navigation, about the year 1608; but finished by Mr. (afterwards Sir Hugh) Middleton, five years after. This Canal commences near Ware, in Hertfordshire, and takes a course of 60 miles before it reaches the cistern at Islington, which supplies the several water-pipes that convey it to the city and parts adjacent. In some

places it is 30 feet deep, and in others it is conveyed over a valley between two hills, by means of a trough ſupported on wooden arches, and riſing above 23 feet in height.

The Duke of Bridgwater's Canal, projected and executed under the direction of Mr. Brindley, was begun about the year 1759. It was firſt deſigned only for conveying coals to Mancheſter, from a mine in the duke's eſtate; but has ſince been applied to many other uſeful purpoſes of inland navigation. This Canal begins at a place called Worſley-mill, about 7 miles from Mancheſter, where a baſon is made capable of holding all the boats, and a great body of water which ſerves as a reſervoir or head to the navigation. The Canal runs through a hill by a ſubterraneous paſſage, large enough for admitting long flat-bottomed boats, which are towed by a rail on each hand, near three quarters of a mile, to the coal-works. There the paſſage divides into two channels, one of which goes off 300 yards to the right, and the other as many to the left; and both may be continued at pleaſure. The paſſage is in ſome places cut through the ſolid rock, and in others arched over with brick; and air funnels, ſome of which are near 37 yards perpendicular, are cut, at certain diſtances, through the rock to the top of the hill. The arch at its entrance is about 6 feet wide, and about 5 feet high from the ſurface of the water; but widens within, ſo that in ſome places the boats may paſs one another, and at the pits it is 10 feet wide. When the boats are loaded and brought out of the baſon, five or ſix of them are linked together, and drawn along the Canal by a ſingle horſe, and thus reaching Mancheſter in a courſe of nine miles. It is broad enough for two barges to paſs or go abreaſt; and on one ſide there is a good road for the paſſage of the people, and the horſes or mules employed in the work. The Canal is raiſed over public roads by means of arches; and it paſſes over the navigable river Irwell near 50 feet above it; ſo that large veſſels in full ſail paſs under the Canal, while the duke's barges are at the ſame time paſſing over them. This Canal joins that which paſſes from the river Merſey towards the Trent, taking in the whole a courſe of 34 miles.

The Lancaſter Canal begins near Kendal, and terminates near Eccleſton, comprehending the diſtance of 72½ miles.

The Canal from Liverpool to Leeds is 108¼ miles: that from Leeds to Selby, 23¼ miles; from Chicheſter to Middlewich, 26¾ miles; from the Trent to the Merſey, 88 miles; from the Trent to the Severn, 46½ miles. The Birmingham Canal joins this near Wolverhampton, and is 24¼ miles: the Droitwich Canal is 5½ miles; the Coventry Canal, commencing near Lichfield, and joining that of the Trent, is 36¼ miles: the Oxford Canal breaks off from this, and is 82 miles: the Cheſterfield Canal joins the Trent near Gainſborough, and is 44 miles.

A communication is now formed, by means of this inland navigation, between Kendal and London, by way of Oxford; between Liverpool and Hull, by the way of Leeds; and between the Briſtol channel and the Humber, by the junction formed between the Trent and the Severn. Other ſchemes have been projected, which the preſent ſpirit of improvement will probably ſoon carry into execution, of opening a communication between the German and Iriſh ſeas, ſo as to reduce a hazardous navigation of more than 800 miles by ſea, into a little more than 150 miles by land, or inland navigation; and alſo of joining the Iſis with the Severn.

In Scotland, a navigable Canal between the Forth and Clyde, which divides that country into two parts, was thought of more than a century ſince, for tranſports and ſmall ſhips of war. It was again projected in the year 1722, and a ſurvey made; but nothing more was done till 1761, when the then lord Napier, at his own expence, had a ſurvey, plan, and eſtimate made on a ſmall ſcale. In 1764, the truſtees for fiſheries, &c, in Scotland, procured another ſurvey, plan, and eſtimate of a Canal 5 feet deep, which was to coſt 79,000 pounds. In 1766, a ſubſcription was obtained by a number of the moſt reſpectable merchants in Glaſgow, for making a Canal 4 feet deep and 24 feet in breadth; but when the bill was nearly obtained in parliament, it was given up on account of the ſmallneſs of the ſcale, and a new ſubſcription ſet on foot for a Canal 7 feet deep, eſtimated at 150,000 pounds. This obtained the ſanction of parliament; and the work was begun in 1768, by Mr. Smeaton the engineer. The extreme length of the Canal from the Forth to the Clyde is 35 miles, beginning at the mouth of the Carron, and ending at Dalmure Burnfoot on the Clyde, 6 miles below Glaſgow, riſing and falling 160 feet by means of 39 locks, 20 on the eaſt ſide of the ſummit, and 19 on the weſt, as the tide does not ebb ſo low in the Clyde as in the Forth by 9 feet; and it was deepened to upwards of 8 feet. This Canal was finiſhed a few years ſince, after having experienced ſome interruptions and delays, for want of reſources, and is eſteemed the greateſt work of the kind in this iſland. Veſſels drawing 8 feet water, with 19 feet in the beam and 73 feet in length, paſs with eaſe; and the whole enterpriſe diſplays the art of man in a high degree. To ſupply the Canal with water was of itſelf a very great work. There is one reſervoir of 50 acres 24 feet deep, and another of 70 acres 22 feet deep, in which many rivers and ſprings terminate, which it is expected will afford ſufficient ſupply of water at all times.

The Practice of Canal Digging and Inland Navigations.

The particular operations neceſſary for making artificial navigations, depend upon a number of circumſtances. The ſituation of the ground; the vicinity or connection with rivers; the eaſe or difficulty with which a proper quantity of water can be obtained: theſe and many other circumſtances neceſſarily produce great variety in the ſtructure of artificial navigations, and augment or diminiſh the labour and expence of executing them. When the ground is naturally level, and unconnected with rivers, the execution is eaſy, and the navigation is not liable to be diſturbed by floods: but when the ground riſes and falls, and cannot be reduced to a level, artificial methods of raiſing and lowering veſſels muſt be employed; which likewiſe vary according to circumſtances.

Sometimes a kind of temporary ſluices are employed; to raiſe boats over falls or ſhoals in rivers, by a very ſimple operation. Two pillars of maſon-work, with grooves, are fixed, one on each bank of the river, at ſome

3

ſome diſtance below the ſhoal. The boat having paſſed theſe pillars, ſtrong planks are let down acroſs the river by pulleys into the grooves; by which means the water is dammed up to a proper height for allowing the boat to paſs up the river over the ſhoal.

The Dutch and Flemings at this day ſometimes, when obſtructed by caſcades, form an inclined plane or rolling-bridge upon dry land, along which their veſſels are drawn from the river below the caſcade, into the river above it. This it is ſaid was the only method employed by the Ancients, and ſtill ſometimes uſed by the Chineſe. Theſe rolling-bridges conſiſt of a number of cylindrical rollers which turn eaſily on pivots. And a mill is commonly built near; ſo that the ſame machinery may ſerve the double purpoſe of working the mill and drawing up veſſels.

But in the preſent improved ſtate of inland navigation, theſe falls and ſhoals are commonly ſurmounted by means of what are called locks or ſluices. A lock is a baſon placed lengthwiſe in a river or Canal, lined with walls of maſonry on each ſide, and terminated by two gates placed acroſs the Canal, where there is a caſcade or natural fall of the country; and ſo conſtructed, that the baſon being filled with water by an upper ſluice to the level of the waters above, a veſſel may aſcend through the upper gate; or the water in the lock being reduced to the level of the water at the bottom of the caſcade, the veſſel may deſcend through the lower gate: for when the waters are brought to a level on either ſide, the gate on that ſide may be eaſily opened.

But as the lower gate is ſtrained in proportion to the depth of water it ſupports, when the perpendicular height of the water exceeds 12 or 13 feet, it becomes neceſſary to have more locks than one. Thus, if the fall be 16 feet, two locks are required, each of 8 feet fall; and if the fall be 25 feet, three locks are neceſſary, each having 8 feet 4 inches fall.—It is evident that the ſide-walls of locks ſhould be made very ſtrong: and where the natural foundation is bad, they ſhould be founded on piles and platforms of wood. They ſhould likewiſe ſlope outwards, in order to reſiſt the preſſure of the earth from behind.

To illuſtrate this by repreſentations: Plate 37, fig. 1, is a perſpective view of part of a Canal, with ſeveral locks &c; the veſſel L being within the lock AC.—Fig. 2 is an elevation or upright ſection along the Canal; the veſſel L about to enter.—Fig. 3, a like ſection of a lock full of water; the veſſel L being raiſed to a level with the water in the ſuperior Canal.—And fig. 4 is the plan or ground ſection of a lock: where L is a veſſel in the inferior Canal; C, the under gate; A, the upper gate; GH, a ſubterraneous paſſage for letting water from the ſuperior Canal run into the lock; and KF, a ſubterraneous paſſage for water from the lock to the inferior Canal.

X and Y (fig. 1) are the two flood-gates, each of which conſiſts of two leaves, reſting upon one another, ſo as to form an obtuſe angle, the better to reſiſt the preſſure of the water. The firſt (X) prevents the water of the ſuperior Canal from falling into the lock; and the ſecond (Y) dams up and ſuſtains the water in the lock. Theſe flood-gates ought to be very ſtrong, and to turn freely upon their hinges. They ſhould alſo be made very tight and cloſe, that as little water as poſſible may be loſt. And, to make them open and ſhut with eaſe, each leaf is furniſhed with a long lever A*b*, A*b*; C*b*, C*b*.

By the ſubterraneous paſſage GH (fig. 2, 3, 4) which deſcends obliquely, by opening the ſluice G, the water is let down from the ſuperior Canal D into the lock, where it is ſtopped and retained by the gate C when ſhut, till the water in the lock comes to be on a level with the water in the ſuperior Canal D; as repreſented in fig. 3. When, on the other hand, the water contained by the lock is to be let out, the paſſage GH muſt be ſhut, by letting down the ſluice G; the gate A muſt alſo be ſhut, and the paſſage KF opened by raiſing the ſluice K. A free paſſage being thus given to the water, it deſcends through KF, into the inferior Canal, until the water in the lock be on a level with the water in the inferior Canal B; as repreſented in fig. 2.

Now ſuppoſe it be required to raiſe the veſſel L (fig. 2) from the inferior Canal B to the ſuperior one D. If the lock be full of water, the ſluice G muſt be ſhut, as alſo the gate A, and the ſluice K opened, ſo that the water in the lock may run out till it become to a level with the water in the inferior Canal B. When the water in the lock comes to be on a level with the water at B, the leaves of the gate C are opened by the levers C*b*, which is eaſily performed, the water on each ſide of the gate being in equilibrio; the veſſel then ſails into the lock. After this, the gate C and the ſluice K are ſhut, and the ſluice G opened, in order to fill the lock, till the water in the lock, and conſequently the veſſel, be upon a level with the water in the ſuperior Canal D; as is repreſented in fig. 3. The gate A is then opened, and the veſſel paſſes into the Canal D.

Again let it be required to make a veſſel deſcend from the Canal D into the inferior Canal B. If the lock be empty, as in fig. 2, the gate C and ſluice K muſt be ſhut, and the upper ſluice G opened, ſo that the water in the lock may riſe to a level with the water in the upper Canal D. Then, opening the gate A, the veſſel will paſs through into the lock. This done, ſhut the gate A and the ſluice G; then open the ſluice K, till the water in the lock be on a level with the water in the inferior Canal; this done, the gate C is opened, and the veſſel paſſes along into the Canal B, as was required.

CATENARY. Line 4, *for* ACB *read* BAC.—l. 6, *for* A and B *read* C and B. *After which add*, It is otherwiſe called the *Elaſtic Curve*.

CHALDRON. Line 4, *for* 2000 pounds, *read* 28 cwt. or 3136 pounds. *At the end add*, By act of parliament, a Newcaſtle Chaldron is to weigh $52\frac{1}{2}$ cwt, or 3 waggons of $17\frac{1}{2}$ cwt, or 6 carts of $8\frac{3}{4}$ cwt each, making $52\frac{1}{2}$ cwt to the Chaldron. The ſtatute London Chaldron is to conſiſt of 36 buſhels heaped up, each buſhel to contain a Wincheſter buſhel and one quart, and to be $19\frac{1}{2}$ inches diameter externally. Now it has been found by repeated trials, that 15 London Chaldrons are equal to 8 Newcaſtle Chaldrons, which, reckoning $52\frac{1}{2}$ cwt to the latter, gives 28 cwt to the former, or 3136 lbs to the London Chaldron.

This I find nearly confirmed by experiment. I weighed

weighed one peck of coals, which amounted to $21\frac{3}{4}$ lb. Then 4 times this gives 87 lb for the weight of the bushel; and 36 times the bushel gives 3132 lb for the Chaldron; to which if the weight of the odd quart be added, or 3 lb nearly, it gives 3135 lb for the weight of the Chaldron, which is only one pound less than by statute.

Pa. 287, col. 2, l. 20, *for* $YX - a - x$, *read* $YX = a - x$.

CIRCLE *of Curvature*. To what is said of this article in the Dictionary, may be added what follows.

A circular arc is the only curve line that is equally curved in every point. In all other curve lines, such as the arc of an ellipse, or a parabola, or an hyperbola, or a cycloid, the curvature is different in different points, and the degree of curvature in any point is estimated by the curvature of a Circle which is said to have the same curvature as the proposed curve line in that point; by which is understood the Circle which, having the tangent of the proposed curve in the said point for its tangent, approaches so nearly to the proposed curve that no other Circle whatever can be drawn between it and that curve.

This Circle is also said to *osculate* the curve in the said point, and is therefore often called the *osculating Circle*, as well as the *Circle of equal curvature* with the curve in the said point. And the radius of this Circle is called the *radius of curvature* of the proposed curve in the said point; also its centre is called the *centre of curvature*.

Now there are some curve lines so very highly curved in some particular points, that every Circle, of how small a radius soever, having the tangent to the curve in one of those points for its tangent, will pass without the curve, or between the curve and its tangent. This, for example, is the case with the curve of a cycloid in the two points contiguous to its base, as also with the cissoid at its vertex. And in such points the curvature of these curves is said to be *infinite*, because it is greater than the curvature of any Circle, how small soever. Also the radius of the Circle of curvature in such points is nothing; the length of that radius being always inversely or reciprocally as the degree of curvature at any point.

The theory of these Circles of equal curvature with curves in particular points was first cultivated by Apollonius in his Conic Sections: and it has since been carried much farther by several great mathematicians of modern times; particularly by Mr. Huygens in his doctrine of Evolute Curves and Curves of Evolution, and by the great Sir Isaac Newton. See CURVATURE.

CLARKE (Dr. SAMUEL), a celebrated English divine, philosopher, and metaphysician, was the son of Edward Clarke, Esq. alderman of Norwich, and for several years one of its representatives in parliament; and was born there the 11th of October 1675. He was instructed in classical learning at the free-school of that town; and in 1691 removed thence to Caius college in Cambridge; where his uncommon abilities soon began to display themselves. Though the philosophy of Des Cartes was at that time the established philosophy of the university, yet Clarke easily mastered the new system of Newton; and in order to his first degree of arts, performed a public exercise in the schools upon a question taken from it. He greatly contributed to the establishment of the Newtonian philosophy by an excellent translation of Rohault's Physics, with notes, which he finished before he was 22 years of age: a book which had been for some time the system used in the university, and founded upon Cartesian principles. This was first published in the year 1697, and it soon after went through several other editions, all with improvements.

Mr. Whiston relates that, in that year, 1697, while he was chaplain to Dr. Moore bishop of Norwich, he met with young Clarke, then wholly unknown to him, at a coffee-house in that city; where they entered into a conversation about the Cartesian philosophy, particularly Rohault's Physics, which Clarke's tutor, as he tells us, had put him upon translating. "The result of this conversation was, says Whiston, that I was greatly surprised that so young man as Clarke then was, should know so much of those sublime discoveries, which were then almost a secret to all, but to a few particular mathematicians. Nor did I remember (continues he) above one or two at the most, whom I had then met with, that seemed to know so much of that philosophy as Mr. Clarke."

He afterwards turned his thoughts to divinity; and having taken holy orders, in 1698 he succeeded Mr. Whiston as chaplain to Dr. Moore bishop of Norwich, who was ever after his constant friend and patron. In 1699 he published two treatises: the one on Baptism, Confirmation, and Repentance; the other, Reflections on that part of a book called Amyntor, or a Defence of Milton's Life, which relates to the Writings of the Primitive Fathers, and the Canon of the New Testament. In 1701 he published A Paraphrase upon the Gospel of St. Matthew; which was followed in 1702 by the Paraphrases upon the Gospels of St. Mark and St. Luke, and soon after by a third volume upon St. John.

Mean while bishop Moore gave him the rectory of Drayton near Norwich, with a lectureship in that city. In 1704 he was appointed to preach Boyle's lecture; and the subject he chose was, The Being and Attributes of God. He succeeded so well in this, and gave so much satisfaction, that he was appointed to preach the same lecture the next year, when he chose for his subject, The Evidences of Natural and Revealed Religion. These sermons were first printed in two volumes, in 1705 and 1706; and contained some remarks on such objections as had been made by Hobbes and Spinoza, and other opposers of natural and revealed religion. In the 6th edition was added, A Discourse concerning the Connection of the Prophecies of the Old Testament, and the application of them to Christ.

About this time, Mr. Whiston informs us, he discovered that Mr. Clarke (having read much of the primitive writers) began to suspect that the Athanasian doctrine of the Trinity was not the doctrine of those early ages; and it was particularly remarked of him, that he never read the Athanasian Creed at his parish church.

In 1706 he published A Letter to Mr. Dodwell; answering all the arguments in his epistolary discourse against the immortality of the soul. Bishop Hoadley observes,

observes, that in this letter he answered Mr. Dodwell in so excellent a manner, both with regard to the philosophical part, and to the opinions of some of the primitive writers, upon whom these doctrines were fixed, that it gave universal satisfaction. But this controversy did not stop here; for the celebrated Mr. Collins, coming in as a second to Dodwell, went much farther into the philosophy of the dispute, and indeed seemed to produce all that could be said against the immateriality of the soul, as well as the liberty of human actions. This enlarged the scene of the dispute; into which our author entered, and wrote with such a spirit of clearness and demonstration, as at once shewed him greatly superior to his adversaries in metaphysical and physical knowledge; making every intelligent reader rejoice that such an incident had happened to provoke and extort from him such excellent reasoning and perspicuity of expression.

In the midst of these labours, Mr. Clarke found time to shew his regard to mathematical and philosophical studies, with his exact knowledge and skill in them. And his natural affection and capacity for these studies were not a little improved by the friendship of Sir Isaac Newton; at whose request he translated his Optics into Latin in 1706. With this version Sir Isaac was so highly pleased, that he presented him with the sum of 500l. or 100l. to each of his five children.

The same year also, bishop Moore procured for him the rectory of St. Bennett's, Paul's Wharf, in London; and soon after carried him to court, and recommended him to the favour of queen Anne. She appointed him one of her chaplains in ordinary; and also presented him to the rectory of St. James's, Westminster, when it became vacant in 1709. Upon this occasion he took the degree of D. D. when the public exercise which he performed for it at Cambridge was highly admired.

The same year 1709, Dr. Clarke revised and corrected Whiston's translation of the Apostolical Constitutions into English, at his earnest request. In 1712 he published a most beautiful and pompous edition of Cæsar's Commentaries. And the same year, his celebrated book called, The Scripture Doctrine of the Trinity. Whiston informs us, that some time before the publication of this book, there was a message sent to the author by lord Godolphin, and others of queen Anne's ministers, importing, "That the affairs of the public were with difficulty then kept in the hands of those that were for liberty; that it was therefore an unseasonable time for the publication of a book that would make a great noise and disturbance; and that therefore they desired him to forbear till a fitter opportunity should offer itself:" which message, says he, the doctor paid no regard to, but went on according to the dictates of his own conscience with the publication of his book. The ministers however were very right in their conjectures; for the work made noise and disturbance enough, and occasioned a great many books and pamphlets, written by himself and others. Nor were these the whole that his work occasioned: it rendered the author obnoxious to the ecclesiastical power, and his book was complained of by the lower house of convention. The doctor drew up a preface, and afterwards gave in several explanations, which seemed to satisfy the upper house; at least the affair was not brought to any issue, the members appearing desirous to prevent dissensions and divisions.

In 1715 and 1716 he had a dispute with the celebrated Leibnitz, concerning the principles of natural philosophy and religion; and a collection of the papers which passed between them, was published in 1717. This work was addressed to queen Caroline, then princess of Wales, who was pleased to have the controversy pass through her hands. It related chiefly to the subjects of liberty and necessity.

About the year 1718 he was presented by the lord Lechmere, to the mastership of Wigston's hospital in Leicestershire. In 1724 and 1725 he published 18 sermons, preached on several occasions. In 1727, on the death of Sir Isaac Newton, he had the offer of succeeding him as Master of the Mint, a place worth from 12 to 15 hundred a year: but to this secular preferment he could not reconcile himself, and therefore absolutely refused it.—In 1728 was published, a Letter from Dr. Clarke to Mr. Benjamin Hoadley, occasioned by the Controversy relating to the Proportion of Velocity and Force of Bodies in Motion; and printed in the Philosophical Transactions, num. 401.—In the beginning of 1729 he published the first 12 books of Homer's Iliad: a work which bishop Hoadley calls an accurate performance; and his notes, a treasury of grammatical and critical knowledge. And the same year came out, his Exposition of the Church Catechism, and 10 volumes of Sermons: books so well known and so generally approved, that they need no recommendation. But the same year, on Sunday the 11th of May, going to preach before the Judges at Serjeant's Inn, he was seized with a pain in his side, which made it impossible for him to perform his office. He was carried home and continued under his disorder till the 17th of the same month, when he died, in the 54th year of his age, after long enjoying a vigorous state of health, having scarce ever known sickness.

Three years after the doctor's death, appeared the other 12 books of the Iliad, published in 4to by his son, Mr. Samuel Clarke, who says in the preface, that his father had finished the annotations to the first three of those books, and as far as the 359th verse of the 4th; and had revised the text and version as far as verse 510 of the same book.

Dr. Clarke married Catherine, the only daughter of the Rev. Mr. Lockwood, rector of Little Missingham in the county of Norfolk, by whom he had seven children, four of whom survived him.

Queen Caroline took great pleasure in the doctor's conversation and friendship, seldom missing a week in which she did not receive some proof of the greatness of his genius, and the force of his understanding.

As to the character of Dr. Clarke, he is represented as possessing one of the best dispositions in the world, remarkably humane and tender, free and easy in his conversation, cheerful and even playful in his manner. Bishop Hare says of him, "He was a man who had all the good qualities that could meet together to recommend him. He was possessed of all the parts of learning that are valuable in a clergyman, in a degree that few

few poſſeſs any ſingle one. He has joined to a good ſkill in the three learned languages, a great compaſs of the beſt philoſophy and mathematics, as appears by his Latin works; and his Engliſh ones are ſuch a proof of his own piety, and of his knowledge in divinity, and have done ſo much ſervice to religion, as would make any other man, that was not under a ſuſpicion of hereſy, ſecure of the friendſhip of all good churchmen, eſpecially the clergy. And to all this piety and learning was joined, a temper happy beyond expreſſion; a ſweet, eaſy, modeſt, obliging behaviour adorned all his actions; and neither paſſion, vanity, inſolence, or oſtentation appeared either in what he ſaid or wrote. This is the learning, this the temper of the man, whoſe ſtudy of the Scriptures has betrayed him into a ſuſpicion of ſome heretical opinions. Biſhop Hoadley too having remarked how great the doctor was in all branches of learning, adds, If in any one of theſe he had excelled only ſo much as he did in all, he would have been juſtly entitled to the character of a great man: but there is ſomething ſo very extraordinary, that the ſame perſon ſhould excel not only in thoſe parts of knowledge which require the ſtrongeſt judgment, but in thoſe which require the greateſt memory too. So that, in a very high degree, divinity and mathematics, experimental philoſophy and claſſical learning, metaphyſics and critical ſkill, were united in Dr. Clarke.—Much more may be ſeen, ſaid in his praiſe by biſhop Hoadley, Dr. Sykes, and Mr. Whiſton, in their Memoirs of his life.

CLEF, or Cliff, in Muſic, a mark at the beginning of the lines of a ſong, which ſhews the tone or key in which the piece is to begin. Or, it is a letter marked on any line, which explains and gives the name to all the reſt.

Anciently, every line had a letter marked for a Clef; but now a letter on one line ſuffices; ſince by this all the reſt are known; reckoning up and down, in the order of the letters.

It is called the Clef, or key, becauſe that by it are known the names of all the other lines and ſpaces; and conſequently the quantity of every degree, or interval. But becauſe every note in the octave is called a key, though in another ſenſe, this letter marked is called peculiarly the *ſigned Clef*; becauſe, being written on any line, it not only ſigns and marks that one, but it alſo explains all the reſt. By Clef, therefore, for diſtinction ſake, is meant that letter, ſigned on a line, which explains the reſt; and by key, the principal note of a ſong, in which the melody cloſes.

There are three of theſe ſigned Clefs, *c*, *f*, *g*. The Clef of the higheſt part in a ſong, called *treble*, or *alt*, is *g*, ſet on the ſecond line counting upwards. The Clef of the baſs, or the loweſt part, is *f* on the 4th line upwards. For all the other mean parts, the Clef is *c*, ſometimes on one, ſometimes on another line. Indeed, ſome that are really mean parts, are ſometimes ſet with the *g* clef. It muſt however be obſerved, that the ordinary ſignatures of Clefs bear little reſemblance to thoſe letters. Mr. Malcolm thinks it would be well if the letters themſelves were uſed. Kepler takes great pains to ſhew, that the common ſignatures are only corruptions of the letters they repreſent. The figures of theſe now are as follow:

 Character of the treble Clef.

 The mean Clef.

 The baſs Clef.

The Clefs are always taken fifths to one another. So the Clef *f* being loweſt, *c* is a fifth above it, and *g* a fifth above *c*.

When the place of the Clef is changed, which is not frequent in the mean Clef, it is with a deſign to make the ſyſtem comprehend as many notes of the ſong as poſſible, and ſo to have the fewer notes above or below it. So that, if there be many lines above the Clef, and few below it, this purpoſe is anſwered by placing the Clef in the firſt or ſecond line: but if there be many notes below the Clef, it is placed lower in the ſyſtem. In effect, according to the relation of the other notes to the Clef note, the particular ſyſtem is taken differently in the ſcale, the Clef line making one in all the variety.

But ſtill, in whatever line of the particular ſyſtem any Clef is found, it muſt be underſtood to belong to the ſame of the general ſyſtem, and to be the ſame individual note or ſound in the ſcale. By this conſtant relation of Clefs, we learn how to compare the ſeveral particular ſyſtems of the ſeveral parts, and to know how they communicate in the ſcale, that is, which lines are uniſon, and which not: for it is not to be ſuppoſed, that each part has certain bounds, within which another muſt never come. Some notes of the treble, for example, may be lower than ſome of the mean parts, or even of the baſs. Therefore to put together into one ſyſtem all the parts of a compoſition written ſeparately, the notes of each part muſt be placed at the ſame diſtances above and below the proper Clef, as they ſtand in the ſeparate ſyſtem: and becauſe all the notes that are conſonant, or heard together, muſt ſtand directly over each other, that the notes belonging to each part may be diſtinctly known, they may be made with ſuch differences as ſhall not confound, or alter their ſignifications with reſpect to time, but only ſhew that they belong to this or that part. Thus we ſhall ſee how the parts change and paſs through one another; and which, in every note, is higheſt, loweſt, or uniſon.

It muſt here be obſerved, that for the performance of any ſingle piece, the Clef only ſerves for explaining the intervals in the lines and ſpaces: ſo that it need not be regarded what part of any greater ſyſtem it is; but the firſt note may be taken as high or low as we pleaſe. For as the proper uſe of the ſcale is not to limit the abſolute degree of tone; ſo the proper uſe of the *ſigned* Clef is not to limit the pitch, at which the firſt note of any part is to be taken; but to determine the tune of the reſt, with reſpect to the firſt; and conſidering all the parts together, to determine the relation of their ſeveral notes by the relations of their Clefs in the ſcale: thus, their pitch of tune being determined in a certain note of one part, the other notes of that part are determined by the conſtant relations of the letters

letters of the fcale, and the notes of the other parts by the relations of their Clefs.

In effect, for performing any fingle part, the Clef note may be taken in an octave, that is, at any note of the fame-name; provided we do not go too high, or too low, for finding the reft of the notes of a fong. But in a concert of feveral parts, all the Clefs muft be taken, not only in the relations, but alfo in the places of the fyftem abovementioned; that every part may be comprehended in it.

The natural and artificial note expreffed by the fame letter, as *c* and *c*✱, are both fet on the fame line or fpace. When there is no character of flat or fharp, at the beginning with the Clef, all the notes are natural: and if in any particular place the artificial note be required, it is denoted by the fign of a flat or fharp, fet on the line a fpace before that note.

If a fharp or flat be fet at the beginning in any line or fpace with the Clef, all the notes on that line or fpace are artificial ones; that is, are to be taken a femitone higher or lower than they would be without fuch fign. And the fame affects all their octaves above and below, though they be not marked fo. In the courfe of the fong, if the natural note be fometimes required, it is fignified by the character ♮.

COMPASS. Pa. 314, col. 1, after l. 6 from the bottom, add, See alfo a new one in the Supplement to Cavallo's Treatife on Magnetifm.

CONDORCET (John-Anthony Nicholas *de* Caritat, *Marquis of*), member of the Inftitute of Bologna, of the Academies of Turin, Berlin, Stockholm, Upfal, Philadelphia, Peterfbourg, Padua, &c, and fecretary of the Paris Academy of Sciences, was born at Ribemont in Picardie, the 17th of September 1743. His early attachment to the fciences, and progrefs in them, foon rendered him a confpicuous character in the commonwealth of letters. He was received as a member of the Academy of Sciences at 25 years of age, namely, in March 1769, as Adjunct-Mecanician; afterwards, he became Affociate in 1710, Adjunct-Secretary in 1773, and fole Secretary foon after, which he enjoyed till his death, or till the diffolution of the Academy by the Convention.

Condorcet foon became an author, and that in the moft fublime branches of fcience. He publifhed his *Effais d'Analyfe* in feveral parts; the firft part in 1765 (at 22 years of age); the fecond, in 1767; and the third, in 1768. Thefe works are chiefly on the Integral Calculus, or the finding of Fluents, and make one volume in 4to.

He publifhed the Eloges of the Academicians or members of the Academy of Sciences, from the year 1666 till 1700, in feveral volumes. He wrote alfo fimilar Eloges of the Academicians who died during the time that he difcharged the important office of Secretary to the Academy; as well as the very ufeful hiftories of the different branches of fcience commonly prefixed to the volumes of Memoirs, till the volume for the year 1783, when it is to be lamented that fo ufeful a part of the plan of the Academy was difcontinued.

His other memoirs contained in the volumes of the Academy, are the following.

1. Tract on the Integral Calculus; 1765.
2. On the problem of Three Bodies; 1767.
3. Obfervations on the Integral Calculus; 1767.
4. On the Nature of Infinite Series; on the Extent of the Solutions which they give; and on a new method of Approximation for Differential Equations of all Orders; 1769.
5. On Equations for Finite Differences; 1770.
6. On Equations for Partial Differences; 1770.
7. On Differential Equations; 1770.
8. Additions to the foregoing Tracts; 1770.
9. On the Determination of Arbitrary Functions which enter the Integrals of Equations to Partial Differences; 1771.
10. Reflexions on the Methods of Approximation hitherto known for Differential Equations; 1771.
11. Theorem concerning Quadratures; 1771.
12. Inquiry concerning the Integral Calculus; 1772.
13. On the Calculation of Probabilities, part 1 and 2; 1781.
14. Continuation of the fame, part 3; 1782.
15. Ditto, part 4; 1783.
16. Ditto, part 5; 1784.

Condorcet had the character of being a very worthy honeft man, and a refpectable author, though perhaps not a firft-rate one, and produced an excellent fet of Eloges of the deceafed Academicians, during the time of his fecretaryfhip. A late French political writer has obferved of him, that he laboured to fucceed to the literary throne of d'Alembert, but that he cannot be ranked among illuftrious authors; that his works have neither animation nor depth, and that his ftyle is dull and dry; that fome bold attacks on religion and declamations againft defpotifm have chiefly given a degree of fame to his writings.

On the breaking out of the troubles in France, Condorcet took a decided part on the fide of the people, and fteadily maintained the caufe he had efpoufed amid all the fhocks and intrigues of contending parties; till, under the tyranny of Robefpierre, he was driven from the convention, being one of thofe members profcribed on the 31ft of May 1793, and he died about April 1794. The manner of his death is thus defcribed by the public prints of that time. He was obliged to conceal himfelf with the greateft care for the purpofe of avoiding the fate of Briffot and the other deputies who where executed. He did not, however, attempt to quit Paris, but concealed himfelf in the houfe of a female, who, though fhe knew him only by name, did not hefitate to rifk her own life for the purpofe of preferving that of Condorcet. In her houfe he remained till the month of April 1794, when it was rumoured that a domiciliary vifit was to be made, which obliged him to leave Paris. Although he had neither paffport nor civic card, he efcaped through the Barrier, and arrived at the Plain of Mont rouge, where he expected to find an afylum in the country-houfe of an intimate friend. Unfortunately this friend had fet out for Paris, where he was to remain for three days.—During all this period, Condorcet wandered about the fields and in the woods, not

not daring to enter an inn on account of not having a civic card. Half dead with hunger, fatigue, and fear, and scarcely able to walk on account of a wound in his foot, he passed the night under a tree.

At length his friend returned, and received him with great cordiality; but as it was deemed imprudent that he should enter the house in the day-time, he returned to the woods till night. In this short interval between morning and night his caution forsook him, and he resolved to go to an inn for the purpose of procuring food. He went to an inn at Clamars, and ordered an omlette. His torn clothes, his dirty cap, his meagre and pale countenance, and the greediness with which he devoured the omlette, fixed the attention of the persons in the inn, among whom was a member of the Revolutionary Committee of Clamars. This man conceiving him to be Condorcet, who had effected his escape from the Bicetre, asked him whence he came, whither he was going, and whether he had a passport? The confused manner in which he replied to these questions, induced the member to order him to be conveyed before the Committee, who, after an examination, sent him to the district of Boury la Reine. He was there interrogated again, and the unsatisfactory answers which he gave, determined the directors of the district to send him to prison on the succeeding day.—During the night he was confined in a kind of dungeon. On the next morning, when his keeper entered with some bread and water for him, he found him stretched on the ground without any signs of life.

On inspecting the body, the immediate cause of his death could not be discovered, but it was conjectured that he had poisoned himself. Condorcet indeed always carried a dose of poison in his pocket, and he said to the friend who was to have received him into his house, that he had been often tempted to make use of it, but that the idea of a wife and daughter, whom he loved tenderly, restrained him. During the time that he was concealed at Paris, he wrote a history of the Progress of the Human Mind, in two volumes.

CUBICS. The method of resolving all the cases of Cubic equations by the tables of sines, tangents and secants, are thus given by Dr. Maskelyne, p. 57, Taylor's Logarithms.

"The following method is adapted to a Cubic equation, wanting the second term; therefore, if the equation has the second term, it must be first taken away in the usual manner. There are four forms of Cubic equations wanting the second term, whose roots, according to known rules equivalent to Cardan's, are as follow:

1st. $x^3+px-q=0 \;\cdots\cdots\; x=\sqrt[3]{\frac{q}{2}+\sqrt{\frac{q^2}{4}+\frac{p^3}{27}}}-\sqrt[3]{-\frac{q}{2}+\sqrt{\frac{q^2}{4}+\frac{p^3}{27}}}$

2d. $x^3+px+p=0 \;\cdots\cdots\; x=\sqrt[3]{-\frac{q}{2}+\sqrt{\frac{q^2}{4}+\frac{p^3}{27}}}-\sqrt[3]{\frac{q}{2}+\sqrt{\frac{q^2}{4}+\frac{p^3}{27}}}$

3d. $x^3-px-q=0 \;\cdots\cdots\; x=\sqrt[3]{\frac{q}{2}+\sqrt{\frac{q^2}{4}-\frac{p^3}{27}}}+\sqrt[3]{\frac{q}{2}-\sqrt{\frac{q^2}{4}-\frac{p^3}{27}}}$

4th. $x^3-px+q=0 \;\cdots\cdots\; x=-\sqrt[3]{\frac{q}{2}-\sqrt{\frac{q^2}{4}-\frac{p^3}{27}}}-\sqrt[3]{\frac{q}{2}+\sqrt{\frac{q^2}{4}-\frac{p^3}{27}}}$

The roots of the first and second forms are negatives of each other; and those of the third and fourth are also negatives of each other. The first and second forms have only one root each. The third and fourth forms have also only one root each, when the quadratic surd $\sqrt{\frac{q^2}{4}-\frac{p^3}{27}}$ is possible; but have three roots each when that surd is impossible.

The roots of all the four forms may, in all cases, be easily computed as follows:

Forms 1st and 2d. Put $\frac{q}{2}\times\left.\frac{3}{p}\right|^{\frac{3}{2}}=$ tang. z; and $\sqrt[3]{\text{tan. } 45^\circ-\frac{1}{2}z}=$ tan. u. Then $x=\pm\sqrt{\frac{4p}{3}}\times$ cot. $2u$; where the upper sign belongs to the first form, and the lower sign to the second form.

Forms 3d and 4th. But $\frac{2}{q}\times\left.\frac{p}{3}\right|^{\frac{3}{2}}$ if less than unity, else its reciprocal $\frac{q}{2}\times\left.\frac{3}{4}\right|^{\frac{3}{2}}=$ cos. z. Then,

Case 1st. $\frac{2}{q}\times\left.\frac{p}{3}\right|^{\frac{3}{2}}<$ unity. Put $\sqrt[3]{\text{tan. } 45^\circ-\frac{1}{2}z}=$ tan. u. Then $x=\pm\sqrt{\frac{4p}{3}}\times$ cosec. $2u$; where the upper sign belongs to the third form, and the lower sign to the fourth form.

Case 2d. $\frac{2}{q}\times\left.\frac{p}{3}\right|^{\frac{3}{2}}>$ unity. Then x has three values in each form, viz, $x=\pm\sqrt{\frac{4p}{3}}\times$ cos. $\frac{z}{3}=\mp\sqrt{\frac{4p}{3}}\times$ cos. $\overline{60^\circ-\frac{z}{3}}=\mp\sqrt{\frac{4p}{3}}\times$ cos. $\overline{60^\circ+\frac{z}{3}}$; where the upper signs belong to the third form, and the lower signs to the fourth form.

By Logarithms.

Forms 1st and 2d. $\text{Log.}\,\frac{q}{2} + 10 - \frac{3}{2} \times \log.\frac{p}{3} =$ log. tan. z, and $\frac{\log.\tan.\overline{45^\circ - \frac{1}{2}z} + 20}{3} = \log.\tan.u$.

Then $\log. x = \frac{1}{2}\log.\frac{4p}{3} + \log.\cot. 2u - 10$; and x will be affirmative in the first form, and negative in the second form.

Forms 3d and 4th. $\frac{3}{2} \times \log.\frac{p}{3} + 10 - \log.\frac{q}{2}$ being less than 10 (which is case first) or $\log.\frac{q}{2} + 10 - \frac{3}{2} \times \log.\frac{p}{3}$ being less than 10 (which is case 2d) $=$ log. cos. z.

Case 1st. $\frac{\text{Log.}\tan.\overline{45^\circ - \frac{1}{2}z} + 20}{3} = \log.\tan. u$.

Then $\log. x = \frac{1}{2}\log.\frac{4p}{3} + 10 - \log.\sin. 2u$; and x will be affirmative in the third form, and negative in the 4th form.

Case 2d. Here x has three values.

1st. $\text{Log.} \pm x = \frac{1}{2}\log.\frac{4p}{3} + \log.\cos.\underline{\frac{z}{3} - 10}$.

2d. $\text{Log.} \mp x = \frac{1}{2}\log.\frac{4p}{3} + \log.\cos.\underline{60^\circ - \frac{z}{3}}$,

3d. $\text{Log.} \mp x = \frac{1}{2}\log.\frac{4p}{3} + \log.\cos. 60^\circ + \frac{z}{3} - 10$;

where the upper signs belong to the third form, and the lower signs to the fourth form; that is, the first value of x in the third form is positive, and its second and third values negative; and the first value of x in the fourth form is negative, and its second and third values affirmative."

DIPPING *Needle*. Pa. 383, col. 2, after line 38 *add*, See a new Dipping-needle by Dr. Lorimer, in the Philos. Trans. 1775, also in the Supplement to Cavallo's Treatise on Magnetism.

DOME. In plate 33 is represented the plan and elevation of a Dome constructed without centring, by Mr. S. Bunce; viz, Fig. 1 the plan, and Fig. 2 the elevation. The first course consists of the stones marked 1, 1, 1, &c, of different sizes, the large ones exactly twice the height of the small ones, placed alternately, and forming intervals to receive the stones marked 2, 2, 2. The other courses are continued in the same manner, according to the order of the figures to the top.

It is evident, from the converging or wedgelike form of the intervals, that the stones they receive can only be inserted from the outside, and cannot fall through: therefore the whole Dome may be built without centring or temporary support. To break the upright joints, the stones may be cut of the form marked in Fig. 3; and those marked 16, 17, &c, near the key-stones, may be enlarged as at Fig. 4.

E.

EUTOCIUS, a respectable Greek mathematician, lived at Ascalon in Palestine about the year of Christ 550. He was one of the most considerable mathematicians that flourished about the decline of the sciences among the Greeks, and had for his preceptor Isidorus the principal architect of the church of St. Sophia at Constantinople. He is chiefly known however by his commentaries on the works of the two ancient authors, Archimedes and Apollonius. Those two commentaries are both excellent compositions, to which we owe many useful circumstances in the history of the mathematics.

His commentaries on Apollonius are published in Halley's edition of the works of that author; and those on Archimedes, first in the Basle edition, in Greek and Latin, in 1543, and since in some others, as the late Oxford edition. Of these commentaries, those rank the highest, which illustrate Archimedes's work on the Sphere and Cylinder; in one of which we have a recital of the various methods practised by the ancients in the solution of the Delian problem, or that of doubling the cube. The others are of less value; though it cannot but be regretted that Eutocius did not pursue his plan of commenting on all the works of Archimedes, with the same attention and diligence which he employed in his remarks on the sphere and cylinder.

GROIN, with Builders, is the angle made by the intersection of two arches. It is of two kinds, regular and irregular; viz, Regular when both the arches have the same diameter, but an Irregular Groin when one arch is a semicircle and the other a semiellipsis. Groins are chiefly used in forming arched roofs, where one hollow arched vault intersects with another; as in the roofs of most churches, and some cellars in large houses.

I.

IMPOSSIBLE *Binomial*. See BINOMIAL.

IRREDUCIBLE *Case*, in Algebra. Mr. Bonnycastle has communicated the following additional observations on this case, and, an improved solution by a table of sines. The

IRREDUCIBLE *Case, in Algebra*, is a cubic equation of the form $x^3 - ax = \pm b$, having $\frac{1}{27}a^3$ greater than $\frac{1}{4}b^2$, or $4a^3$ greater than $27b^2$; in which case, it is well known, that the solution cannot be generally obtained, either by Cardan's rule, or any other which has yet been devised.

One of the most convenient methods of determining the roots of equations of this kind, is by means of a Table of Natural Sines, &c, for which purpose the following formulæ will be found extremely commodious, the arc, in each case, being always less than a quadrant, and therefore attended with no ambiguity.

If

If the equation be $x^3 - ax = b$; let A be put = arc whoſe coſ. is $\frac{3b}{2a}\sqrt{\frac{3}{a}}$ to rad. 1, then the three roots, or values of x, will be as follows:

$$x = 2\sqrt{\frac{a}{3}} \times \text{coſine}\,\frac{A}{3}$$

$$x = -2\sqrt{\frac{a}{3}} \times \text{ſine}\,\frac{90^\circ+A}{3}$$

$$x = -2\sqrt{\frac{a}{3}} + \text{ſine}\,\frac{90^\circ-A}{3}$$

And, if the equation be $x^3 - ax = -b$; let A be put = arc whoſe ſine is $\frac{3b}{2a}\sqrt{\frac{3}{a}}$ to rad. 1; then the three roots, or values of x, will be as follows:

$$x = 2\sqrt{\frac{a}{3}} \times \text{ſine}\,\frac{A}{3}$$

$$x = 2\sqrt{\frac{a}{3}} \times \text{coſ.}\,\frac{90^\circ+A}{3}$$

$$x = -2\sqrt{\frac{a}{3}} \times \text{coſ.}\,\frac{90^\circ+A}{3}$$

Ex. 1. Let $x^3 - 3x = 1$, to find the 3 roots of the equation.

Here $\frac{3b}{2a}\sqrt{\frac{3}{a}} = \frac{3}{6}\sqrt{\frac{3}{3}} = \frac{1}{2} = {}^{\cdot}5 = \text{coſ.}\,60^\circ = A$.

$$\text{Hence}\begin{cases} x = 2\,\text{coſ.}\frac{60^\circ}{3} = 2\,\text{coſ.}\,20^\circ = 1{\cdot}8793852 \\ x = -2\,\text{ſine}\frac{150^\circ}{3} = +2\,\text{ſine}\,50^\circ = -1{\cdot}5320888 \\ x = -2\,\text{ſine}\,\frac{30^\circ}{3} = -2\,\text{ſine}\,10^\circ = -{\cdot}3472964 \end{cases}$$

Ex. 2d. Let $x^3 - 3x = -1$, to find the 3 roots of the equation.

Here $\frac{3b}{2a}\sqrt{\frac{3}{a}} = \frac{3}{6}\sqrt{\frac{3}{3}} = \frac{1}{2} = {}^{\cdot}5 = \text{ſine}\,30^\circ = A$,

$$\text{Hence}\begin{cases} x = 2\,\text{ſine}\,\frac{30^\circ}{3} = 2\,\text{ſine}\,10^\circ = {\cdot}3472964 \\ x = 2\,\text{coſ.}\frac{120^\circ}{3} = 2\,\text{coſ.}\,40^\circ = 1{\cdot}5320888 \\ x = -2\,\text{coſ.}\,\frac{60^\circ}{3} = -2\,\text{coſ.}\,20^\circ = -1{\cdot}8793852 \end{cases}$$

The inveſtigation of this method is as follows:

It is ſhewn, by the writers on Trigonometry, that if c be the coſine of any arc to rad. 1, $4c^3 - 3c$, will be the coſine of 3 times that arc; and conſequently c is the coſine of $\frac{1}{3}$ of the arc whoſe coſine is $4c^3 - 3c$, or any other equal quantity.

In order, therefore, to reduce the equation $x^3 - ax = b$ to this form, let $x = \frac{y}{z}$; then $\frac{y^3}{z^3} - a \times \frac{y}{z} = b$, or $y^3 - az^2y = bz^3$, or $4y^3 - 4az^2y = 4bz^3$; whence if $4az^2$ be put = 3, we ſhall have $z = \sqrt{\frac{3}{4a}} = \frac{1}{2}\sqrt{\frac{3}{a}}$, and conſequently $4y^3 - 3y = \frac{3b}{2a}\sqrt{\frac{3}{a}}$.

From which laſt equation, it appears that y = coſ. $\frac{1}{3}$ arc whoſe coſ. is $\frac{3b}{2a}\sqrt{\frac{3}{a}}$, and therefore $x = \frac{y}{z} = \frac{y}{\frac{1}{2}\sqrt{\frac{3}{a}}}$ $= 2\sqrt{\frac{a}{3}} \times y = 2\sqrt{\frac{a}{3}} \times$ (coſ. $\frac{1}{3}$ arc whoſe coſ. is $\frac{3b}{2a}\sqrt{\frac{3}{a}}$), or, if A be put = arc whoſe coſ. is $\frac{3b}{2a}\sqrt{\frac{3}{a}}$, x is $= 2\sqrt{\frac{a}{3}} \times \text{coſ.}\,\frac{A}{3}$.

But the arc of which $\frac{3b}{2a}\sqrt{\frac{3}{a}}$ is the coſine, is either A, $A + 360^\circ$ or $A + 720^\circ$; whence $x = 2\sqrt{\frac{a}{3}} \times \text{coſ.}\,\frac{A}{3}$ or $2\sqrt{\frac{a}{3}} \times \text{coſ.}\,\frac{A+360^\circ}{3}$, or $2\sqrt{\frac{a}{3}} \times \text{coſ.}\,\frac{A+720^\circ}{3}$; the two latter of which being converted into ſines, will give the ſame formulæ as in the rule.

In like manner, if s be the ſine of any arc to rad. 1, $3s - 4s^3$ is well known to be the ſine of 3 times that arc; and conſequently s is the ſine of $\frac{1}{3}$ of the arc whoſe ſine is $3s - 4s^3$. Whence, to reduce the equation $x^3 - ax = -b$, to this form, let $x = \frac{y}{z}$, as before; then $\frac{y^3}{z^3} - a \times \frac{y}{z} = -b$, or $y^3 - az^2y = -bz^3$, or $az^2y - y^3 = bz^3$, or $4az^2y - 4y^3 = 4bz^3$; where, if $4az^2$ be put = 3, we ſhall have $z = \frac{1}{2}\sqrt{\frac{3}{a}}$, and conſequently $3y - 4y^3 = \frac{3b}{2a}\sqrt{\frac{3}{a}}$.

From which laſt equation it appears that y = ſine $\frac{1}{3}$ *arc* whoſe ſine is $\frac{3b}{2a}\sqrt{\frac{3}{a}}$; and therefore $x = \frac{y}{z} = 2\sqrt{\frac{a}{3}} \times$ (ſine $\frac{1}{3}$ *arc* whoſe ſine is $\frac{3b}{2a}\sqrt{\frac{3}{a}}$), which is the ſame as the rule, the other two roots being found as in the former caſe.

L.

LOCK, for Canals, in Inland Navigations. See Canal.

LOGARITHMS. Mr. Bonnycaſtle has communicated the following new method of making theſe uſeful numbers:

Logarithms. The ſeries now chiefly uſed in the computation of Logarithms were originally derived from the hyperbola, by means of which, and the logiſtic curve, the nature and properties of theſe numbers are clearly and elegantly explained.

The doctrine, however, being purely arithmetical, this mode of demonſtrating it, by the intervention of certain curves, was conſidered, by Dr. Halley, as not conformable to the nature of the ſubject.

He

He has, accordingly, investigated the same series from the abstract principles of numbers; but his method, which is a kind of disguised fluxions, is, in many places, so extremely abstruse and obscure, that few have been able to comprehend his reasoning.

An easy and perspicuous demonstration, of this kind, was therefore still wanting; which may be obtained from the pure principles of Algebra, independently of the doctrine of Curves, as follows:

The Logarithm of any number, is the index of that power of some other number, which is equal to the given number.

Thus, if $r^x = a$, the logarithm of a is x, which may be either positive or negative, and r any number whatever, according to the different systems of Logarithms.

When $a = 1$, it is plain that x must be $= 0$, whatever be the value of r; and consequently the Logarithm of 1 is always 0 in every system.

If $x = 1$, it is also plain that a must be $= r$; and therefore r is always the number in every system, whose Logarithm in that system is 1.

To find the Logarithm of any number, in any system, it is only necessary, from the equation $r^x = a$, to find the value of x in terms of r and a.

This may be strictly effected, by means of a new property of the binomial theorem of Newton; which is given under its proper article in this Appendix. The general Logarithmic equation being $r^x = a$, let

$$a = 1 + p, \text{ and } \frac{1}{x} = z; \text{ then } r = a^{\frac{1}{x}} = \overline{1+p}^{\frac{1}{x}} = \overline{1+p}^{z} =$$

$$1 + \left(p - \frac{p^2}{2} + \frac{p^3}{3} - \frac{p^4}{4} \&c\right)z + \tfrac{1}{2}\left(p - \frac{p^2}{2} + \frac{p^3}{3} - \frac{p^4}{4} \&c\right)^2 z^2$$

$$+ \frac{1}{2.3}\left(p - \frac{p^2}{2} + \frac{p^3}{3} - \frac{p^4}{4} \&c\right)^3 z^3 + \frac{1}{2.3.4}\left(p - \frac{p^2}{2} + \frac{p^3}{3} - \frac{p^4}{4} \&c\right)^4 z^4$$

$$+ \frac{1}{2.3.4.5}\left(p - \frac{p^2}{2} + \frac{p^3}{3} - \frac{p^4}{4} \&c\right)^5 z^5, \&c.$$ See *Binomial* THEOREM, Appendix.

And if $p - \frac{p^2}{2} + \frac{p^3}{3} - \frac{p^4}{4} + \frac{p^5}{5}$ &c be put $= s$, we shall have

$$1 + sz + \tfrac{1}{2}s^2z^2 + \frac{1}{2.3}s^3z^3 + \frac{1}{2.3.4}s^4z^4 + \frac{1}{2.3.4.5}s^5z^5 \&c = r,$$

or $$sz + \tfrac{1}{2}s^2z^2 + \frac{1}{2.3}s^3z^3 + \frac{1}{2.3.4}s^4z^4 + \frac{1}{2.3.4.5}s^5z^5 \&c = r-1,$$

which let be put $= q$; then, by reverting the series z or $\frac{1}{x}$ will be found

$$= \frac{q - \frac{1}{2}q^2 + \frac{1}{3}q^3 - \frac{1}{4}q^4 + \frac{1}{5}q^5 \&c}{s} = \frac{q - \frac{1}{2}q^2 + \frac{1}{3}q^3 - \frac{1}{4}q^4 + \frac{1}{5}q^5 \&c}{p - \frac{1}{2}p^2 + \frac{1}{3}p^3 - \frac{1}{4}p^4 + \frac{1}{5}p^5 \&c}$$

and consequently $$x = \frac{p - \frac{1}{2}p^2 + \frac{1}{3}p^3 - \frac{1}{4}p^4 + \frac{1}{5}p^5 \&c}{q - \frac{1}{2}q^2 + \frac{1}{3}q^3 - \frac{1}{4}q^4 + \frac{1}{5}q^5 \&c}.$$

The Logarithm of a, or $1 + p$, is therefore

$$= \frac{p - \frac{1}{2}p^2 + \frac{1}{3}p^3 - \frac{1}{4}p^4 + \frac{1}{5}p^5 \&c}{q - \frac{1}{2}q^2 + \frac{1}{3}q^3 - \frac{1}{4}q^4 + \frac{1}{5}q^5 \&c};$$ or, since $p = a - 1$, and $q = r - 1$, the Logarithm of a is

$$= \frac{(a-1) - \frac{1}{2}(a-1)^2 + \frac{1}{3}(a-1)^3 - \frac{1}{4}(a-1)^4 + \frac{1}{5}(a-1)^5}{(r-1) - \frac{1}{2}(r-1)^2 + \frac{1}{3}(r-1)^3 - \frac{1}{4}(r-1)^4 + \frac{1}{5}(r-1)^5} \&c;$$

Which is a general expression for the Logarithm of any number, in any system of Logarithms, the radix r being taken of any value, greater or less than 1.

But as r in every system, is a constant quantity, being always the number whose Logarithm in the system to which it belongs is 1, the above expression may be simplified, either by assuming r = to some particular number, and from thence finding the value of the series constituting the denominator, or by assuming this whole series = to some particular number, and from thence finding the value which must be given to the radix r.

By the latter of these methods, the denominator may be made to vanish, by assuming the value of the series of which it consists $= 1$, in which case, the Logarithm of $1 + p$ becomes $= p - \frac{p^2}{2} + \frac{p^3}{3} - \frac{p^4}{4} + \frac{p^5}{5}$ &c, or the Logarithm of

$a = (a-1) - \frac{1}{2}(a-1)^2 + \frac{1}{3}(a-1)^3 - \frac{1}{4}(a-1)^4 + \frac{1}{5}(a-1)^5$ &c [illegible]

and r, by reversion of series is [illegible]

The sy[illegible]

value [illegible]

bee[illegible]

pe[illegible]

mi[illegible]

[illegible]

som[illegible] number, as for instance 10, the value of the series $q - \frac{1}{2}q^2 + \frac{1}{3}q^3 - \frac{1}{4}q^4 + \frac{1}{5}q^5$ &c, or its equal $(r-1) - \frac{1}{2}(r-1)^2 + \frac{1}{3}(r-1)^3 - \frac{1}{4}(r-1)^4 + \frac{1}{5}(r-1)^5$ &c will become $= 2.30258509$, &c, and the

$$\text{Log. of } 1+p = \frac{1}{2.30258509} \times \left(p - \tfrac{1}{2}p^2 + \tfrac{1}{3}p^3 - \tfrac{1}{4}p^4 + \tfrac{1}{5}p^5 \&c\right)$$

or the Log. of a

$$= \frac{1}{2.30258509} \times \left((a-1) - \tfrac{1}{2}(a-1)^2 + \tfrac{1}{3}(a-1)^3 - \tfrac{1}{4}(a-1)^4 + \tfrac{1}{5}(a-1)^5\right)$$

&c, which gives the system that furnishes Briggs's or the common Logarithms.

And, in like manner, by assuming any particular value for r, and thence determining the value of the series $q - \frac{1}{2}q^2 + \frac{1}{3}q^3 - \frac{1}{4}q^4 + \frac{1}{5}q^5$ &c, or its equal $(r-1) - \frac{1}{2}(r-1)^2 + \frac{1}{3}(r-1)^3 - \frac{1}{4}(r-1)^4 + \frac{1}{5}(r-1)^5$ &c; or by assuming the same series of some particular value, and thence determining the value of r, any system of Logarithms may be derived.

The series $q - \frac{1}{2}q^2 + \frac{1}{3}q^3 - \frac{1}{4}q^4 + \frac{1}{5}q^5$ &c, or its equal $(r-1) - \frac{1}{2}(r-1)^2 + \frac{1}{3}(r-1)^3 - \frac{1}{4}(r-1)^4 + \frac{1}{5}(r-1)^5$ &c, which forms the denominator of the above compound expression, exhibiting the Logarithms of numbers according to any system, is what was first called, by Cotes, the Modulus of the system, being always a constant quantity, depending only on the assumed value of r.

And, as the form of this series is exactly the same as that which constitutes the numerator, and which has been shewn to be the hyperbolic Logarithm of a, it follows that the Modulus of any system of Logarithms is equal to the hyperbolic Logarithm of the radix of that system,

system, or of the number whose proper Logarithm is the system to which it belongs is 1.

The form of the series here obtained for the hyperbolic Logarithm of a, is the same as that which was first discovered by Mercator; and if the series of Wallis be required, it may be investigated in a similar manner as follows:

The general Logarithmic equation being $r^x = a$, as before, let $a = \frac{1}{1-p}$ and $z = \frac{1}{x}$; then $r = a^{\frac{1}{x}} =$

$$\overline{\frac{1}{1-p}}\Big|^{z} = \frac{1}{\overline{1-p}|^{z}}, \text{ and } \frac{1}{r} = \overline{1-p}|^{z} = 1-(p+\frac{p^2}{2}+\frac{p^3}{3}+\frac{p^4}{4}\ \&c)$$

$$+\tfrac{1}{2}(p+\frac{p^2}{2}+\frac{p^3}{3}+\frac{p^4}{4}\ \&c)^2z^2 - \frac{1}{2.3}(p+\frac{p^2}{2}+\frac{p^3}{3}+\frac{p^4}{4}\ \&c)^3z^3$$

$$+\frac{1}{2.3.4}(p+\frac{p^2}{2}+\frac{p^3}{3}+\frac{p^4}{4}\ \&c)^4z^4 - \frac{1}{2.3.4.5}(p+\frac{p^2}{2}+\frac{p^3}{3}+\frac{p^4}{4}\ \&c)^5z^5$$

&c.

And if $p + \frac{p^2}{2} + \frac{p^3}{3} + \frac{p^4}{4} + \frac{p^5}{5}$ &c be put $= s$, we [illegible] $sz + \frac{1}{2}s^2z^2 - \frac{1}{2.3}s^3z^3 + \frac{1}{2.3.4}s^4z^4$ &c $= \frac{1}{r}$, [illegible] $z^2 + \frac{1}{2.3}s^3z^3 - \frac{1}{2.3.4}s^4z^4$ &c $= 1 - \frac{1}{r}$, [illegible] be put $= q$; then, by conversion of series, z or $\frac{1}{x}$ will be found

$$= \frac{q+\frac{1}{2}q^2+\frac{1}{3}q^3+\frac{1}{4}q^4+\frac{1}{5}q^5\ \&c}{s} = \frac{q+\frac{1}{2}q^2+\frac{1}{3}q^3+\frac{1}{4}q^4+\frac{1}{5}q^5}{p+\frac{1}{2}p^2+\frac{1}{3}p^3+\frac{1}{4}p^4+\frac{1}{5}p^5}$$

and consequently $x = \frac{p+\frac{1}{2}p^2+\frac{1}{3}p^3+\frac{1}{4}p^4+\frac{1}{5}p^5\ \&c}{q+\frac{1}{2}q^2+\frac{1}{3}q^3+\frac{1}{4}q^4+\frac{1}{5}q^5\ \&c}$.

The Logarithm of a or $\frac{1}{1-p}$ is, therefore,

$$= \frac{p+\frac{1}{2}p^2+\frac{1}{3}p^3+\frac{1}{4}p^4+\frac{1}{5}p^5\ \&c}{q+\frac{1}{2}q^2+\frac{1}{3}q^3+\frac{1}{4}q^4+\frac{1}{5}q^5\ \&c};$$ or since

$$p = 1 - \frac{1}{a} = \frac{a-1}{a} \text{ and } q = 1 - \frac{1}{r} = \frac{r-1}{r},$$

the Logarithm of a is $=$

$$\frac{\frac{a-1}{a}+\frac{1}{2}\left(\frac{a-1}{a}\right)^2+\frac{1}{3}\left(\frac{a-1}{a}\right)^3+\frac{1}{4}\left(\frac{a-1}{a}\right)^4+\frac{1}{5}\left(\frac{a-1}{a}\right)^5\ \&c}{\frac{r-1}{r}+\frac{1}{2}\left(\frac{r-1}{r}\right)^2+\frac{1}{3}\left(\frac{r-1}{r}\right)^3+\frac{1}{4}\left(\frac{r-1}{r}\right)^4+\frac{1}{5}\left(\frac{r-1}{r}\right)^5\ \&c}$$

Which is another general expression for the Logarithm of any number a, in any system of Logarithms, that may be simplified in the same manner as the former, the denominator being still equal to the hyperbolic Logarithm of the radix r; or, which is the same thing, to the Modulus of the system.

For if the series $q + \frac{1}{2}q^2 + \frac{1}{3}q^3 + \frac{1}{4}q^4 + \frac{1}{5}q^5$ &c, or its equal

$$\frac{r-1}{r}+\frac{1}{2}\left(\frac{r-1}{r}\right)^2+\frac{1}{3}\left(\frac{r-1}{r}\right)^3+\frac{1}{4}\left(\frac{r-1}{r}\right)^4+\frac{1}{5}\left(\frac{r-1}{r}\right)^5\ \&c,$$

be assumed $= 1$, the hyperbolic Logarithm of $\frac{1}{1-p}$ will be $= p + \frac{1}{2}p^2 + \frac{1}{3}p^3 + \frac{1}{4}p^4 + \frac{1}{5}p^5$ &c, or the hyperbolic Logarithm of a

$$= \frac{a-1}{a}+\frac{1}{2}\left(\frac{a-1}{a}\right)^2+\frac{1}{3}\left(\frac{a-1}{a}\right)^3+\frac{1}{4}\left(\frac{a-1}{a}\right)^4+\frac{1}{5}\left(\frac{a-1}{a}\right)^5\ \&c;$$

and r, by reversion of series will be found $= 2.7182818$, as before. And if, on the contrary, the radix r be assumed $= 10$, the value of the series

$q + \frac{1}{2}q^2 + \frac{1}{3}q^3 + \frac{1}{4}q^4 + \frac{1}{5}q^5$ &c, or its equal

$$\frac{r-1}{r}+\frac{1}{2}\left(\frac{r-1}{r}\right)^2+\frac{1}{3}\left(\frac{r-1}{r}\right)^3+\frac{1}{4}\left(\frac{r-1}{r}\right)+\frac{1}{5}\left(\frac{r-1}{r}\right)^5\ \&c,$$

will become $= 2.30258509$, as before; and the common Logarithm of

$$\frac{1}{1-p} = \frac{1}{2.30258509} \times (p+\tfrac{1}{2}p^2+\tfrac{1}{3}p^3+\tfrac{1}{4}p^4+\tfrac{1}{5}p^5\ \&c),$$

or the common Logarithm of $a = \frac{1}{2.302585C9}$

$$\times .\frac{a-1}{a}+\frac{1}{2}\left(\frac{a-1}{a}\right)^2+\frac{1}{3}\left(\frac{a-1}{a}\right)^3+\frac{1}{4}\left(\frac{a-1}{a}\right)^4+\frac{1}{5}\left(\frac{a-1}{a}\right)^5\ \&c.$$

Or the latter formula, for the Logarithm of $\frac{1}{1-p}$, or its equal a, may be more concisely derived from the first, as follows:

The Logarithm of $1 + p$ has been shewn to be $= \frac{p-\frac{1}{2}p^2+\frac{1}{3}p^3-\frac{1}{4}p^4+\frac{1}{5}p^5\ \&c}{q-\frac{1}{2}q^2+\frac{1}{3}q^3-\frac{1}{4}q^4+\frac{1}{5}q^5\ \&c}$, and if $-p$ be substituted in the place of $+p$, the logarithm of $1-p$ will become $= \frac{-p-\frac{1}{2}p^2-\frac{1}{3}p^3-\frac{1}{4}p^4-\frac{1}{5}p^5\ \&c}{q-\frac{1}{2}q^2+\frac{1}{3}q^3-\frac{1}{4}q^4+\frac{1}{5}q^5\ \&c}$, whence the Logarithm of $\frac{1}{1-p} = \text{Log. } 1 - \text{Log. } (1-p) = 0 -$

$$\left(\frac{-p-\frac{1}{2}p^2-\frac{1}{3}p^3-\frac{1}{4}p^4-\frac{1}{5}p^5\ \&c}{q-\frac{1}{2}q^2+\frac{1}{3}q^3-\frac{1}{4}q^4+\frac{1}{5}q^5\ \&c} = \frac{p+\frac{1}{2}p^2+\frac{1}{3}p^3+\frac{1}{4}p^4+\frac{1}{5}p^5\ \&c}{q-\frac{1}{2}q^2+\frac{1}{3}q^3-\frac{1}{4}q^4+\frac{1}{5}q^5\ \&c}\right)$$

$$\text{or Log. } a = \frac{\frac{a-1}{a}+\frac{1}{2}\left(\frac{a-1}{a}\right)^2+\frac{1}{3}\left(\frac{a-1}{a}\right)^3+\frac{1}{4}\left(\frac{a-1}{a}\right)^4\ \&c}{(r-1)-\frac{1}{2}(r-1)^2+\frac{1}{3}(r-1)^3-\frac{1}{4}(r-1)^4\ \&c};$$

where the denominator is the same as in the first formula, q being here $= r-1$.

If the denominator, in either of these general formulæ, be put $= m$, the Logarithm of $1 + p$ will be denoted by $\frac{1}{m} \times (p-\frac{1}{2}p^2+\frac{1}{3}p^3-\frac{1}{4}p^4+\frac{1}{5}p^5$ &c, or the Logarithm of a by

$$\frac{1}{m} \times : (a-1)-\tfrac{1}{2}(a-1)^2+\tfrac{1}{3}(a-1)^3-\tfrac{1}{4}(a-1)^4+\tfrac{1}{5}(a-1)^5\ \&c.$$

And the Logarithm of $\frac{1}{1-p}$ will be denoted by

$$\frac{1}{m} \times (p + \tfrac{1}{2}p^2 + \tfrac{1}{3}p^3 + \tfrac{1}{4}p^4 + \tfrac{1}{5}p^5\ \&c,$$

or the Logarithm of a by

$$\frac{1}{m} \times : \frac{a-1}{a}+\frac{1}{2}\left(\frac{a-1}{a}\right)^2+\frac{1}{3}\left(\frac{a-1}{a}\right)^3+\frac{1}{4}\left(\frac{a-1}{a}\right)^4+\frac{1}{5}\left(\frac{a-1}{a}\right)^5\ \&c.$$

And since the sum of the Logarithms of any two numbers is equal to the Logarithm of their product, the Logarithm of $\frac{1+p}{1-p}$ will become

$= \frac{2}{m}$

$$= \frac{2}{m} \times (p + \tfrac{1}{3}p^3 + \tfrac{1}{5}p^5 + \tfrac{1}{7}p^7 \text{ \&c}),$$

or the Logarithm of a

$$= \frac{2}{m} \times : \frac{a-1}{a+1} + \tfrac{1}{3}\left(\frac{a-1}{a+1}\right)^3 + \tfrac{1}{5}\left(\frac{a-1}{a+1}\right)^5 + \tfrac{1}{7}\left(\frac{a-1}{a+1}\right)^7 \text{ \&c.}$$

Which is a third general formula, that converges faster than either of the former.

The Logarithm of any number may, therefore, be exhibited universally, or according to any system of Logarithms, in the three following forms:

$$\text{Log.}(1+p) = \frac{1}{m} \times : p - \tfrac{1}{2}p^2 + \tfrac{1}{3}p^3 - \tfrac{1}{4}p^4 + \tfrac{1}{5}p^5 \text{ \&c.}$$

$$\text{Log.}\frac{1}{1-p} = \frac{1}{m} \times : p + \tfrac{1}{2}p^2 + \tfrac{1}{3}p^3 + \tfrac{1}{4}p^4 + \tfrac{1}{5}p^5 \text{ \&c.}$$

$$\text{Log.}\frac{1+p}{1-p} = \frac{2}{m} \times : p + \tfrac{1}{3}p^3 + \tfrac{1}{5}p^5 + \tfrac{1}{7}p^7 + \tfrac{1}{9}p^9 \text{ \&c.}$$

Or

$$\text{Log.}a = \frac{1}{m} \times : (a-1) - \tfrac{1}{2}(a-1)^2 + \tfrac{1}{3}(a-1)^3 - \tfrac{1}{4}(a-1)^4$$ [illegible]

$$\text{Log.}a = \frac{1}{m} \times : \frac{a-1}{a} + \tfrac{1}{2}\left(\frac{a-1}{a}\right)^2 + \tfrac{1}{3}\left(\frac{a-1}{a}\right)^3 + \tfrac{1}{4}\left(\frac{a-1}{a}\right)^4$$ [illegible]

$$\text{Log.}a = \frac{2}{m} \times : \frac{a-1}{a+1} + \tfrac{1}{3}\left(\frac{a-1}{a+1}\right)^3 + \tfrac{1}{5}\left(\frac{a-1}{a+1}\right)^5 + \tfrac{1}{7}\left(\frac{a-1}{a+1}\right)^7 \text{ \&c.}$$

And if $a+b$ be put $= s$, and $a \backsim b = d$, these general formulæ may be easily converted into the following:

$$\text{Log.}\frac{a}{b} = \frac{1}{m} \times : \frac{d}{b} - \frac{d^2}{2b^2} + \frac{d^3}{3b^3} - \frac{d^4}{4b^4} + \frac{d^5}{5b^5} \text{ \&c.}$$

$$\text{Log.}\frac{a}{b} = \frac{1}{m} \times : \frac{d}{a} + \frac{d^2}{2a^2} + \frac{d^3}{3a^3} + \frac{d^4}{4a^4} + \frac{d^5}{5a^5} \text{ \&c.}$$

$$\text{Log.}\frac{a}{b} = \frac{2}{m} \times : \frac{d}{s} + \frac{d^3}{3s^3} + \frac{d^5}{5s^5} + \frac{d^7}{7s^7} + \frac{d^9}{9s^9} \text{ \&c.}$$

From which last expressions, if d or its equal $a \backsim b$ be put $= 1$, we shall have, by proper substitution, and the nature of Logarithms:

$$\text{Log.}a = \text{Log.}(a-1) + \frac{1}{m} \times : \frac{1}{a} + \frac{1}{2a^2} + \frac{1}{3a^3} + \frac{1}{4a^4} \text{ \&c.}$$

$$\text{Log.}a = \text{Log.}(a-1) + \frac{1}{m} \times : \frac{1}{a-1} - \frac{1}{2(a-1)^2} + \frac{1}{3(a-1)^3} - \frac{1}{4(a-1)^4} \text{ \&c}$$

$$\text{Log.}a = \text{Log.}(a-2) + \frac{1}{m} \times : \frac{1}{a-1} + \frac{1}{3(a-1)^3} + \frac{1}{5(a-1)^5} + \frac{1}{7(a-1)^7} \text{ \&c.}$$

And from the addition and subtraction of these series, several others may be derived; but in the actual computation of Logarithms they will be found to possess little or no advantage above those here given. The same general formula may be derived from the original Logarithmic equation $r^x = a$ in a different way, thus:

Let $r = 1+q$, then $r^x = \overline{1+q}|^x = 1 + (q - \tfrac{1}{2}q^2 + \tfrac{1}{3}q^3 - \tfrac{1}{4}q^4 \text{ \&c})x + \tfrac{1}{2}(q - \tfrac{1}{2}q^2 + \tfrac{1}{3}q^3 - \tfrac{1}{4}q^4 \text{ \&c})^2x^2 + \frac{1}{2.3}(q - \tfrac{1}{2}q^2 + \tfrac{1}{3}q^3 - \tfrac{1}{4}q^4 \text{ \&c})^3x^3 + \frac{1}{2.3.4}(q - \tfrac{1}{2}q^2 + \tfrac{1}{3}q^3 - \tfrac{1}{4}q^4 \text{ \&c})^4x^4 \text{ \&c} = a$; or if r be put $= \frac{1}{1-q}$, we shall have $\overline{1-q}|^{-x} = 1 - (q + \tfrac{1}{2}q^2 + \tfrac{1}{3}q^3 + \tfrac{1}{4}q^4 \text{ \&c})x + \tfrac{1}{2}(q + \tfrac{1}{2}q^2 + \tfrac{1}{3}q^3 + \tfrac{1}{4}q^4 \text{ \&c})^2x^2 - \frac{1}{2.3}(q + \tfrac{1}{2}q^2 + \tfrac{1}{3}q^3 + \tfrac{1}{4}q^4 \text{ \&c})^3x^3 + \frac{1}{2.3.4}(q + \tfrac{1}{2}q^2 + \tfrac{1}{3}q^3 + \tfrac{1}{4}q^4 \text{ \&c})^4x^4 \text{ \&c} = \frac{1}{a}$.

And by denoting $q - \tfrac{1}{2}q^2 + \tfrac{1}{3}q^3 - \tfrac{1}{4}q^4$ &c in the first case, or its equal $q + \tfrac{1}{2}q^2 + \tfrac{1}{3}q^3 + \tfrac{1}{4}q^4$, in the latter case, by m, these expressions will become

$$1 + mx + \tfrac{1}{2}m^2x^2 + \frac{1}{2.3}m^3x^3 + \frac{1}{2.3.4}m^4x^4 + \text{\&c} = a;$$

and $1 - mx + \tfrac{1}{2}m^2x^2 - \frac{1}{2.3}m^3x^3 + \frac{1}{2.3.4}m^4x^4 \text{ \&c} = \frac{1}{a}$ [illegible] made and sold by W. and S. Jones, opticians, No. 135, Holborn, London. See fig. 4, pl. 33.

"This Microscope is adapted to the viewing of all sorts of objects, whether *transparent*, or *opake;* and for *insects*, *flowers*, *animalcules*, and the infinite variety of the *minutiæ* of Nature and Art, will be found the most complete and portable for the price, of any hitherto contrived.

Place the square pillar of the Microscope in the square socket at the foot D, and fasten it by the pin, as shewn in the figure. Place also in the foot, the reflecting mirror C. There are three lenses at the top shewn at A, which serve to magnify the objects. By using these lenses separately or combined, you make seven different powers. When transparent objects, such as are in the ivory sliders, number 4, are to be viewed, you place the sliders over the spring, at the underside of the stage B; then looking through the lens or magnifier, at A, at the same time reflect up the light, by moving the mirrour C below, and move gently upwards or downwards as may be necessary, the stage B, upon its square pillar, till you see the object illuminated and distinctly magnified; and in this manner for the other objects.

For animalcules, you unscrew the brass box that is fitted at the stage B, containing two glasses, and leave the undermost glass upon the stage, to receive the fluids. If you wish to view thereon any moving insect, &c, it may be confined by screwing on the cover: of the two glasses, the concave is best for fluids. Should the objects be opake, such as seeds, &c; they are to be placed upon the black and white ivory round piece, number 3, which is fitted also to the stage B. If the objects are of a dark colour, you place them contrastedly on the white side of the ivory. If they are of a white, or a light colour, upon the blackened side. Some objects will

will be more conveniently viewed, by sticking them on the point of number 2; or between the nippers at the other end, which open by pressing the two little brass pins. This apparatus is also fitted to a small hole in the stage, made to receive the support of the wire.

The brass forceps, number 1, serve to take up any small object by, in order to place them on the stage for view. The instrument may be readily converted into an hand Microscope, to view objects against the common light; and which, for some transparent ones, is better so. It is done by only taking out the pillar from its foot in D, turning it half round, and fixing it in again; the foot then becomes a useful handle, and the reflector C is laid aside.

The whole apparatus packs into a fish-skin case, 4½ inches long, 2¼ inches broad, and 1½ inches deep.

For persons more curious and nice in these sort of instruments, there is contrived a useful adjusting screw to the stage, represented at *e*. It is first moved up and down like the other, to the focus nearly, and made fast by the small screw. The utmost distinctness of the object is then obtained, by gently turning the long fine threaded screw, at the same time you are looking through the magnifier A. In this case, there may be [illegible]ded an extraordinary deep magnifier, and a con-[illegible]e silver speculum, with a magnifier to screw on at A, which will serve for viewing the very small, and opake objects, in the completest manner, and render the instrument as comprehensive in its uses and powers, as those formerly sold under the name of *Wilson's Microscope*."

MODULUS, and MODULAR *Ratio*. See p. 49 at the bottom.

N.

NUTATION, in Astronomy, a kind of libratory motion of the earth's axis; by which its inclination to the plane of the ecliptic is continually varying, by a certain number of seconds, backwards and forwards. The whole extent of this change in the inclination of the earth's axis, or, which is the same thing, in the apparent declination of the stars, is about 19″, and the period of that change is little more than 9 years, or the space of time from its setting out from any point and returning to the same point again, about 18 years and 7 months, being the same as the period of the moon's motions, upon which it chiefly depends; being indeed the joint effect of the inequalities of the action of the sun and moon upon the spheroidal figure of the earth, by which its axis is made to revolve with a conical motion, so that the extremity of it describes a small circle, or rather an ellipse, of 19·1 seconds diameter, and 14″·2 conjugate, each revolution being made in the space of 18 years 7 months, according to the revolution of the moon's nodes.

This is a natural consequence of the Newtonian system of universal attraction; the first principle of which is, that all bodies mutually attract each other in the direct ratio of their masses, and in the inverse ratio of the squares of their distances. From this mutual attraction, combined with motion in a right line, Newton deduces the figure of the orbits of the planets, and particularly that of the earth. If this orbit were a circle, and if the earth's form were that of a perfect sphere, the attraction of the sun would have no other effect than to keep the earth in its orbit, without causing any irregularity in the position of its axis. But neither is the earth's orbit a circle, nor its body a sphere; for the earth is sensibly protuberant towards the equator, and its orbit is an ellipsis, which has the sun in its focus. Now when the position of the earth is such, that the plane of the equator passes through the centre of the sun, the attractive power of the sun acts only so as to draw the earth towards it, still parallel to itself, and without changing the position of its axis; a circumstance which happens only at the time of the equinoxes. In proportion as the earth recedes from those points, the sun also goes out of the plane of the equator, and approaches that of the one or other of the tropics; the semidiameter of the earth, then exposed to the sun, being unequal to what it was in the former case, the equator is more powerfully attracted than the rest of the globe, which causes some alteration in its position, and its inclination to the plane of the ecliptic: and as that part of the orbit, which is comprised between the autumnal and vernal equinox, is less than that which is comprised between the vernal and autumnal, it follows, that the irregularity caused by the sun, during his passage through the northern signs, is not entirely compensated by that which he causes during his passage through the southern signs; and that the parallelism of the terrestrial axis, and its inclination to the ecliptic, is thence a little altered.

The like effect which the sun produces upon the earth, by his attraction, is also produced by the moon, which acts with greater force, in proportion as she is more distant from the equator. Now, at the time when her nodes agree with the equinoxial points, her greatest latitude is added to the greatest obliquity of the ecliptic. At this time therefore, the power which causes the irregularity in the position of the terrestrial axis, acts with the greatest force; and the revolution of the nodes of the moon being performed in 18 years 7 months, hence it happens that in this time the nodes will twice agree with the equinoxial points; and consequently, twice in that period, or once every 9 years, the earth's axis will be more influenced than at any other time.

That the moon has also a like motion, is shewn by Newton, in the first book of the Principia; but he observes indeed that this motion must be very small, and scarcely sensible.

As to the history of the Nutation, it seems there have been hints and suspicions of the existence of such a circumstance, ever since Newton's discovery of the system of the universal and mutual attraction of matter; some traces of which are found in his Principia, as above mentioned.

We find too, that Flamsteed had hoped, about the year 1690, by means of the stars near his zenith, to determine the quantity of the Nutation which ought to follow from the theory of Newton; but he gave up that project, because, says he, if this effect exists, it must remain insensible till we have instruments much longer than 7 feet, and more solid and better fixed than mine. Hist. Cælest. vol. 3, pa. 113.

And Horrebow gives the following passage, extracted from the manuscripts of his master Roemer, who died in 1710, whose observations he published in 1753, under

der the title of *Basis Astronomiæ*. By this paragraph it appears that Roemer suspected also a Nutation in the earth's axis, and had some hopes to give the theory of it: it runs thus; " Sed de altitudinibus non perinde certus reddebar, tàm ob refractionum varietatem quàm ob aliam nondum liquido perspectam causam; scilicet per hos duos annos, quemadmodum & alias, expertus sum esse quandam in declinationibus varietatem, quæ nec refractionibus nec parallaxibus tribui potest, sine dubio ad vacillationem aliquam poli terrestris referendam, cujus me verisimilem dare posse theoriam, observationibus munitam, spero." Basis Astronomiæ, 1735, pa. 66.

These ideas of a Nutation would naturally present themselves to those who might perceive certain changes in the declinations of the stars; and we have seen that the first suspicions of Bradley in 1727, were that there was some Nutation of the earth's axis which caused the star γ Draconis to appear at times more or less near the pole; but farther observations obliged him to search another cause for the annual variations (art. ABERRATION): it was not till some years after that he discovered the second motion which we now treat of, properly called the Nutation. See the art. STAR, pa. 500 &c, where Bradley's discovery of it is given at length; to which may be farther added the following summary.

For the better explaining the discovery of the Nutation by Bradley, we must recur to the time when he observed the stars in discovering the aberration. He perceived in 1728, that the annual change of declination in the stars near the equinoxial colure, was greater than what ought to result from the annual precession of the equinoxes being supposed 50″, and calculated in the usual way; the star η Ursæ Majoris was in the month of September 1728, 20″ more south than the preceding year, which ought to have been only 18″; from whence it would follow that the precession of the equinoxes should be $55''\frac{1}{2}$ instead of 50″, without ascribing the difference between the 18 and 20″ to the instrument, because the stars about the solstitial colure did not give a like difference. Philos. Trans. vol. 35, pa. 659.

In general, the stars situated near the equinoctial colure had changed their declination about 2″ more than they ought by the mean precession of the equinoxes, the quantity of which is very well known, and the stars near the solstitial colure the same quantity less than they ought; but, Bradley adds, whether these small variations arise from some regular cause, or are occasioned by some change in the sector, I am not yet able to determine. Bradley therefore ardently continued his observations for determining the period and the law of these variations; for which purpose he resided almost continually at Wansted till 1732, when he was obliged to repair to Oxford to succeed Dr. Halley; he still continued to observe with the same exactness all the circumstances of the changes of declination in a great number of stars. Each year he saw the periods of the aberration confirmed according to the rules he had lately discovered; but from year to year he found also other differences; the stars situated between the vernal equinox and the winter solstice approached nearer to the north pole, while the opposite ones receded farther from it: he began therefore to suspect that the action of the moon upon the elevated equatorial parts of the earth might cause a variation or libration in the earth's axis: his sector having been left fixed at Wansted, he often went there to make observations for many years, till the year 1747, when he was fully satisfied of the cause and effects, an account of which he then communicated to the world. Philos. Trans. vol. 45, an. 1748.

" On account of the inclination of the moon's orbit to the ecliptic, says Dr. Maskelyne (Astronomical Observations 1776, pa. 2), and the revolution of the nodes in antecedentia, which is performed in 18 years and 7 months, the part of the precession of the equinoxes, owing to her action, is not uniform: but subject to an equation, whose maximum is 18″: and the obliquity of the ecliptic is also subject to a periodical equation of 9″·55; being greater by 19·1″ when the moon's ascending node is in Aries, than when it is in Libra. Both these effects are represented together, by supposing the pole of the earth to describe the periphery of an ellipsis, in a retrograde manner, during each period of the moon's nodes, the greater axis, lying in the solstitial colure, being [illegible] a continuation of those by which he had discovered the aberration of light. But the exact law of the motion of the earth's axis has been settled by the learned mathematicians d'Alembert, Euler, and Simpson, from the principles of gravity. The equation hence arising in the place of a fixed star, whether in longitude, right ascension, or declination (for the latitudes are not affected by it) has been sometimes called Nutation, and sometimes Deviation." And again (says the Doctor, pa. 8), the above " quantity 19·1″, of the greatest Nutation of the earth's axis in the solstitial colure, is what I found from a scrupulous calculation of all Dr. Bradley's observations of γ Draconis, which he was pleased to communicate to me for that purpose. From a like examination of his observation of η Ursæ majoris, I found the lesser axis of the ellipsis of Nutation to be 14·1″, or only $\frac{1}{10}$th of a second less than what it should be from the observations of γ Draconis. But the result from the observations of γ Draconis is most to be depended upon."

Mr. Machin, secretary of the Royal Society, to whom Bradley communicated his conjectures, soon perceived that it would be sufficient to explain, both the Nutation and the change of the precession, to suppose that the pole of the earth described a small circle. He stated the diameter of this circle at 18″, and he supposed that it was described by the pole in the space of one revolution of the moon's nodes. But later calculations and theory, have shewn that the pole describes a small ellipsis, whose axes are 19·1″ and 14·2″, as above mentioned.

To shew the agreement between the theory and observations, Bradley gives a great multitude of observations of a number of stars, taken in different positions; and out of more than 300 observations which he made, he found but 11 which were different from the mean by

so

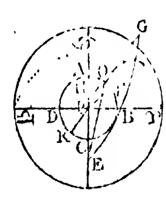
so much as 2″. And by the supposition of the elliptic rotation, the agreement of the theory with observation comes out still nearer.

By the observations of 1740 and 1741, the star η Ursæ majoris appeared to be 3″ farther from the pole than it ought to be according to the observations of other years. Bradley thought this difference arose from some particular cause; which however was chiefly the fault of the circular hypothesis. He suspected also that the situation of the apogee of the moon might have some influence on the Nutation. He invited therefore the mathematicians to calculate all these effects of attraction, which has been ably done by d'Alembert, Euler, Walmesley, Simpson, and others; and the astronomers to continue to observe the positions of the smallest stars, as well as the largest, to discover the physical derangements which they may suffer, and which had been observed in some of them.

Several effects arise from the Nutation. The first of these, and that which is the most easily perceived, [illegible]hange in the obliquity of the ecliptic; the quan[illegible]ich ought to be varied from that cause by 18″ [illegible] years. Accordingly, the obliquity of the [illegible]s observed [illegible] to be 23° 28′ 15″, and [illegible]nly 23° 28′ 5″; [illegible] therefore had it [illegible]shed by 8″, [illegible] accord[illegible]ing to the regular [illegible] of that obliquity; but it had even augmented [illegible]; making tog[illegible] 18″, for the effect of the Nutation in the 9 years.

The Nutation changes equally the longitudes, the right-ascensions, and the declinations of the stars, as before observed; it is the latitudes only which it does not affect, because the ecliptic is immoveable in the theory of the Nutation.

Dr. Bradley illustrates the foregoing theory of Nutation in the following manner. Let P represent the mean place of the pole of the equator, about which point, as a centre, suppose the true pole to move in the small circle ABCD, whose diameter is 18″. Let E be the pole of the ecliptic, and EP be equal to the mean distance between the poles of the equator and ecliptic; and suppose the true pole of the equator to be at A, when the moon's ascending node is in the beginning of Aries; and at B,



when the node gets back to Capricorn; and at C, when the same node is in Libra: at which time the north pole of the equator being nearer the north pole of the ecliptic, by the whole diameter of the little circle AC, equal to 18″; the obliquity of the ecliptic will then be so much less than it was, when the moon's ascending node was in Aries. The point P is supposed to move round E, with an equal retrograde motion, answerable to the mean precession arising from the joint actions of the sun and moon: while the true pole of the equator moves round P, in the circumference ABCD, with a retrograde motion likewise, in a period of the moon's nodes, or of 18 years and 7 months. By this means, when the moon's ascending node is in Aries, and the true pole of the equator, at A, is moving from A towards B; it will approach the stars that come to the meridian with the sun about the vernal equinox, and recede from those that come with the sun near the autumnal equinox, faster than the mean pole P does. So that, while the moon's node goes back from Aries to Capricorn, the apparent precession will seem so much greater than the mean, as to cause the stars that lie in the equinoctial colure to have altered their declination 9″, in about 4 years and 8 months, more than the mean precession would do; and in the same time, the north pole of the equator will seem to have approached the stars that come to the meridian with the sun of our winter solstice about 9″, and to have receded as much from those that come with the sun at the summer solstice.

Thus the phenomena before recited are in general conformable to this hypothesis. But to be more particular; let S be the place of a star, PS the circle of declination passing through it, representing its distance from the mean pole, and ♈PS its mean right-ascension. Thus if O and R be the points where the circle of declination cuts the little circle ABCD, the true pole will be nearest that star at O, and farthest from it at R; the whole difference amounting to 18″, or to the diameter of the little circle. As the true pole of the equator is supposed to be at A, when the moon's ascending node is in Aries; and at B, when that node gets back to Capricorn; and the angular motion of the true pole about P, is likewise supposed equal to that of the moon's node about E, or the pole of the ecliptic; since in these cases the true pole of the equator is 90 degrees before the moon's ascending node, it must be so in all others.

When the true pole is at A, it will be at the same distance from the stars that lie in the equinoctial colure, as the mean pole P is; and as the true pole recedes back from A towards B, it will approach the stars which lie in that part of the colure represented by P♈, and recede from those that lie in P♎; not indeed with an equable motion, but in the ratio of the sine of the distance of the moon's node from the beginning of Aries. For if the node be supposed to have gone backwards from Aries 30°, or to the beginning of Pisces, the point which represents the place of the true pole will, in the mean time, have moved in the little circle through an arc, as AO, of 30° likewise; and would therefore in effect have approached the stars that lie in the equinoctial colure P♈, and have receded from those that lie in P♎ by 4½ seconds, which is the sine of 30° to the radius AP. For if a perpendicular fall from O upon AP, it may be conceived as part of a great circle, passing through the true pole and any star lying in the equinoctial colure. Now the same proportion that holds in these stars, will obtain likewise in all others; and from hence we may collect a general rule for finding how much nearer, or farther, any star is to, or from, the mean pole, in any given position of the moon's node.

For, If *from the right-ascension of the star, we subtract the distance of the moon's ascending node from Aries; then radius will be to the sine of the remainder, as 9″ is to the number of seconds that the star is nearer to, or farther from, the true, than the mean pole.*

This motion of the true pole, about the mean at P, will also produce a change in the right-ascension of the stars,

stars, and in the places of the equinoctial points, as well as in the obliquity of the ecliptic; and the quantity of the equations, in either of these cases, may be easily computed for any given position of the moon's nodes.

Dr. Bradley then proceeds to find the exact quantity of the mean precession of the equinoctial points, by comparing his own observations made at Greenwich, with those of Tycho Brahe and others; the mean of all which he states at 1 degree in $71\frac{1}{2}$ years, or $50\frac{1}{3}''$ per year; in order to shew the agreement of the foregoing hypothesis with the phenomena themselves, of the alterations in the polar distances of the stars; the conclusions from which approach as near to a coincidence as could be expected on the foregoing circular hypothesis, the diameter of which is $18''$; instead of the more accurate quantity $19\cdot1''$, as deduced by Dr. Maskelyne, and the elliptic theory as determined by the mathematicians, in which the greater axis ($19\cdot1''$) is to the less axis ($14\cdot2''$), as the cosine of the greatest declination is to the cosine of double the same.

To give an idea now of the Nutation of the stars, in longitude, right-ascension, and declination; suppose the pole of the equator to be at any time in the point O, also S the place of any star, and OH perpendicular to AE: then, like as AE is the solstitial colure when the pole of the equator was at A, and the longitude of the star S equal to the angle AES; so OE is the solstitial colure when that pole is at O, and the longitude is then only the angle OES; less than before by the angle AEO, which therefore is the Nutation in longitude: counting the longitudes from the solstitial instead of the equinoctial colure, from which they differ equally by 90 degrees, and therefore have the same difference AEO. Now the angle AEO will be as the line HO = sin. AO to radius PB = sin. AO × PB = sin. AO × 9″; therefore as EO : HO : radius 1 :

$$\frac{HO}{EO} = \frac{\text{sin. AO} \times 9''}{\text{sin. } 23^\circ\, 28'} = \frac{\text{sin. node} \times 9''}{\text{sin. } 23^\circ\, 28'},$$ since AO

is equal to longitude of the moon's node. This expression therefore gives the Nutation in longitude, supposing the maximum of Nutation, with Bradley, to be $18''$; and it is negative, or must be subtracted from the mean longitude of the stars, when the moon's node is in the first 6 signs of its longitude, but additive in the latter 6, to give the true apparent longitude.

This equation of the Nutation in longitude is the same for all the stars; but that for the declination and right-ascension is various for the different stars. In the foregoing figure, PS is the mean polar distance, or mean codeclination, of the star S, when the true place of the pole is O; and SO the apparent codeclination; also, the angle SPE is the mean right-ascension, and SOE the apparent one, counted from the solstitial colure; consequently OPS or OPF the difference between the right-ascension of the star and that of the pole, which is equal to the longitude of the node increased by 3 signs or 90 degrees; supposing OF to be a small arc perpendicular to the circle of declination PFS; then is SF = SO, and PF the Nutation in declination, or the quantity the declination of the star has increased; but radius 1 : 9″ : : cosin. OPF : PF = 9″ × cos. OPF; so that the equation of declination will be found by multiplying 9″ by the sine of the star's right-ascension diminished by the longitude of the node; for that angle is the complement of the angle SPO. This Nutation in declination is to be added to the mean declination to give the apparent, when its argument does not exceed 6 signs; and to be subtracted in the latter 6 signs. But the contrary for the stars having south declination.

To calculate the Nutation in right-ascension, we must find the difference between the angle SOE the apparent, and SPE the mean right-ascension, counted from the solstitial colure EO. Now the true right-ascension SOE is equal to the difference between the two variable angles GOE and GOS; the former of which arises from the change of one of the variable circles EO, and depends only on the situation of the node or of that of the pole O; the latter GOS depends on the angle GPS which is the difference between the right ascension of the star and the place of the pole O. Now in the spherical triangle GPE, which changes into GOE, the side GE and the angle G remain constant, and the other parts are variable; hence therefore the small variation [illegible] small [illegible] the angle [illegible] to [illegible] GE [illegible] and GPE [illegible] OPE [illegible] sin. OPE [illegible] tang. 23° 28′ the difference between the angles GOE and GPE. This is the change which the Nutation PO produces in the angle GPF, being the first part of the Nutation sought, and is common to all the stars and planets. It is to be subtracted from the mean right-ascension in the first 6 signs of the longitude of the node, and added in the other six.

In like manner is found the change which the Nutation produces in the other part of the right-ascension SPE, that is, in the angle SPG, which becomes SOG by the effect of the Nutation. This small variation will be calculated from the same analogy, by means of the triangle SOG, in which the angle G is constant, as well as the side SG, whilst SP changes it to SO. Hence therefore, tang. SP : sin. SPG : : 9″ : variation of SPG, that is, the cotangent of the declination is to the cosine of the distance between the star and the node, as 9″ are to the quantity the angle SPG varies in becoming the angle SOG, being the second part of the Nutation in right-ascension; and if there be taken for the argument, the right ascension of the star minus the longitude of the node, the equation will be subtractive in the first and last quadrant of the argument, and additive in the 2d and 3d, or from 3 to 9 signs. But the contrary for stars having south declination.

This second part of the Nutation in right-ascension affects the return of the sun to the meridian, and therefore it must be taken into the account in computing the equation of time. But the former part of the Nutation does not enter into that computation; because it only changes the place of the equinox, without changing the point of the equator to which a star corresponds, and consequently without altering the duration of the returns to the meridian.

All

All these calculations of the Nutation, above explained, are upon Machin's hypothesis, that the pole describes a circle; however Bradley himself remarked that some of his observations differed too much from that theory, and that such observations were found to agree better with theory, by supposing that the pole, instead of the circle, describes an ellipse, having its less axis DB = 16″ in the equinoctial colure, and the greater axis AC = 18″, lying in the solstitial colure. But as even this correction was not sufficient to cause all the inequalities to disappear entirely, Dr. Bradley referred the determination of the point to theoretical and physical investigation. Accordingly several mathematicians undertook the task, and particularly d'Alembert, in his Recherches sur la précession des equinoxes, where he determines that the pole really describes an ellipse, and that narrower than the one assumed above by Bradley, the greater axis being to the less, as the cosine of 23° 28′ to the cosine of double the same. And as Dr. Maskelyne found, from a more accurate reduction of Bradley's observations, that the maximum of the Nutation gives 19·1″ for the greater axis, therefore the above proportion gives 14·2″ for the less axis of it; and according to these data, the theory and observations are now found to agree very near together.

See La Lande's Astron. vol. 3, art. 2874 &c, where he makes the corrections for the ellipse. He observes however that by the circular hypothesis alone, the computations may be performed as accurately as the observations can be made; and he concludes with some corrections and rules for computing the Nutation in the elliptic theory.

The following set of general tables very readily give the effect of Nutation on the elliptical hypothesis; they were calculated by the late M. Lambert, and are taken from the Connoissance des Temps for the year 1788.

General Tables for Nutation in the Ellipse.

The

The Use of the Tables.

The right-ascension of a star minus the moon's mean longitude, gives the argument of the first of these three tables. The sum of the same two quantities gives the argument of the 2d table. Then the sum or the difference of the quantities found with these two arguments, will give the correction to be applied to the mean declination of the star, if it is north declination; but if it is southern, the signs + or − are to be changed into − and +.

From each of those two arguments for the declination subtracting 3 signs, or 90°, gives the arguments for correcting the right-ascension; the sum or difference of the quantities found, with these two arguments, in tables 1 and 2, is to be multiplied by the tangent of the star's declination, and to the product is to be added the quantity taken out of table 3, the argument of which is the mean longitude of the moon's ascending node: when the declination of the star is south, the tangent will be negative.

Example. To find the Nutation in right-ascension and declination for the star α Aquilæ, the 1st of July 1788.

	s	°	′	″
Right-ascension of the star	9	25	7	
Long. of the moon's node	8	15	40	
Diff. being argument 1,	1	9	27	+ 4·99
Sum, argument 2, - -	6	10	47	− 0·22
Correction of the declination - - -				+ 4·77

The above two arguments being each diminished by 3 signs, gives

	s	°	′	″
Argument 1 - - - - - - -	10	9	27	− 6·06
Argument 2 - - - - - - -	3	10	47	+ 1·13
				− 4·93
Declin. of star north, its tangent - - -				0·146
The product is - - - - - -				− 0·72
Long. of the ☾'s node, argum. 3 -				+ 14·94
Correction of right-ascension - - -				+ 14·22

In general, let ☊ denote the longitude of the moon's ascending node; *r* the right-ascension of a star or planet; *d* its declination; the Nutation in declination and right-ascension will be expressed by the two following formulæ; viz, the Nutation in declination

$= 7''\cdot85 \times \text{sin.}\,(r - ☊) + 1''\cdot15 \times \text{sin.}\,(r + ☊)$;

and the Nutation in right-ascension

$= [7''\cdot85 \times \text{sin.}\,(r - ☊ - 90°) + 1''\cdot15 \times \text{sin.}\,(r + ☊ - 90°)] \times \text{tang.}\,d - 15''\cdot43 \times \text{sin.}\,☊$.

For the mathematical investigation of the effects of universal attraction, in producing the Nutation, &c, see d'Alembert's Recherches sur la Precession des Equinoxes; Silvabelle's Treatise on the Precession of the Equinoxes &c, in the Philos. Trans. an. 1754, p. 385; Walmesley's treatise De Præcessione Equinoctiorum et Axis Terræ Nutatione, in the Philos. Trans. an. 1756, pa. 700; Simpson's Miscellaneous Tracts, pa. 1; and other authors.

S

STEAM. The observations on the different degrees of temperature acquired by water in boiling, under different pressures of the atmosphere, and the formation of the vapour from water under the receiver of an air-pump, when, with the common temperatures, the pressure is diminished to a certain degree, have taught us that the expansive force of vapour or Steam is different in the different temperatures, and that in general it increases in a variable ratio as the temperature is raised.

But there was wanting, on this important subject, a series of exact and direct experiments, by means of which, having given the degree of temperature in boiling water, we may know the expansive force of the Steam rising from it: and vice versa. There was wanting also an analytical theorem, expressing the relation between the temperature of boiling water, and the pressure with which the force of its Steam is in equilibrium. These circumstances then have lately been accomplished by M. Betancourt, an ingenious Spanish philosopher, the particulars of which are described in a memoir communicated to the French Academy of Sciences in 1790, and ordered to be printed in their collection of the Works of Strangers.

The apparatus which M. Betancourt makes use of, is a copper vessel or boiler, with its cover firmly soldered on. The cover has three holes, which close up with screws: the first is to put the water in and out; through the second passes the stem of a thermometer, which has the whole of its scale or graduations above the vessel, and its ball within, where it is immersed either in the water or the Steam according to the different circumstances; through the third hole passes a tube making a communication between the cavity of the boiler and one branch of an inverted syphon, which, containing mercury, acts as a barometer for measuring the pressure of the elastic vapour within the boiler. There is a fourth hole, in the side of the vessel, into which is inserted a tube, with a turn cock, making a communication with the receiver of an air pump, for extracting the air from the boiler, and to prevent its return.

The apparatus being prepared in good order, and distilled water introduced into the boiler by the first hole, and then stopped, as well as the end of the inverted syphon or barometer, M. Betancourt surrounded the boiler with ice, to lower the temperature of the water to the freezing point, and then extracting all the air from the boiler by means of the air pump, the difference between the columns of mercury in the two branches of the barometer is the measure of the spring of the vapour arising from the water in that temperature. Then, lighting the fire below the boiler, he raised gradually the temperature of the water from 0 to 110 degrees of Reaumur's thermometer; being the same as from 32 to 212 degrees of Fahrenheit's; and for each degree of elevation in the temperature, he observed the height of the column of mercury which measured the elasticity or pressure of the vapour.

The results of M. Betancourt's experiments are contained

tained in a table of four columns, which are but little different, according to the different quantities of water in the vessel. It is here observable, that the increase in the expansive force of the vapour, is at first very slow; but gradually increasing faster and faster, till at last it becomes very rapid. Thus, the strength of the vapour, at 80 degrees, is only equal to 28 French inches of mercury; but at 110 degrees it is equal to no less than 98 inches, that is 3 times and a half more for the increase of only 30 degrees of heat.

To express analytically the relation between the degrees of temperature of the vapour, and its expansive force, this author employs a method devised by M. Prony. This method consists in conceiving the heights of the columns of mercury, measuring the expansive force, to represent the ordinates of a curve, and the degrees of heat as the abscisses of the same; making the ordinates equal to the sum of several logarithmic ones, which contain two indeterminates, and determining these quantities so that the curve may agree with a good number of observations taken throughout the whole extent of them. Then constructing the curve which results immediately from the experiments, and that given by the formula, these two curves are found to coincide almost perfectly together; the small differences being doubtless owing to the little irregularities in the experiments and in dividing the scale; so that the pheonomena may be considered as truly represented by the formula.

M. Betancourt made also experiments with the vapour from spirit of wine, similar to those made with water; constructing the curve, and giving the formula proper to the same. From which is derived this remarkable result, that, for any one and the same degree of heat, the strength of the vapour of spirit of wine, is to that of water, always in the same constant ratio, viz, that of 7 to 3 very nearly; the strength of the former being always $2\frac{1}{3}$ times the strength of the latter, with the same degree of heat in the liquid.

Of the Formula, or Equation to the Curve.

The equation to the curve of temperature and pressure, denoting the relation between the abscisses and ordinates, or between the temperature of the vapour and its strength, is, for water,

$$y = b^{a+cx} - b^{a+c'x} - b^{e+c''x} + b^{e+c'''x}.$$

Where x denotes the abscisses of the curve, or the degrees of Reaumur's thermometer; and y the corresponding ordinates, or the heights of the column of mercury in Paris inches, representing the strength or elasticity of the vapour answering to the number x of degrees of the thermometer. Then, by comparing this *formula with a proper number of the experiments, the values of the constant quantities come out as below:*

$b = 10\cdot$

$a = 0\cdot068831$

$c = 0\cdot019438$

$c' = 0\cdot013100$

$e = -4\cdot689760$

$c'' = 0\cdot058622$

$e' = -3\cdot937600$

$c''' = 0\cdot049220$

Hence it is evident by inspection, that the terms of the equation are very easy to calculate. For, b being the radix or root of the common system of logarithms, and all the terms on the second side of the equation being the powers of b, these terms are consequently the tabular natural numbers having the variable exponents for their logarithms. Now as x rises only to the first power, and is multiplied by a constant number, and another constant number being added to the product, gives the variable exponent, or logarithm; to which then is immediately found the corresponding natural number in the table of logarithms.

In the above formula, the two last terms may be entirely omitted, as very small, as far as to the 90th degree of the thermometer; and even above that temperature those two terms make but a small part of the whole formula.

And for the spirit of wine the formula is

$$y = b^{a+cx} + b^{a'+c'x} - b^{e+c''x} + b^{e'+c'''x} - A.$$

Where x and y, as before, denote the abscis and ordinate of the curve, or the temperature and expansive force of the vapour from the spirit of wine; also the values of the constant quantities are as below:

$b = 10\cdot$

$a = -0\cdot04853$

$c = 0\cdot02393$

$a' = -0\cdot63414$

$c' = -0\cdot096532$

$e = -2\cdot509542$

$c'' = 0\cdot046473$

$e' = -1\cdot790192$

$c''' = 0\cdot029448$

$A = 1\cdot12647$

This formula is of the same nature as the former, having also the like ease and convenience of calculation; and perhaps more so; as the second term $b^{a'+c'x}$, having its exponent wholly negative, soon diminishes to no value, so as to be omitted from the 10th degree of temperature; also the difference between the last two terms $-b^{e+c''x} + b^{e'+c'''x}$ may be omitted till the 70th degree, for the same reason. So that, to the 10th degree of temperature the theorem is only $y = b^{a+cx} + b^{a'+c'x} - A$; and from the 10th to the 70th degree it is barely $y = b^{a+cx} - A$; after which, for the last 15 or 20 degrees, for great *accuracy, the last two terms may be taken in.*

A compendium of the table of the experiments here follows, for the vapour of both water and spirit of wine, the temperature by Reaumur's thermometer, and the barometer in French inches.

Table of the Temperature and Strength of the Vapour of Water and Spirit of Wine, by Reaumur's Thermometer, and French Inches.

M. Betancourt deduces several useful and ingenious consequences and applications from this course of experiments. He shews, for instance, that the effect of Steam engines must, in general, be greater in winter than in summer, owing to the different degrees of temperature in the water of injection. And from the very superior strength of the vapour of spirit of wine, over that of water, he argues that, by trying other fluids, some may be found, not very expensive, whose vapour may be so much stronger than that of water, with the same degree of heat, that it may be substituted instead of water in the boilers of Steam-engines, to the great saving in the very heavy expence of fuel: nay, he even declares, that spirit of wine itself might thus be employed in a machine of a particular contruction, which, with the same quantity of fuel, and without any increase of expence in other things, shall produce an effect greatly superior to what is obtained from the steam of water. He makes several other observations on the working and improvement of Steam-engines.

Another use of these experiments, deduced by M. Betancourt, is, to measure the height of mountains, by means of a thermometer, immersed in boiling water, which he thinks may be done with a precision equal, if not superior, to that of the barometer. As soon as I had obtained exact results of my experiments, says he, and was convinced that the degree of heat received by water depends absolutely on the pressure upon its surface, I endeavoured to compare my observations with such as have been made on mountains of different heights, to know what is the degree of heat which water can receive when the barometer stands at a determinate height; but from so few observations having been made of this kind, and the different ways employed in graduating instruments, it is difficult to draw any certain consequences from them.

The first observation which M. Betancourt compared with his experiments, is one mentioned in the Memoirs of the Academy of Sciences, anno 1740, page 92. It is there said, that M. Monnier having made water boil upon the mountain of Canigou, where the barometer stood at 20·18 inches, the thermometer immersed in this water stood at a point answering to 71 degrees of Reaumur: whereas in M. Betancourt's table of experiments, at an equal pressure upon the surface of the water, the thermometer stood at 73·7 degrees. This difference he thinks is owing partly to the want of precision in the observation, and partly to the different method of graduating the thermometer, and the neglect of purging the barometer tube of air.

M. Betancourt next compared his experiments with some observations made by M. De Luc on the tops of several mountains; in which, after reducing the scales of this gentleman to the same measures as his own, he finds a very near degree of coincidence indeed. The following table contains a specimen of these comparisons, the instances being taken at random from De Luc's treatise on the Modifications of the Atmosphere.

Degrees of Heat in Boiling Water upon the Tops of Mountains, observed by De Luc.				Heat of the Water in M. Betancourt's Experim.

Glaciere de B.	6½	19·077	72·56	73·24

Where it is remarkable, that the difference between the two is of no consequence in such matters.

Many other advantages might be deduced from the exact knowledge of the effect which the pressure of the atmosphere has upon the heat which water can receive: one of which, M. Betancourt observes, is of too great importance in physics not to be mentioned. As soon as the thermometer became known to philosophers, almost every one endeavoured to find out two fixed points to direct them in dividing the scale of the instrument; having found that those of the freezing and boiling of water were nearly constant in different places, they gave these the preference over all others: but having discovered that water is capable of receiving a greater or less quantity of heat, according to the pressure of the atmosphere upon its surface, they felt the necessity of fixing a certain constant value to that pressure, which it was almost generally agreed should be equal to a column of 28 French inches of mercury. This agreement however did not remove all the difficulties. For instance, if it were required to construct at Madrid a thermometer that might be comparable with another made at Paris, the thing would be found impossible by the means hitherto known, because the barometer never rises so high as 27 inches at Madrid; and it was not certainly known how much the scale of the thermometer ought to be increased to have the point of boiling water in a place where the barometer is at 28 inches. But by making use of the foregoing observations, the thing appears very easy, and it is to be hoped that by the general knowledge of them, thermometers may be brought to great perfection, the accurate use of which is of the greatest importance in physics.

Besides, without being confined to the height of the barometer in the open air, in a given place, we may regulate a thermometer according to any one assigned heat of water, by means of such an apparatus as M. Betancourt's. For, in order to graduate a thermometer, having a barometer ready divided; it is evident that by knowing, from the foregoing table of experiments, the degree of heat answering to any one expansive force, we can thence assign the degree of the thermometer corresponding to a certain height of the barometer. A determination admitting of great precision, especially in the higher temperatures, where the motion of the barometer is so considerable in respect to that of the thermometer.
